The Gladiator, one of the vessels forming the "Squadron of Evolution," is a beautiful example of the perfection of workmanship exhibited in the construction of British marine engines.

Before, however, describing those peculiarities in the engines of the Gladiator, which are illustrated in the accompanying plates, we wish to remark with respect to the observations which have been made on the performances of the steam vessels of the Squadron of Evolution, that those remarks apply exclusively to the powers of the steam vessels as sailers when deprived of the assistance of their engines. To compare the powers of a steam vessel as a sailer with those of a ship built to be propelled by its sails exclusively, seems to us as absurd as to compare the speed of two animals possessing altogether different organs of locomotion. It can be no matter of wonder that a vessel containing the enormous weight of marine engines, and built of a form suitable for containing them, should not sail so fast as one which does not contain this load, and is built of the form best adapted for sailing. Between steam-ships and sail-ships no correct comparison can be drawn.* Not only are their means of propulsion entirely different, but the circumstances under which each acts most usefully, are altogether dissimilar, so that for the purposes of war each in its turn would be invaluable, where the other would be inefficient. The most rational method therefore seems to be to keep the individual characteristics of the two classes of vessels perfectly distinct,—to render each as perfect as possible in those qualities which constitute its peculiar advantages—in other words, to speak to those whom we have the most interest in addressing, to render the war-steamer as perfect as possible *as a steamer*, and not to injure her powers by injudicious attempts of combining with them the peculiar qualities of sailing vessels.

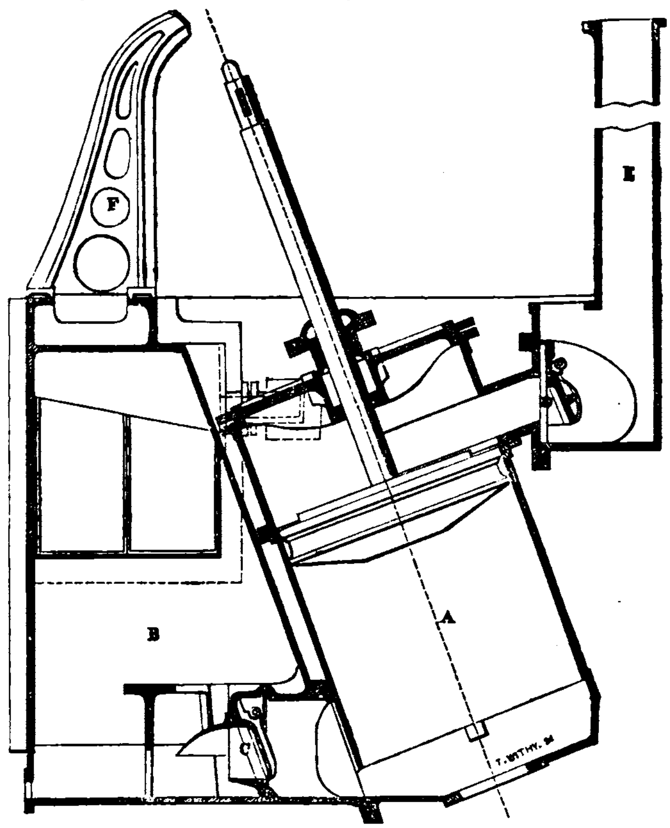
The engines of the Gladiator were constructed by the well-known firm of Miller, Ravenhill, and Co., of Blackwall. The principal feature of these engines is their compactness, the cranks, and consequently the cylinders being brought close to each other, to give deck room for moving the cannons fore and aft. The air pumps are constructed on a principle patented by Mr. Miller, being inclined towards each other, and worked by a crank common to both, on the same shaft with the cylinder cranks.

The following are the references, Plates IX and X.

A A, Cylinders 78¾ inches in diameter, 5 feet 9 inch stroke.
B B, Piston rods.
C C, Connecting rods.
D D, Cranks on working shaft.
E, Upright steam-pipe. At its lower end are brackets *e e*, cast on the slide-valve casing, to support the steam-pipe.
F, Expansion valve box.
G, Beam working the refrigerator pump of Howard's patent condensing apparatus. The beam, of which the bearings are supported by the upright steam-pipe, forms part of the parallel motion.
H, Slide valve casing. *h h h*, Openings from the steam-pipes on which the expansion valves work.
I I, Cross-bar, and K K, Eccentric rods, for working the slide valves.
L, Opening between slide valve casing and condenser.
M M, Condensers.
N N, Air-pumps. *n n*, Delivering valve openings.
O, Crank for working air pumps.
P P, Hot water cisterns. Q Q, Feed pumps. R R, Bilge pumps.

The annexed diagram represents a section of one of the air-pumps and condenser of the Gladiator.

Fig. 1.—Section of one of the Air Pumps and Condenser of the Gladiator.

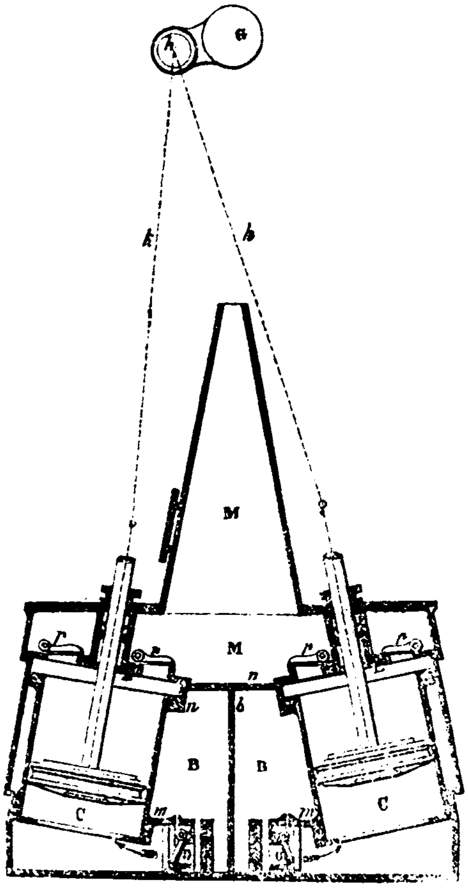


A, Air-pump.—B, Part of condenser.—C, Foot-valve.—D, Delivering valve.—E, Hot water cistern.—F, Bracket for supporting guide-rods for air-pump cross-bar.

The following extract from the specification of a Patent, granted March 22, 1842, to Mr. Joseph Miller, will further explain the construction of the air-pumps and condenser.

The engraving fig. 2, show a vertical section of the condensers B B, and air-pumps C C, disposed within the condensers, and between the steam cylinders, in a different manner to that hereinbefore described, one pump being before the other, instead of the two pumps being side by side. The pumps C C are inclined from the vertical, in contrary directions, so that the direction of the centre line of each pump will point to the centre of the rotative axis G, and both pumps are worked by the same crank *h*, on that axis, by means of two crank rods *k k*, of which only the centre lines are shown dotted, and the upper ends whereof may be applied side by side on the pin of that crank *h*, one of those crank-rods *k* being for working one pump C, and the other of those crank-rods *k* for working the other pump C. In case of the two crank rods being so applied, side by side, on the said pin of the crank, then the two air pumps (when viewed from the front) cannot stand exactly in the same vertical plane one with the other, but the centre line of one pump will be as much at one side of the centre line of the other pump as is requisite to suit the crank-rods *k k*, in case they are one at the side of the other, in order that they may both work upon the same crank-pin *h*, as already mentioned ; or one of the crank, rods *k k* may be made forked at the upper end, when it is applied upon the crank-pin, with two joints on that pin, side by side, and including the joint of the other crank-rod between them, and in such case the centre lines of both air-pumps may be in the same vertical plane. In such an arrangement of the air-pumps, the steam cylinders will stand nearer together, and the middle portion G of the rotative axis will be very short, and there will be only one crank *h* on that middle portion. The condensers will be narrower in the direction between the cylinders, but longer in the opposite direction. The vertical partition *b*, by which the condenser is divided into two compartments or distinct condensers, may stand in the direction from the centre of one steam cylinder to the centre of the other, provided that, by means of another partition or a branch of one partition suitably disposed within the condenser, one of the eduction passages G of one of the cylinders cut only one of those passages, is prolonged and continued withinside the condenser beyond or through the partition *b*, so as to communicate very freely from that said cylinder to that condenser or compartment of the condenser which is most remote from the sliding valves and the eduction passages G. The manner of fixing the air-pums C C into apertures through partitions *m* and *n*, and the manner of placing the foot-valves *o o*, is much the same as already described, except that instead of the said partitions being horizontal, they are as much inclined as will suit the inclining position of the air-pumps C C. The discharge valves p p may be applied at the top of the cover L of each air-pump to discharge the water into the space above the upper partition n, which space constitutes the hot well M, and may be common to both pumps. The condensers will have the same kind of flanges, with vertical surfaces of contact and union, with the corresponding surfaces of the two steam cylinders, as already described, except that those surfaces will not be quite at the angles of the condensers when the same are made as shown, but the mode of uniting the two steam cylinders to the condensers by such surfaces, with bolts through the flanges thereof, will be the same as hereinbefore described, and need not be repeated. And note, it is not necessary that the inclined air-pumps should be put within the condenser, as is there represented, for each pump may be joined to the condenser at bottom, beneath the lower partition m, by means of a branch projecting laterally from the bottom of the pump, or else projecting laterally from the condenser, and by another branch projecting from the top of the pump it may be connected with the upper part of the condenser above the upper partition n. Those branches

Fig. 2.—Section of Air Pumps and Condensers.



being united to the condenser at the lower and at the upper parts thereof, in a similar manner to that whereby the air-pump of a marine steam engine, of the kind heretofore made by Messrs. Boulton and Watt, with side-levers, is most commonly connected to the condenser and hot-well of such an engine, except that the pumps will be inclined instead of being vertical, and the pumps may, in that last-mentioned case, be somewhat more inclined than they are represented, if that is requisite, in order to give as much more space of condenser between the two pumps as will give the required capacity of condenser. The lower branch by which each air-pump is joined to the lower part of the condenser (whether that branch is formed as part of the pump, or as part of the condenser,) will join to the condenser below the lower partition m, and the foot-valve o may be within the interior of the condenser, or it may be within the lower branch thereof, to which the air-pump is joined. If the said lower branch is formed in the same casting or piece of metal with the condenser, it may project out from the lower part of the condenser, and the air-pump may join thereto, with a bottom flange around the lower end of the pump, or if the branch is formed with the air-pump, it may join laterally to the front side of the condenser, at the lower part of that side. The branch at the upper part of the air-pump will have the discharge-valve or valves applied to it, those valves being within the hot well, which hot well may either be a space M within the condenser at the upper part thereof, above the upper partition, or inside of the condenser, or the discharge valves may be in a hot well, which is formed by a vessel distinct from the condenser. Although two distinct condensers and two distinct air-pumps have been described (that being preferable in most cases), nevertheless, that is not essential to my improved arrangement and combination; but the same is equally applicable if the condenser is made without the partition b so as to be only one condenser, and with only one large air-pump, equivalent in its capacity to the two air-pumps represented in the drawing."

NEW METROPOLITAN CHURCHES.

Westbourne Terrace, Hyde Park.—The plan of this church is nearly a rectangle, and comprises a nave with low pitched roofs, north and south aisles, with lean-to roofs, a chancel, an octagonal vestry at the north-east angle of the church, and a tower and spire at the west end of the nave. The spire is very lofty, and rises to a height of 212 feet. The length of the church from east to west is 150 feet.

In the interior of the church the nave is divided from the aisles by piers which are intersected at mid-height by galleries, which of course partially obstruct the north and south windows. There is also an organ gallery which communicates with the staircases by doors having straight jambs and lintels like the doors of an ordinary dwelling house.

The walls of the church, the piers, the groined roofs, the walls of the porches, staircases, &c. are all coated with stucco, on which are drawn lines to mimic the jointing of masonry; the hood mouldings of the windows are run in vile patent cement, the bosses of the roof, the capitals and bases of the columns are all of the same material—moulded first and stuck on afterwards. You see lying about the church the halves of bases, black dingy things, not yet whitened by drying, that resemble detached *hoofs* rather than real architectural members—these are to be fitted into their places directly they are dry, and if coated with a delicate layer of colour will defy detection.—Boz describes one of his humble heroines who had small means of gratifying her love of dress and consoled herself with the reflection that "a brave show may be made with ribbands for sixpence."

The ceilings of the church are quite dazzling with white wash. The connoisseur in imitations will not fail to admire also the stained deal panelling, and probably will not object to the indentations in the plaster which suggest sham windows.

The architecture of the exterior perfectly corresponds to that of the interior. To those who have familiarized themselves with the architecture of our English country churches, the tracery of the windows of the new church might appear of somewhat "formal cut," but then it is very showy for the money, and an approved specimen of *pattern* Gothic. Beneath the parapet, which is panelled, is a row of grotesque masks; for the architect, determined to have at least some point of resemblance to ancient Christian art, has selected for imitation the least admirable feature of it—those barbarous and ridiculous imitations of the human form which were excusable in an age, when a familiar connection of solemn and ludicrous subjects was tolerated, but which would now be pronounced impious or indecent. But here the disciple has out-done his masters; in his reverence for antiquity he has produced forms more monstrous than ever disfigured ancient freemasonry—Bacchanalian visages with huge tongues hanging below their chins, or with fists forced into their distended cheeks, and similar distortions which might make the fortune of the clown in a penny theatre but seem rather out of place in a religious edifice. To compensate however for these barbarities we have over each porch an angel, who fervently clasps a shield to his breast, and by his beaming countenance exhibits a perfect ecstasy of pious beatitude.

The general character of the architecture is ostentation in the forms and unreality in the materials—two things, by the by, which always accompany each other; for where fictitious and dishonest materials are employed, the fatal facility which they afford for introducing ornament is usually too strong a temptation for vulgar display to be easily resisted. Of this truth the multitude of terraces and crescents which are springing up in the vicinity of the new church are lamentable examples. They look uncommonly showy and fine in the lithographic views which are got up for the purpose of letting the houses, but we trust that the time is not distant when by the force of universal public detestation this common-place architecture will be abolished for ever.

South Hackney.—A new church is being erected here from the design of Mr. E. C. Hakewill, and although the building is not in a very advanced state, the progress made is sufficient to lead us to hope that this new church when completed will be an additional proof of the advance made in the knowledge of Christian architecture during the last few years.

South Hackney New Church.

The plan of the building shows a nave, transepts and chancel, and a western tower. The archway of the entrance in the tower is *seven feet* in depth,—a gratifying contrast to the miserably shallow doorways of some of our recent churches. The following will be the principal dimensions of this Church when completed:—

Length from east to west internally	169 feet.
Width of nave and aisles	61 „
Length from north to south in the transepts	92 „
Width of the transepts	34 „
Height internally to the top of the walls	37 „
Height to apex of the roof	65 „
Height of tower and spire	200 „

Unlike the churches which we had occasion to notice last month, this edifice will have north and south windows in the aisles, and will not be lighted by a clerestory exclusively. We should however like to have seen more light admitted from the lower, and less from the upper, windows. It is not necessary to repeat what we have already insisted upon, that to let in a flood of light near the roof is to admit it to the greatest disadvantage as regards picturesque effect. The roofs ought to appear dim, shadowy and obscure—especially in a church of the early style here chosen; it was not until the decline of art in the Perpendicular period that the upper parts of churches were brilliantly illuminated.

No criticism is complete without it detect some faults, we must therefore endeavour to find some, though we confess that our feeling in favour of the general merits of Mr. Hakewill's design renders the task somewhat difficult. The tower is perhaps too much cut up into parts by string courses, &c.; some of these might be omitted with advantage, for a tower should have the character of massiveness and strength, and consequently the parts should be large and well defined. Neither do we much admire the position of the statues at the base of the spire: there is always an idea of awkwardness and insecurity attached to a statue perched upon a point, or in any way overhanging its base. In the drawing which Mr. Hakewill has been kind enough to send us, the form of the flying buttresses seemed rather formal, and the manner in which the upper parts of the buttresses at the angles of the transept met the wall appeared abrupt.

However, these are matters of detail which the architect will be able to alter, if he see fit, during the progress of the works; the general character of the church, the massiveness and boldness of the features, and the consequent depth of the shadows contrast very advantageously with the *flatness* and showiness which modern churches too frequently exhibit. The materials are Kentish ragstone, with Bath-stone dressings; the good taste of the architect will, we are confident, lead him to reject fictitious or imitative materials.

Our acknowledgements are due to several architects, to whom we have applied, for the readiness with which they have afforded information of churches in the course of erection under their superintendence. We shall feel obliged by receiving notices of new churches in or near London: these notices should be accompanied by a list of principal dimensions, and must not contain any remarks of a critical character. We shall also be glad to publish views of churches of which the general composition is good, or illustrations of interesting details; in the latter the jointing of the masonry should always be distinctly shown.

ROYAL ACADEMY EXHIBITION: ARCHITECTURE.

SECOND NOTICE.

It might be imagined that of Interiors there would be an abundance rather than a deficiency, because each single building contains a great many divisions within, and although only two or three of the principal parts or apartments may be of any architectural importance, subjects of that kind would still greatly out number the buildings themselves. Nevertheless, such drawings—whether designs or views—are rarities and exceptions, notwithstanding that designs for rooms and their decorations would be somewhat less chimerical than those for cathedrals and other buildings on "monster" scale. Unless the private mansions and other edifices, of which we meet with drawings at the exhibitions, be totally devoid of architectural interest within, there must be a great deal that is withheld from us; which is the more to be regretted, because it is through drawings alone that the public can become acquainted with what lies on the other side of the threshold of a private residence. We should therefore have been thankful had we been favoured by the sight of a drawing or two—nay, even of a single one, in evidence of the taste displayed by the noble President of the Institute of British architects, in his newly fitted-up mansion, Wrest House. Either it has been fulsomely flattered by newspaper paragraphs, and the "sumptuousness" which, it seems, characterises it, is after all, little better than extravagantly costly commonplace, or there must be something in it well worth seeing; whereas now we have neither verbal nor graphic description to give us any idea of what it really is. Earl de Grey, however, chooses to conceal his light under a bushel,—at least, from such as ourselves, and by so doing he shows one thing—that he is oblivious of, or else indifferent to, his connection with architecture as the President of the Institute;—whose members, by the by, require to be spurred on to support the Academy's exhibitions.

After these very *grumbling* remarks, it may be some relief when we say that the present season is not more barren of Interiors than usual, for which we have chiefly to thank Mr. Sang, who exhibits four subjects of the kind, Nos. 1262, 1336, 1337, and 1358, the first of them a sectional view of the ambulatory of the merchants' area in the Royal Exchange, and the other three, views of the Grand Staircase, Lower Hall, and Upper Hall of the Conservative Club-house. These last are especially welcome, because the Club-house is not open to every one, as the Exchange is, and even those who like ourselves have had the opportunity of going over the building, cannot have such favour renewed at pleasure. Yet, for seeing any drawings of it at all we are perhaps entirely indebted to Mr. Sang's share in the work, which, we hardly need say, is confined to the encaustic polychromic decorations of the architecture. Except that they are in perspective, the drawings themselves make very little more pretension to pictorial expression than coloured sections would do, artist-like treatment and effect of light and shade being renounced in them for the purpose of showing with all possible distinctness the actual colours and ornamental patterns. Hence they are to be looked upon not as pictures, but merely as graphic descriptions and explanations of those parts of the interior which they represent. As respects the decoration, we think it is rather too minute and showy to be altogether in character for the places where it is introduced, the most effect of all in the building being thrown into what requires to be rather subdued than exaggerated, and not allowed to overpower all that follows. What strikes us as a fault in the general design—one, however, for which Mr. Sang is not answerable—is the want of stained glass of some kind in the glazed skylight dome of the upper hall, which is now rather too much of a blank, and which must, we think, have not only a blank, but even a black and therefore dismal look by night, when it must show as a dark yawning void overhead. Such, indeed, would still have been the case had it been filled in with painted or embossed glass, unless it could also have been lighted of an evening from the outside; wherefore it would perhaps have been better to close the opening of the dome by a cove and *plafond* or horizontal ceiling, with transparent panels of painted glass, letting the present dome be an external skylight, and within the intermediate space there might have been gas-burners to shed light through the panels of the ceiling by night.

But our pen is running away from us, and we are running away from our proper subject. So let us return to the Exhibition.—No. 1160, "A Library," (W. W. Deane) possesses much merit in its idea, and a very unusual degree of scenic effect is produced by the semicircular recess lighted from above and separated from the room by a screen of Corinthian columns (forming five open intercolumns); which order is continued by antæ on the other walls, those on the window side being placed not as pilasters against the piers, but at their angles, with the draperies hung within the embrasures or window recesses, so that, instead of at all concealing, those curtains serve to relieve and set off the architectural forms. So far, this design seems to us to fulfil even better than No. 1270 does the title given to the latter, viz., "A design to illustrate an architectural arrangement of draperies in a drawing-room," (J. Dwyer). Though drawings of the kind are so few that as much show as possible should be made with them, Mr Dwyer's is so placed as to frustrate examination, but were it not for the intimation in the catalogue we should never have suspected it to be intended as a study of "arrangement of draperies," there being nothing at all novel—as far as we can perceive—in that respect, except it be that what is either an open doorway or mirror at the end of the room, has a drapery corresponding with those of the windows.—Nos. 1279 and 1355 show us the "Staircase and Music Hall of Mr. Hullah's Singing School." (W. Westmacott); but where the building is, or is to be, is not said. The style partakes of Tudor, modernized and enfeebled in character; however, we have not a right to expect much in what we suppose is only the speculation of a private individual. Less indulgently are we disposed towards the very next No., viz. 1356, "The hall and staircase of a gentleman's residence executing from the designs and under the superintendence of G. Mair." In its general idea it is rather the reverse of what would be thought of as suitable in a residence at the present day, it being upon the old system of hall and staircase thrown together, so as to form a lofty space that seems to occupy too much of the house, unless it be a very large one. Neither is space here made to contribute to display; while as to character and detail, there is more of what is faulty, objectionable, and inconvenient in the Elizabethan style, than of what is meritorious in it, and applicable in modern houses; in short, it is rather what one would preserve, had it previously existed, than now produce.—No. 1312, "Interior of the Upper Chapel, San Benedetto, Subiaco" (D. Wyatt), is the finest picture drawing in the room—others equal to it we may occasionally have seen—certainly some that we should prefer in point of subject; for instance, the Loggia of the Villa Madama, by G. Moore,—but for power and mastery of execution, we cannot call to recollection anything superior. With the force of oil it has a clearness which we seldom find in the very best architectural pictures in oil, although there seems to be nothing to hinder the highest finish and most deceptive degree of imitation being obtained in them, just as well as in still-life subjects—seldom worth the skill and labour bestowed upon them. This production of Mr. D. Wyatt's—whom we can hardly suppose to be a young hand, although we never met with his name before—is a perfect study for its execution, all the details and different materials being most admirably expressed; yet the whole is in perfect keeping.—No. 1342, "Milan Cathedral," (F. W. Stent) is another interior not a little remarkable, but more so for the singularity than the excellence of its execution, force being here exaggerated into caricature, for the tone of the whole is so exceedingly dark, and the lights which fall upon a few prominent parts, so unnaturally brilliant, that the latter look like so many pieces of mother-of-pearl inlaid on a ground of ebony.—No. 1258, "Interior of the Church of the Apostles, Rome," (J. P. Crew), is a drawing marked by the directly contrary fault of want of depth and solidity, not however to such a degree as to be therefore faulty in itself, and we only wish the artist had employed his pencil upon a better subject, the building being in poor and tawdry taste:—however, rather this than so very stale a subject as that of Mr. Crew's other drawing, (No. 1248, A View of the Coliseum from the Arch of Titus). Sadly at a loss for subjects for interiors must architectural draftsmen be, when they give us such a one as No. 1176, than which one more destitute of merit or interest of any kind could hardly have been found in all London. Had the author of that production walked into Moses' shop, he might have found a rather striking subject, at all events something quite fresh, but that any one should think it worth while now to show us the "Interior of the Chapel of the Foundling Hospital," is to us perfectly unaccountable. We should have been very suspicious of its being merely a copy from a print.

There are still one or two drawings of interiors, which we have not yet mentioned, because they belong rather to the class of designs for churches;—of which it will be expected that we should say something, yet it is but little that we have to say, there being few of them at all distinguished by any thing particularly good in them, or the contrary, except it happen to be by the sort of merits and defects that are extolled or vituperated by the "Ecclesiologist." What strikes us as rather singular, is, that among them there are scarcely any drawings of Churches or Chapels in or near the metropolis. St. John's, Charlotte-street, Fitzroy-square; St. Michael's, Pimlico; St. Andrew's, Well's-street; the Catholic Church, Farm-street; Bedford Chapel, the newly erected campanile of the Catholic Chapel in Spanish-place, Manchester-square—not one of these are in the Exhibition. Those which are, are exclusively in the Gothic or mediæval style, there being not a single drawing for church or chapel in any other, although Grecian or rather Greco-Italian seems fitter for buildings of the kind in towns, and so far from being prejudiced against such style, by the wretched and insipid productions in it twenty years ago, they might now be serviceable to us as warnings, and might convince us that should we resume the style at all, we ought to treat it very differently from what it then was. As to Gothic, it is undoubtedly very much better understood and practised than it was a quarter of a century ago or even much less, still it seems now to be got into a sort of respectable mannerism and method. Instead of design being left to be moulded by circumstances, every part of a church must be shaped according to certain arbitrary regulations; there must be this thing or that, though so far from its being at all required, inconvenience should be incurred by adopting it. Lucky is it for Eton College Chapel that it is not a modern structure, since it falls short of the present orthodox standard, in having neither aisles nor chancel, nor spire, nor even tower; neither has it more than a single range of windows, and those at a considerable height from the floor; yet it is not only a very fine specimen of architecture both internally and externally—but also exceedingly well suited for the Protestant worship. Nor is it without reason that we here mention it, there being three designs (1288, 1290, and 1296) by J. M. Derick, and J. Shaw, for restoring the interior.—No. 1260, described only as "View of a Church, designed by G. Alexander," without the name of its locality;—and Nos. 1295 and 1307, exterior and interior of "St. James, Seacroft, near Leeds, Yorkshire," (T. Hellyer,) are among the best productions of this class. But none displays more forcibly the enviable talent of being able to infuse a strong degree of character and originality into what in most hands would prove a very insignificant subject,—than No. 1329, "Healy Church, now erecting in the parish of Masham, Yorkshire," (E. B. Lamb). Small as it is in dimensions, and simple as it is in style, this little edifice is so full of piquant expression that it might pass for the *ideal* of an English *village* church. There is a great deal of effect with scarcely any thing to account for it,—it being that of a felicitous aggregate, and artist-like combination of parts. A design of this kind is a very severe reproach upon the soulless and idealess compounds of vulgar tawdry calling themselves designs for cathedrals and townhalls, which however we will pass by, in mercy, without pointing to them by their numbers or names.—The show of models this season is even poorer than usual, and things of the sort are always so badly shown at the Academy, so huddled up and jumbled together, that we almost wonder any should be sent at all.

SUPPRESSION OF SMOKE.

A report has been recently addressed to the Government by Sir Henry De la Beche and Dr. Lyon Playfair, respecting the means and effects of preventing the smoke of furnaces. The following extracts will sufficiently explain the conclusions arrived at.

"The general principles upon which the combustion, or rather the prevention of smoke, may be effected are now well known, and admitted to be applicable in practice. Smoke consists of vapours produced by the partial combustion or distillation of coal, carrying up small particles of the fuel in mechanical suspension, and depositing, by the combustion of one of their constituents, carbonaceous matter in a fine state of division. The mode of preventing this smoke is to admit a sufficient quantity of air to effect the combustion of the carbonaceous matter, when the vapours are of a sufficiently elevated temperature to unite entirely with the oxygen of the air. If the temperature be not sufficiently elevated, the hydrogen of the vapours alone is consumed, and the carbon is separated in the fine state of division referred to. The gases produced by the complete combustion of fuel are colourless and invisible, and therefore do not come under the definition of the term smoke.

"As the prevention of smoke implies the complete combustion of fuel, the result, as an abstract statement, always is, that more heat is generated, and a saving of fuel effected, when it is so consumed as to prevent the emission of smoke; but although this theoretical conclusion is undoubtedly correct, the practical results are not always consonant with this statement.

"In consuming smoke in the usual way a quantity of cold air is introduced into the fire, and as this must be heated up to the temperature of the surrounding fuel, the loss of the latter may be equal to, or even greater than, the saving of the fuel from the combustion of the products of distillation. This often results in the careless use of furnaces constructed on the principle of smoke prevention, and thus leads to the contradictory statements given by those who have used such furnaces. But in all carefully conducted experiments the saving of fuel has been considerable, and the reason of this will be at once perceived, when it is considered that in addition to the combustion of the products of distillation there is a large amount of fuel saved by the combustion of a gas called carbonic oxide, formed by the proper product of combustion, carbonic acid, taking up in its passage through the incandescent fuel, another portion of carbon, which escapes useless as regards the production of heat, unless burned by the air introduced at the bridge of the furnace, for the purpose of consuming the products of distillation.

"From these considerations, and from experiments conducted under our inspection, with a view to determine this point to our satisfaction, we arrive at the conclusion, that although from careless management of fires there is often no saving, and that indeed there is frequently a loss of heat in the prevention of smoke, still that with careful management the prevention of smoke is in many cases attended with, and may in most cases be made to produce, an economy of fuel.

"It may be unnecessary to remind your lordship that the cause of the emission of smoke in manufactories may be classed under three different heads, the relative importance of which involves very different considerations in any attempt to legislate for its prevention. These are—1. The want of proper construction and adjustment between the fire-places and the boilers, and the disproportionate size of the latter to the amount of work which they are expected to perform;—2. The deficiency of draught, and improper construction of the flues leading to a chimney of inadequate height or capacity;—3. The carelessness of stoking and management by those entrusted with the charge of the fire-places and boilers."

It cannot for a moment be questioned, that the continued emission of smoke is an unnecessary consequence of the combustion of fuel, and that, as an abstract statement, it can be dispensed with. But your lordship will perceive that there are grave difficulties connected with a general law to the effect that it shall be unlawful for chimnies, after a certain date, to emit smoke. With regard to steam-engines, the processes for the prevention of smoke have been matured, and in very many instances successfully employed. In this case, therefore, a law to that effect could be most easily and promptly carried out. In other cases mentioned in Lord Lincoln's letter, such as distilleries, dye-works, &c., the legislature has already granted powers in the Manchester Local Act; and as there are certain instances in which processes for the prevention of smoke have with them proved successful, it may be anticipated that the nuisance arising from these sources may be much abated, if they be subjected to the general law with that forbearance and caution which, under certain cases, is so advisable. There are certain processes in glass-works, iron-furnaces, and potteries, in which it is neither possible nor desirable to apply a general law for the prevention of smoke; although the nuisance may be partially mitigated, by causing the steam-engines employed in them to be so constructed as not to emit smoke.

It is useless to expect, in the present state of our knowledge, that any law can be practically applied to the fire-places of common houses, which, in a large town like London, contribute very materially to the pollution of the atmosphere; but it may confidently be expected, that by a wise administration of a legislative enactment, carefully framed, a great progressive diminution of the smoke of large manufacturing towns will be effected, and that the most happy results will thus flow from this improvement, in the increased health and moral feeling of their population, the intimate connection of which with facilities for cleanliness has been so often pointed out.

PLATE-GLASS MAKING IN ENGLAND IN 1846, CONTRASTED WITH WHAT IT WAS IN 1827.

(Compiled from authentic data by Henry Howard, Blackwall, and 4, Railway-Place, Fenchurch-street.—1846.

In 1827	In 1846.
Coals in London were about 31s. 6d. per chaldron in the Pool, which, with lighterage, wharfage, and cartage to the works, rendered them about 40s. per chaldron, or 30s. per ton.	Coals are landed at works near London at about 13s. per ton.
An annealing kiln contained 200 feet.	An annealing kiln contains 400 feet.
A casting furnace produced, say 1,200 feet per week.	A casting furnace produces 4,000 feet per week.
Hooded or covered pots were used for melting the glass, containing about 12 cwt. each.	Open pots are used, requiring less fuel, and containing about 20 cwt. each.
Pearlashes were at a high price, and heavy duty on alkali made therefrom. Pearlashes were in 1836, £43 per ton.	Pearlashes are about £23 per ton.
The casting-table was heated on the top by charcoal, at an expense of £500 per annum.	The casting-table is heated underneath by cylinders, at scarcely any expense.
An engine of 32-horse power ground and polished (12 hours to the day) from 800 to 1,000 feet per week.	An engine of 60-horse power will grind and polish at least 3,600 feet per week.
A grinding-bench ground 200 to 250 feet per week.	A grinding bench at —— Works grinds about 500 feet per week. A grinding-bench may be constructed to grind 600 feet per week.
A polishing-bench polished, 200 to 250 feet per week.	A polishing bench at —— Works polishes about 500 feet per week. A polishing-bench can be constructed to polish better and cheaper, nearly 1,000 feet per week.
A plate-glasswork in London manufactured about 60,000 feet per annum	A company near London is making 8,000 feet per week, or more than 400,000 feet per annum. And that is insufficient, but they can make no more, having no room to extend.
The price of rough and moulded plate varied from 5s. to 6s. per foot.	The price of rough plate (¼ and ½ of an inch thick) is 1s. 6d. to 2s. per foot; (cost 10d. to 1s. per foot.) And one company has an order for 43,000 feet!
Wages were comparatively low.	Wages are high, but they do not amount to so much per foot as in 1827.
Large plates were made with great difficulty, and the cost on the average is estimated at about 10s. per foot.	The largest plates are made with perfect facility, at less than 3s. per foot. And this amount may be still further reduced to about 2s. 6d. per foot.
The manufactures kept a very large stock on hand.	None of the houses can keep stock, but can only supply their customers from hand to mouth, and that very inadequately.

Summary—Average.—In 1827 Plate Glass sold for about 12s. per foot, to the extent of about 5,000 feet per week.
In 1836 Plate Glass sold for from 8s. to 9s. per foot, to the extent of about 7,000 feet per week.
In 1844 Plate Glass sold for from 6s. to 7s. per foot, to the extent of about 23,000 feet per week.
In 1846 Plate Glass sells for 5s. to 6s. per foot, to the extent of about 40,000 feet per week.
May 30.—Now nearly 45,000 feet per week—(Exclusive of foreign glass.)

Looking at the extraordinary increase that has taken place, notwithstanding the severity of excise restrictions, and seeing that the demand now progresses more rapidly than ever, even at 5s. to 6s. per foot,—if the price were reduced to 4s. or 3s. 6d. per foot (which, free as the trade now is from excise interference, would afford ample profit), what must then be the demand?

TRIAL OF MAIL STEAMERS.

The Lords Commissioners of the Admiralty, having ordered a comparative trial to be made, to ascertain the speed of three new boats, recently built for service as mail packets, on the Dover station, the trial was made, and the following is given from impartial persons who were present during the whole time:—

"*Dover, May* 31.

"A most extraordinary trial of speed took place yesterday, between three of Her Majesty's steam-packets—Garland, Onyx, and Violet—the former being of wood, and designed by Mr. O. W. Lang, jun., assistant to the Master-shipwright at Chatham Dockyard (son of Mr. Lang, Master-shipwright at Woolwich Dockyard), and built by Messrs. Fletcher and Sons, of Limehouse; and the two latter well-known iron-boats, the fastest ever built, by Messrs. Ditchburn and Mare, of Blackwall; the dimensions of the vessels being the same, and the engines also of equal power, by Messrs. Penn and Co., of Greenwich.

"The Garland, under the able command of Captain Smithett, and the Onyx, Lieutenant-Commander Mudge, left Dover at 7 o'clock, a.m., the latter having the mail and passengers for Ostend, Captain Mercer, R.N., Superintendent of Her Majesty's packets on this station, being ordered by the Admiralty for this purpose on board the Garland.

"Off Dunkirk these two vessels were met by the Violet, Captain Sherlock, who came out of Ostend to meet them and to return with the others. At this time, about 10 o'clock, the Garland had gone by and distanced the Onyx about a mile and a half.

"The great trial of strength then was to beat the Violet, and although there was a decided superiority in this vessel over the Onyx, the Garland in less than three-quarters of an hour was far enough ahead of the Violet to be able to cross her bowes. After this a second trial was made, the Violet altered her trim, but in this the Garland showed a still greater superiority; and in a third trial it was conclusive that the Garland could beat Violet about one-third of a mile an hour, and Onyx half a mile an hour, which has established the fact that the 'Wooden Walls of Old England' are not to be beaten by any other material or power, and we ought to congratulate ourselves and the country on the fact.

"The Garland returned from Ostend to Dover this day in 3 hours 55 minutes, which is by far the quickest ever known, and has established her reputation as being the fastest steamer in England.

"The Garland also fell in with the Queen of the Belgians, the fastest of the South-Eastern Ramsgate steamers, and went round her in less than a quarter of an hour."

THE NEW LOCOMOTIVE ENGINE "THE GREAT WESTERN."

On June 13th an experimental trip was made on the Great Western, from London to Bristol and back, for the purpose of trying the tractive powers of the new monster engine "The Great Western." The train weighed 100 tons, and consisted of ten first-class carriages, seven of which were ballasted with iron, the other three being occupied by the directors and those interested in the experiment.

The train started from Paddington at 11 hour 47 min. 52 sec. It passed the 1st mile-post at 11 hour 51 min. 1 sec., and came abreast of the 52nd mile (immediately after which the breaks were put on for the stoppage at Didcot), at 12 hour 45 min. 24 sec., running, therefore, the 51 miles, with a rise of 118 feet, in a few seconds over 54 minutes, or at an average speed of upwards of 56 miles per hour.

At Didcot a stoppage of 5 min. 15 sec. took place. The mile-post beyond Didcot, viz. the 54th, was passed at 12 hour 54 min. 27 sec., and the 75th mile-post (just after passing which the breaks were put on for the stoppage at Swindon) was reached at 1 hour 18 min. 6 sec., the distance of 21 miles having been passed over in 23 min. 39 sec., or at the average rate of upwards of 54 miles an hour.

At Swindon there was a stoppage of 4 min. 27 sec. The 78th mile-post was passed at 1 hour 29 min. 30 sec., and the 98th mile-post, which is a short distance on the Paddington side of the Box Tunnel, was reached at 1 hour 49 min. 26 sec., the 20 miles having therefore been accomplished in 19 min. 56 sec., or at upwards of a mile per minute. The train came abreast of the 117th mile-post at 2 hour 12 min. 3 sec. This gives the time occupied in running the distance between the 78th and 117th as 42 min. 33 sec. for the 39 miles, or something like 53 miles per hour.

The maximum speed on the down journey was obtained between the 83rd and 92 mile-posts. From the 80th to the 84th mile there is a falling gradient of 8 feet per mile, and from the 85¾th to about the 86½th mile there is a falling gradient of about 1 in 100, and a fall of 8 feet per mile then reaches to about the 90½ mile-post; a rising gradient of 8 feet per mile then succeeds, and extends beyond the 122nd mile-post. The train came abreast of the 83rd mile-post at 1 hour 34 min. 56 sec., and passed the 92nd mile-post at 1 hour 43 min. 8 sec., performing the 10 miles in 9 min. and 8 sec., or at an average speed of nearly 66 miles per hour. The 87th and 88th miles, on a falling gradient of 8 feet per mile, were run over at the rate of *sixty-nine* miles per hour.

The train arrived at Bristol about 15 min. past 2, thereby making the time occupied in starting from a state of rest to coming to a state of rest, or, in other words, from platform to platform, 2 hours 26 min., including stoppages, which averages a rate of 50 miles per hour.

At Bristol, a collation awaited the invited guests, Mr. C. Russell, M.P., in the chair. In the course of his speech took occasion to remark that a greater speed *might* have been attained, had not one of the pumps for supplying the boiler with water given way shortly after passing Slough, to remedy which they were under the necessity of reducing the pressure in the boilers. The train afterwards returned to London. Mr. Brunel drove the engine both ways.

The principal dimensions of this great locomotive are—Cylinders, 18 in. diam. and 2 ft. stroke; driving wheels, 8 ft. diam.; supporting wheels, 4 ft. 6 in. diam.; has six wheels and uncoupled; 278 tubes, 9 ft. long and 2 in. diam.; fire-box outside, 5 ft. 6 in. by 6 ft.; inside, 4 ft. 10 in. by 5 ft. 4 in., with a partition through the middle, giving 160 ft. of heating surface, and 20 fts for area of fire-grate; total heating surface, 1,750 ft.; from level of rail to top of cylindrical part of boiler, 9 ft. 6 in.; and from level of rail to top of chimney, 14 ft. 8 in.; supporting wheels 16 ft. apart, with the driving wheels in the centre; total length of engine, 24 ft.; tender on six wheels; weight of engine, 30 tons; tender, 15 tons.

The following statement of the time kept between London and Bristol taken from the *Times* slightly differs from the preceding statement, which is given on the authority of the *Railway Chronicle*.

*** The results of this experiment are deemed by the advocates of the broad gauge to settle the controversy in their favour, or, as Mr. Russell, M.P., chairman of the company, expressed it with more emphasis than elegance, "to put an end to the 'humbug' of the narrow gauge." With great deference, however, it may be submitted that this is not quite correct. The observation, that the engine would have gone faster if one of the pumps had not broken, seems a rather innocent one; for that "if" contains the whole gist of the matter. They never get up any astonishing performances on the Great Western Railway without one of these casualties occurring. We are constantly told of the wonderful feats of the express trains, but those who are accustomed to travel by this railway are always on the look out for some accident especially, which, if it do not involve loss of life and limb, causes a detention. There is always "a screw loose somewhere," or if it be not loose at starting, it works loose during the journey.

Now what is wanted in an important *commercial* agent such as the Great Western or the Birmingham Railway, is not a few showy results now and then, but constant uniformity and punctuality—not an excessive speed, but one which may be thoroughly depended upon. Until, therefore, the Great Western Company can work their engines at these high velocities for *months* together, and pass over the points and crossings at the intermediate stations, without accident, they will not have proved their point.

We offer no opinion here as to the superiority of either gauge; it seems to us that too many opinions have been offered already. As far as we can judge, the best railway gauge, if we had to begin *de novo*, would be one of intermediate width, but whether excess or deficiency of width be the greatest evil we cannot decide; of neither gauge have the powers been yet sufficiently developed to render it possible to pronounce an authoritative opinion. However, this is certain, that the diversity of gauge has at least one beneficial result; it stimulates the rival engineers to exert themselves to the utmost.

ROMAN REMAINS AT COLCHESTER.

The fifth number of the Journal of the British Archæological Association contains a description of some remarkable specimens of Roman art, discovered at Colchester. Among them was a sphynx, sculptured in stone, found in the garden of the General Hospital, about ten paces from the west wall, and about fifty-five paces from the London Road, at two feet from the surface of the soil: close to it was dug up a fragment of the tibia of a human leg, bones of oxen, deer, pigs, and fowls, with Roman pottery; and between twenty and thirty paces from the same spot, part of a sepulchral inscription to the memory of one or more legionary soldiers. Within the bounds of the hospital were dug up at the same time a large quantity of building materials, red and white tiles, coarse and unhewn stones, used probably in foundations, and a great many well-hewn fragments of a stone called swanage, from a place in the Isle of Purbeck, where it is chiefly dug; the fragment of the inscription above alluded to is of the same material. The stone in which the sphynx is sculptured is freestone, brought probably from Portland. Very recently, Mr. Taylor, the resident surgeon, has noticed, in the same locality, a Roman wall, from four to five feet wide, and from ten to twenty feet in length, as far as it was excavated. A bronze statuette of a sphynx, about an inch and a half high, was found in 1820, within a few yards of the stone figure. As a work of art, the sculptured sphynx exhibits a good taste and executive skill of no mean order. The fabled monster of Thebes, combining the five-fold attributes of a virgin, a lion, a bird, a dog, and a serpent, is correctly exhibited in accordance with the ancient myths in which it figures so conspicuously. The head, breasts, and arms, are those of a beautiful virgin; the fore-paws are of a lion; the body and fecund dugs indicate a bitch; the hinder part takes the lion's form; and the tail, doubled upon itself in short foldings, is the serpent in repose. The mangled remains of a human being lie beneath the figure, and protrude on both sides. The head of the victim is extremely well executed; the eyelids are closed; the mouth is drawn down at the corners; muscles are strained and set, and the countenance, sunk in death, conveys an expression of exhaustion and agony. Altogether, the composition is good and harmonious, and is probably of early date. On the base is cut a large S, doubtless a mark of the quarrier or of the sculptor.

In the collection of Mrs. Mills, of Lexden Park, is a bronze figure of Cupid riding on a sea-griffin, discovered some years since in excavating for laying the foundations of Colchester bank, but which has been hitherto unpublished. The god of love is often represented riding on the back of a lion, or on dolphins and sea-monsters, emblematical of his omnipotence, which is well symbolised in the triform griffin, a combination of bird, beast, and fish, obedient and tractable under the gentle sway of the youthful divinity.

AUST PASSAGE BRIDGE.

Sir—With respect to Mr. Fulljames's letter on the subject of the Aust Passage Bridge, I beg to state that in the paper published with the names of Mr. Giles and myself in your April number, there was no claim to originality in the proposition to build a bridge across the Old Passage of the Bristol Channel at Chepstow, the idea having been originally suggested by Mr. Telford many years since. A mere reference to the map will at once point out the Aust Passage as the narrowest part of the channel in that neighbourhood. The occurrence of rocks, visible at low water and suitable for the foundation of piers, is a still further recommendation of that locality for a suspension bridge.

The span of the bridge at Freiburg is 820 feet, and Telford proposed one of 1,000 feet at Runcorn. There is no doubt that this could be constructed so far as the mere strength of the main chains is concerned, but the liability to undulation is a very serious obstacle. I see no reason to alter the opinion already expressed that the plan which I have been anxious to lay before the public, would completely remedy that defect, which has proved very injurious to the most celebrated of our suspension bridges in exposed situations. I believe that a bridge with radial bars would, if properly constructed, be quite capable of allowing the passage of railway trains, and that opinion is confirmed by considering the strength which lattice bridges have by actual experience been found to possess.

The form of the suspension bridge proposed by me was first published in Weale's Quarterly Papers for Lady-day, 1845, and I there gave an outline of the design, which was afterwards described in a more complete form in your Journal, for a bridge over the Aust Passage.

Mr. Fulljames appears to intimate some intention of commenting upon my calculations. I shall feel very much obliged to him for pointing out *all the errors* which he is able to detect.

I am, Sir,
Your obedient servant,
Francis Bashforth.

REVIEWS.

Studies of Ancient Domestic Architecture, *with observations on the Application of Ancient Architecture to the Pictorial Composition of Modern Edifices.* By Edward Buckton Lamb, architect. Twenty Plates, 4to. London, Weale. 1846.

A book that comes with a quotation from Candidus for the motto on its title-page, brings with it, as may be supposed, a letter of recommendation to us, nor has the prepossession in its favour, so caused, been at all deceived. Mr. Lamb—whose name has repeatedly been mentioned by us for praise in our notices of the architectural drawings in the Royal Academy's exhibitions—has here produced an exceedingly clever work, replete with original remark and sound instruction. In the generality of architectural publications in which engravings constitute the leading and foremost feature, the letter-press is either of very subordinate quality—little better than mere filling-up stuff, or anything but architectural—sometimes evidently the compilation of some book-maker, who besides pillaging not only his matter, but entire paragraphs verbatim from others, does not seem to have even so much as looked at the plates to which he was writing. Such is not the case here, for, though all the subjects represent actual examples of ancient—that is, Old English-domestic architecture, instead of cramming his pages with gossip history about the houses themselves and the people (all their kindred included) by whom they have been occupied, Mr. Lamb leaves those readers who have a taste for such "information" to seek it in professedly topographical works, contenting himself with speaking of the respective subjects, "exclusively with reference to artistic criticism elucidated by direct example." Criticism of that kind—especially so good of its kind as what we here obtain—is rather a scarce article; at least, it is very rarely served up to the general public, who are kept upon a water-gruel diet of discussion about "styles" alone; as if people needed to have such *incipient* information to be dinned into them on every occasion, and needed no other instruction at all. A very great deal more, it may be suspected, is requisite for enabling them to make use of such "first-step" knowledge, when we find that even those who can show off very fluently, so long as they stick to styles and dates, either become quite mute in regard to anything further, or else betray that their *knowledge* is all got by rote, and does not reach beyond what just enables them to discriminate between one style and another, but leaves them incapable of judging of individual productions of the art, except as they happen to conform to or deviate from precedent. So strongly, indeed, is a blind and servile regard to Precedent now insisted upon, that nothing seems to be left for us to do in architecture but to copy literally what *has* been done; besides which, it might be thought that those who lived in former ages had so completely foreseen and anticipated all the wants of the present one and of our actual social condition, as to render any further modification of the styles we borrow from them wholly unnecessary—and not only unnecessary, but dangerous. If Precedent is to be so followed—not as a guide merely going before us on the road, but one on whose footmarks we must plant our own feet at every step,—we may as well renounce at once, both for ourselves and for architecture, the power of doing anything that has not been done before. Those who cautiously follow Precedent step by step generally hobble along though they may not stumble; yet better is it that some should stumble—perhaps, break their necks—than that a whole generation should go hobbling along, and perhaps, at last, get angry and shove Precedent aside, and fairly take their leave of him altogether.

We are not losing sight of Mr. Lamb all this while, for we are glad to find that he has not at all more respect for that same bugbear Precedent than ourselves. He too considers Precedent—that is, that "slavish adherence to it which paralyses all invention"—to be the "very rust of art—the canker that feeds upon its vitality." After all, too scrupulous a regard to precedeet affords not the slightest defence against bad taste in architecture and decoration, for, as is here observed, "the worst conceits of the Pompeian, the tawdriest crinkum-crankums of the Louis Quatorze style, are *facsimilized* by our decorators, as if the taste displayed in them were so pure and perfect, that to deviate from it would be profanity."—But let us begin at the beginning, *mon ami* Belier, and, *certes*, the opening paragraph of the volume is well penned, and serves as a very appropriate vestibule—to express ourselves architecturally—to what follows.

"At the time of its being re-introduced and adopted into modern practice, so very ill was our mediæval architecture understood, so great was the ignorance that prevailed even as to its very nature, constitution, and physiognomy, and so completely was even that ordinary sort of good taste which is founded upon good sense disregarded, that notwithstanding its evident and almost total unfitness for the purpose, the ecclesiastical style of former times was taken—or, to speak more correctly, mistaken—as one for imitation in modern residences, while our ancient Domestic architecture" (Mr. L. rejects the orthodox final *k* of the Camdenists in "Domestick") "—examples of which are, or were then at least, sufficiently numerous and varied, both in towns and in the country,—was overlooked altogether. Church windows—or something like church windows—spruced up and divested of all characteristic finish and detail, entitled a modern house to be called a Gothic mansion. In like manner, a line of battlements, and perhaps a turret or two besides, were deemed quite sufficient to constitute a very passable 'castellated style.' Then again, we had Gothic cottages—perhaps the race is not yet quite extinct—spruce little things, whose *Gothicism* lay in their having pointed-arch apertures for windows. In short, had it been intended to parody and burlesque our former styles of architecture, for the purpose of bringing them into contempt, hardly any better mode could have been devised."

This is most true; and not the least singular part of the matter is, that the most egregious parody and burlesque of all should have been perpetrated by one who not only set up for but actually was, and by some still is, looked upon as an accomplished antiquary and a profound authority in matters of taste; for in both the one character and the other, most completely does Strawberry Hill damn the credit of Horace Walpole. The Strawberry Hill humbug, however, is over; and, as Mr. Lamb says, "We can now laugh at such things as supremely ridiculous, although the laugh will not be joined in cordially by every one,—not by those who have had such flagrantly absurd taste entailed upon them by their immediate predecessors, and perhaps at an enormous expense. Even yet, however," he continues, "Ancient Domestic architecture is not sufficiently understood. In regard to certain individual features that serve as distinctive marks of buildings of that class, it may be allowed to be tolerably well understood at the present day; yet hardly is it so in its nature as a style—as one capable of expressing itself distinctly, decidedly, and without any affectation, even on ordinary occasions. In like manner, as there may be a great deal of aim at character by means of certain pretensious features, yet, after all, little of it in general composition, and just as little of artistic effect,—so may a very strong degree of character be kept up or produced where there is apparently scarcely anything to account for it. In art—and I would wish to assert such title for architecture—it is only what would be called a few trifling touches that frequently contribute all the difference between the masterly and the trivial. Unfortunately for architecture, it has not been considered necessary to teach more than elementary forms, without regard to their value and effect in combination; in other words, without regard to composition and character. It is true, the really *artistical* lies beyond the limits of the *teachable*, yet for that very reason ought students to be impressed with the necessity for striving to advance beyond mere rules—with the necessity for self thinking."

Now, confound the book! we go on transcribing and transcribing without knowing where to stop; and feel ourselves shrunk from a reviewer into a mere copyist. And, as if on purpose to vex us, what is said is so much to the purpose and so well expressed, that we cannot attempt to condense it without injuring it. We must, therefore, skip over a very great deal, and content ourselves with producing some of the passages which have most arrested our attention, or which are sufficiently intelligible in the separate form of extracts. The following is one of them:—

"The reproduction of ancient forms can never be the means of *continuing* the art as it was practised by those whom we affect to imitate by merely doing exactly as they did under widely different circumstances. The adoption of the improvements necessarily resulting from advancing refinement has ever influenced architecture. The whole history of the art, in our own country in particular, attests this. Almost every successive century produced some marked change—some one of those distinct modes which we designate *styles*, though all belonging to one general style. Be it especially observed, too, that such successive changes were always gradual and uniformly progressive: there was in those days no such thing as the *re-assumption* of any former style. Wherefore there is reason to believe, that had not an entirely new direction been given to architecture in the sixteenth century, the very latest Gothic or best Tudor might have been carried on much longer, and would have acquired fresh spirit and energy. We of the present day are, on the contrary, at once exceedingly strict, and exceedingly lax,—most bigotted in some respects, and most latitudinarian in others; for although shocked at the idea of presuming to treat any one style with artistic freedom, our taste is so pliant that it accommodates itself to nearly all styles alike, just as whim or fashion brings them by turns into vogue. For all the styles we possess we are entirely indebted to those who have gone before us, not even attempting to make any addition of our own to the general stock; whereas, by *continuing* the same spirit which marked the works of preceding ages, we should in a short time work out a style accommodated to our actual requirements, and at the same time marked by æsthetic quality."

Very different is this from—we need not say how much more rational and how much more cheering than—that doctrine which would convert art into mere mechanical routine, and which tacitly proclaims—(mark the bull!)—disbelief in the ability of architecture to do more than copy and repeat its former deeds and doings. It would seem that, though its hands may be as strong as ever, its intellects are impaired—its imagination completely gone; so that it has become not only prosaic, but a twaddler and proser at once boastful and desponding, and for ever and anon exclaiming "Oh! the days when I was young!" Not content with its keeping to one route, pedants and sticklers for precedent insist upon architecture being handcuffed and manacled also. If it presumes to put forth a finger or make a single movement of any kind that is not in conformity with their instructions, they stand aghast at its temerity and audacity. Yet surely there is nothing unreasonable in demanding that we should be allowed to *continue* any style which we have taken up, by modifying and adapting it to existing occasions and purposes. The right of such *continuation-process* has been claimed in Germany, where its good effects have shown themselves in several instances. That it has been uniformly attended with success we do not say; but for what style, we would ask,—let it be adhered to ever so slavishly,—can uniform success be insured? Some have gone astray, quite astray perhaps;—well, what then?—are we to have no more wine because some people get beastly drunk with it?—or "are we to have no more cakes and ale because *Sir Robert* is virtuous?" Let it also be carefully borne in mind that the ultimate efficacy of a *continuation-process* is not to be prejudged from its beginnings. It must have time to operate. A tree does not bear the desired fruit the very day after it has been engrafted. At any rate, those who do not care to venture upon any fresh ideas themselves, ought not to discourage others by "pooh-poohing" and sneering. To say the truth, their doing so betrays what they would most studiously of all conceal, namely, their apprehension not of failure for others, but of their success,—apprehension lest those who are more enterprising and possess more artistic stamina than themselves should get forward by leaping over the fence that bounds the beaten pathway.

It is easy enough, it will perhaps be objected, for any one to say that we *ought* to modify those styles belonging to former periods which we now make use of; the difficulty lies in the doing it. True: and to be reproached for not doing it might seem too much like an inconsiderate if not insolent taunt on the part of a mere writer on architecture, totally unpractised in design. Such a one speaks under the comfortable assurance that his own ability will never be put to the test; but the author of the present volume has shown that he is capable of acting up to his own doctrine, and that while treating a style freely, he can be truer to the spirit of it than many one who pique themselves upon copying from it literally, and can produce "certificate" for each separate part in their designs. There are buildings which cut a very brave figure in description, yet a very sorry one when beheld; for we then ofttimes find that the great something in words, turns out to be a nothing in reality, or at the best, something very feeble and poor. Nor is it in the treatment of style alone that Mr. Lamb shows *forte*, for he is generally exceedingly happy in composition; and on the subject of composition—certainly a very important one—he gives us some excellent remarks in this volume, and they are all the more welcome because scarcely anything of the kind is to be found in books that are otherwise professedly for architectural instruction. In continuation of the general remarks on composition, are others more specific, and in detail forming a connected commentary on the subjects shown in the plates, and which are thereby rendered *studies* in a double sense. In fact, the work altogether abounds with instructive lessons, and is one that deserves to be studied with attentive reflection as well as read; and that it will be read by all those who, if they can't buy, can steal or borrow it—(viz., steal by borrowing, the latter being the approved fashion of book-stealing)—we may venture to prophecy, unless we are altogether mistaken by attributing to the architectural public far greater relish for art than they feel. Although we cannot even pretend to prophecy as much, we would fain hope that this is only the precursor of other publications from the same quarter, for Mr. Lamb has opened a path for himself and entered upon a wide as well as an ungleaned field. At present, he has shown us only actual instances of Old English mansions and country-houses, but though they hold out excellent hints, and possess character and physiognomy, we now require to see some of those or else similar examples accommodated to modern ideas of comfort, and to modern refinements and modes of living. At any rate, he has rendered himself debtor to the public for a corresponding volume on the other division of Domestic Architecture, viz., that which relates to internal arrangement and design, furniture, perhaps, included,—a branch of his profession to which Mr. L. has directed his attention in a more than usual degree, as is attested by various contributions of his on the subject, in "Loudon's Encyclopædia of Cottage and Villa Architecture.

Horizontal Water Wheels, especially Turbines; their history, construction, and theory. By Moritz Ruhlman. *Edited by* Sir R. Kane. Dublin: Hodges and Smith, 1846; *small quarto;* pp. 76. *Six lithographic plates.*

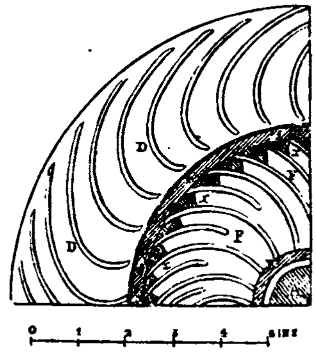
Notices of the construction and power of the turbines, or horizontal water-wheels, have appeared in this Journal in the volume for 1842, p. 265, and in the volume for 1844, p. 85 and p. 325. The publication of the work before us enables us to give some further information respecting the practical results obtained from these machines.

The present treatise is translated by the editor from the German, with the addition of some notes and an introduction. The translation was undertaken on account of numerous inquiries from millwrights and engineers, addressed to Sir Robert Kane, in consequence of his having directed attention to the turbine in his work on the "Industrial Resources of Ireland." He has selected for translation the present treatise by Professor Rühlman, as the most suitable for his purpose: at the same time he gives accounts of several other treatises on the same subject. From one of these, that by M. Morin, we take what we consider a very important extract, because it exhibits the general practical effects of turbines as determined, not from a doubtful theory, but from actual experience, and because these conclusions are confirmed by the authority of a commission consisting of MM. Arago, Prony, Gambey, and Savary, appointed by the Academie des Sciences to report on the subject. The following are the general results of the investigation:—

1. That the wheels are applicable equally to great and to small falls of water.
2. That they transmit a useful effect, equal to from 70 to 78 per cent. of the absolute total moving force.*
3. That they may work at very different velocities, above or below that corresponding to the maximum effect, without the useful effect varying materially from that maximum.
4. That they may work from one to two yards deep under water, without the proportion which the useful effect bears to the total force being sensibly diminished.
5. In consequence of the last preceding property, they utilize at all times the greatest possible proportion of power, as they may be placed below the lowest levels to which the water surface sinks.
6. That they may receive very variable quantities of water without the relation of the useful effect to the force expended being materially lessened.

Rühlman's treatise is divided into three parts—I., a history and description of the turbine; II., rules of construction; III., the mathematical theory. We shall confine our attention chiefly to the first of these sections, for the "rules" in the second section are derived from the "theory" in the third, which theory, whatever may be its value as a speculative inquiry, does not seem sufficiently well established to satisfy the wants of the practical mechanician. M. Rühlman's calculation of the useful effects of the turbine is founded on the principle of the Conservation of Vis Viva, and would perhaps be perfectly satisfactory if that principle held for fluids in motion. But it does not: the theoretical effect calculated from this principle is much greater than the effect really produced in practice; for it is found by actual experience that a large portion of the force of water in motion is absorbed by the mutual action of the molecules of water on each other, and by various resistances far too complicated for calculation. It is true that the results obtained theoretically may be modified by the introduction of "practice-coefficients:" but these coefficients, obtained from experiments on one kind of water machines, are not necessarily accurate when applied to another kind. Indeed, Sir R. Kane himself observes in his introduction, that "the action of the turbine, considered as a problem of hydrodynamics, involves conditions to the discussion of which science in its present state scarcely reaches." The value of the theoretical rules is therefore very doubtful. The most prudent course in this, as all other cases of practical mechanics where the theory is not fully settled, is to trust principally to experience, not neglecting, however, the *general* suggestions obtained from theory.

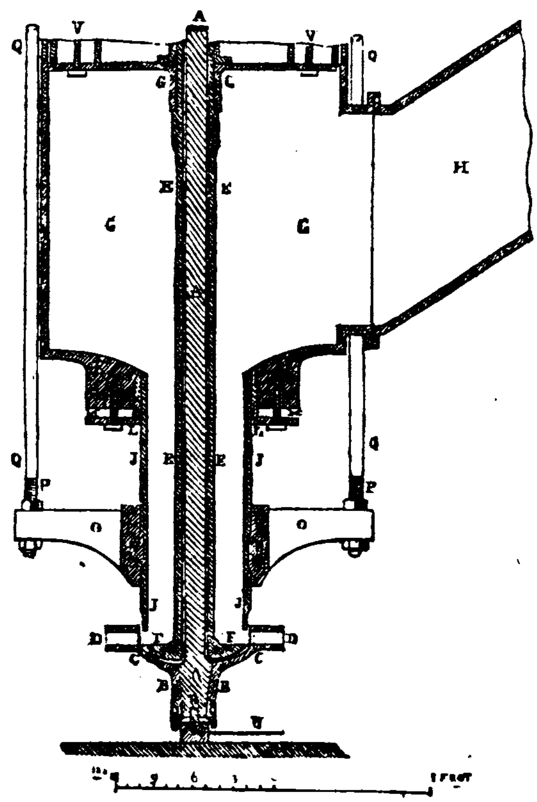
To proceed, however, to that portion of the present treatise which is of more direct interest, we observe that the general result of experience and of all that has been written on the subject tends to show that, of all the forms of the turbine hitherto invented, that by Fourneyron is by far the most useful, and to this, therefore, we may confine our attention. The following is a plan of a quadrant of a horizontal wheel erected on Fourneyron's principle in a cotton factory, at St. Blasien. The plan is drawn to a quarter the actual size.



In order to understand the action of the wheel, the reader must imagine the circles, of which the quarter only is drawn, completed. The machine will then be seen to consist of two parts—an inner wheel *fixed*, and an outer or larger wheel *revolving*. The water comes from the centre, proceeds along the guide curves F, F, which cause it to impinge directly upon the curved paddles D, D, attached to the outer wheel, which consequently revolves in the opposite direction to the impulse of the water.

The shaded parts *x, x*, are stops attached to a drum J J: the object of these stops is to shut off when requisite, the communication between the inner fixed wheel and the revolving one. J J is capable of being raised or lowered by external machinery, and consequently *x,x*, descending between the guide curves regulate the supply of water or shut it off altogether.

The next cut is a vertical section of the whole turbine, and shows the method in which the water is supplied to the revolving wheel.



* From Smeaton's experiments (Phil. Trans. 1759) it appears that in ordinary overshot water-wheels, nearly 80 per cent. of the original moving force is usefully applied; and that in undershot wheels, the useful effect is no more than 30 per cent. of the original power.—Ed. C.E. and A. Journal.

The water comes first from the supply-pipe H, into the cylinder G G, descends E E, and falls on the fixed guide-curves F, F; from these it rushes in horizontal streams against the paddles in the revolving-wheel D D, and finally escapes at the circumference D D.

The revolving wheel is connected by C C with a shaft B B, which turns on a pivot at its lower extremity. B B carries a main axle A A, which goes up through the water cylinder, and is applied to turn the machinery of the cotton factory.

J J, as has been explained, is the sluice which regulates the supply of water. The manner in which J J may be raised or lowered is easily seen from the diagram. The arms O, O contain matrices, in which the screws P, P work: these screws are at the ends of long rods Q, Q, turned by winches not shown in the diagram. It is clear that by turning Q, Q one way or the other, the sluice will be either raised or lowered.

L, K, M, show the means of packing J J to keep it water-tight.

U is a little conduit by which oil is conducted from a small reservoir to keep the pivot R constantly lubricated.

The main shaft and pivot are of steel, the wheel of wrought-iron, and all the other parts of cast iron. Though the wheel is only 12½ inches in diameter, it drives 8,000 water spindles, the roving frames, carding engines, and all the accessory machinery. The number of revolutions, with ¼ of an inch sluice opening, are 2,200 per minute. The available fall of water is 350 feet.

The following is Rühlman's account of his first impressions on examining this machine:—

The second turbine erected by the inventor at St. Blasien, with a fall of 117 yards, has become more important than any other. I can best describe this turbine by detailing what I myself saw and learned upon the spot during the journey already referred to. Already, half an hour before arriving at the remarkable locality of St. Blasien, situated in one of the most beautiful, but also of the wildest and loneliest parts of the Schwartzwald of Baden, a curious noise announces the uncommon spectacle, which becomes more extraordinary as you approach.

On entering into the wheel-room one learns there that what had been heard at a distance about this place was not merely mystification, but reality.

One then feels seized with astonishment, and wonders, more than in any other place, at the greatness of human ingenuity, which knows how to render subject to it the most fearful powers of Nature.

At every moment the powerful pressure appears likely to burst in pieces the little wheel, and the spiral masses of water issuing from it threaten to destroy the surrounding walls and buildings. Often when I went out of the wheel-room, and looked at the enormous height from which the conducting tubes bring down the water to the wheel, the idea forced itself upon me, "that it was impossible," but that idea passed away when I went back into the little room.

Fourneyron has here, for the first time, solved a problem, which will for ever render his name historical in the technical and scientific world, a problem in which he had to overcome not only the greatest obstacles of Nature, but also disfavour and prejudices in a thousand forms. Who could find any other means of utilizing this existing water power? Perhaps a water-pressure engine might be applied? Certainly not; since even without proving, by calculation, how little that kind of machine is suited for rotatory motion, it is only necessary to consider the very difficult and very power-destroying conversion of a vertical reciprocating motion into an uniform rotatory motion, in order to sufficiently appreciate the difficulties.

The conclusions arrived at respecting the general merits of the invention seem well worthy of attention, for they are expressed by an impartial witness, who has taken great pains to get at the truth.

It is certainly not true that turbines are capable of totally displacing vertical water-wheels, as was at first asserted. The greatest obstacles to the erection, construction, and working of turbines, at least in Germany, arise from the fact that many years must elapse before our millwrights will have acquired the necessary theoretical knowledge and practical experience. With these machines everything must be really calculated. It will not do to construct one wheel after the pattern of another, or to trust to what is called the practical shape. But also the construction of these wheels, in the workshop of the machine-maker, requires the greatest care, observation, and prudence, otherwise, no matter how it may be calculated, a good wheel cannot be produced.

It is now also fully admitted that Fourneyron deceived himself in supposing that these wheels economized 80 per cent. and more of the total available force. But the latest and fullest experience has shown that they economize certainly from 60 to 70 per cent., when those precautions are taken which should be attended to in their formation.

Finally, as to the choice between vertical wheels and turbines, in any particular case, it is decidedly to be considered that in every case where an overshot wheel, or a wheel with tolerably high breast, and what are termed overfall sluices, can be erected, such is to be preferred to the turbine; since the former, when carefully constructed, easily economizes more than 70 per cent. of the power. Yet in cases, as in cornmills, where the horizontal motion of the turbine may be immediately made use of, or where there is much back water to contend against, this assertion may require to be modified, since, as mentioned already, the turbine may be sunk to a considerable depth in the back water, without losing any material proportion of its power.

In every case of a fall, either higher or lower than that suitable for an overshot wheel, the turbine deserves decidedly the preference, and their not being erected in all such localities can only arise from want of knowledge, the apprehension of their being badly made, or of their cost being greater than that of the vertical wheel, which it should not really be.

The share which Sir Robert Kane has in this work as translator is by no means an unimportant one. He has reduced all the German and French measures to the English standard, and has interspersed the text with useful notes. His introduction is also valuable, for it directs the inquiries of those who require more information than that given in the present treatise, and his undertaking is, on the whole, a very valuable contribution to the literature of engineering.

The principal practical objection to the use of the turbine is, we believe, the difficulty of preventing the smaller parts of the machine from being stopped up by impurities in the water. The velocity with which the water is required to be discharged from the wheel renders it difficult to strain or filter the water sufficiently without impeding the current.

It may be useful to observe that in order that the full effect of the water may be obtained, it ought, when issuing from the circumference of the wheel, to be moving with the same linear velocity as the point from which it issues. For this is clear, that if the water be moving with *greater* velocity than the extremity of the channel between the paddles from which it issues, then, had the length of the channel been greater, the water would have continued to impinge on the paddles, and would have done more work. Again, if the water be moving at *less* velocity than its point of exit, it is obvious that, for some distance before the exit, the channel has been urging the water forward, instead of the water impelling the channel. But in the case where the velocities of the water and its point of exit are *equal*, neither acts on the other: the water no longer impels the channel, which shows that all the work is got out of it; and the channel does not urge the water, which shows that the motion is not impeded. This is the reason why turbines are made to revolve with so great velocity as that stated above.

Very similar reasoning will show that the end of the channel ought to be a tangent to the circumference of the wheel; for in that case neither does the water act on the wheel nor the wheel on the water at the point of exit; whereas, had the channel been more or less oblique, either the water must have been pressing on the paddles, or the paddles on the water, at the moment of issuing.

It may be useful to some of our readers to know that there is a model of Fourneyron's turbine in the model-room of the Museum of Economic Geology, in Craig's-court, Charing-cross—a museum little visited, because, we suppose, it is one of the most interesting in London, and is perfectly open to the public.

Weale's Quarterly Papers on Engineering, *for Christmas*, 1845; *part X., published June 1st*, 1846. Weale, pp. 204, 16 *Plates*.

The present part contains four papers: the first, a continuation of the "History of the Machinery and Manufactures of Great Britain," occupies 137 pages; the "Memoir on the Thames Tunnel," 29 pages; "an account of the Construction and Statistics of the Railway from Frankfort to Wisbaden," 27 pages with 15 plates; "a description of the proposed Wet Dock on the Wear at Sunderland," 11 pages, with one plate.

The first paper is devoted to the manufactures and improvements in machinery during the seventeenth century, and displays considerable antiquarian research. It contains, among other subjects of interest, an account of the efforts of Parliament to remedy the abuses arising from the royal privilege of granting patents. That wise and revered monarch, king James I., seems, to use a common phrase, to have made a good thing of his power of protecting inventors, for he frequently managed to share the profits, without bearing any part in the risk of the speculation. For example, in 1612 was granted "a patent to Simon Sturtevant for divers mechanic arts and mysteries of his own invention, whereby all kinds of metal workes........ now made after the ordinarie course with woodfuel and charcoal, may bee as well made and wroughte with sea coale, pit coale, earth coale, and brush fewel." The agreement was this—"the profits were to be divided into *thirty-three* parts, ten of which were to go to the King, five to Prince Henry, two to the Duke of York, and one to Viscount Rochester: the remaining *fifteen* shares were to be the property of the patentee, *who was to find all the money and run the whole risk.*" Fortunate Simon Sturtevant! The paper contains also a copy of the Marquis of Worcester's celebrated "Centurie of Inventions." The marquis must have been an extraordinary man, for, by his own account, he effected several physical impossibilities.

The continuation of the memoir of the Thames Tunnel follows. The account of the repeated discouraging failures to which Sir I. Brunel was subjected in the progress of his great work, and the courage with which he persevered, is very interesting. There are not, however, in the present number any of those admirable plates, representing the mechanical contrivance employed by Brunel in the Thames Tunnel, which rendered the former portions of this memoir of specific value to the engineer.

The letter-press description of the Frankfort and Wisbaden railway does not possess an interest commensurate with the excellence of the engravings by which it is illustrated, for the ground traversed by the railway is so level that there are few, if any, engineering works worthy of detailed description. We can speak from personal knowledge of the excellent regulations by which this railway is managed, and the convenience of dividing the passengers into *four classes*, all of whom travel much more cheaply than they would in England, and are seated in comfortable carriages defended from the weather and the smoke and hot cinders of the engine. In Germany, the comforts of the poor are less *talked* about than in England, but we are not certain that they are less attended to.

The new dock at Sunderland is designed by Mr Stephenson and Mr. Murray, and is to be 27 acres in extent. The following extract from the report of Mr. Walker, who was commissioned by the Lords of the Admiralty to examine the plan proposed, will explain the principal novelty in the design:—

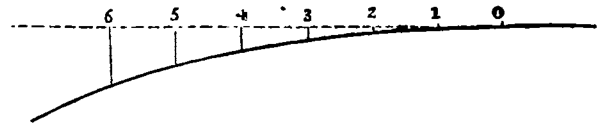
"The lift of a spring tide being only 14 feet 6 inches, the dock is to be 6 feet under low water, giving 20 feet 6 inches water in the dock on a spring, and 17 feet on a neap tide. The above depths can be maintained in the dock, but the depth at the bar at the harbour mouth is two feet less, so that with the "scud" of sea during a north-east gale a vessel drawing more than 14 feet cannot venture over the bar with safety. To have the dock so much deeper than the approach to it would be of little use, and yet, from the great draught of ships from foreign ports, it would be very advisable to have not less than 17 feet at neap and 20 at spring tides. The engineers propose to accomplish this by sending laden vessels chiefly out at the south end through a tidal basin of 4½ acres, with two openings, one having gates of 60 feet, and the other of 45 feet, between the dock and it and other similar gates between the basin and the outer entrance. The outer entrance or rather *exit* points south, south-east nearly,* and is to be formed by means of rough breakwaters, one on the east ride, nearly parallel with the entrance, and the other on the west side, nearly square with it. This southern passage is proposed to be as deep as the dock, and to kept to that level by *dredging* and *scouring*. The very important feature of the plan (the southern passage), is, so far as I remember, *new;* and if it can be effected as proposed, will be a great convenience, by giving laden ships two to four feet more water than can at present be depended on; starting them in the right direction for the south, when the wind is fair, also leaving the Wear or harbour entrance clear for the present harbour, and the entrance of light ships into the docks."

On Staking out Railway Curves. By George Heald. Carlisle, 1846. pp. 7.

This is a small lithographed pamphlet of seven pages, of which the extract given below will give a sufficiently correct idea. The author's plans of setting out curves seems correct; however the investigation does not require any wonderful amount of geometrical ingenuity, and we hope that the time is not far distant when every engineer and surveyor will know enough mathematics to solve so simple a problem for himself, without having recourse to books. This remark is however made without disparagement of the treatise before us.

The curve described in the following extract is strictly speaking a parabola—the curvature of a parabola near its vertex resembles that of a circle with sufficient accuracy for the purpose here proposed, if the offsets be small, and the radius of curvature very large.

"Having by the practice and examination of several methods of staking out railway curves arrived at the conclusion that it is best effected by employing the theodolite; and several friends having requested a detail of the system that I have pursued for that purpose. I have had the following summary of the principles lithographed for the information of those who may be desirous of becoming acquainted with the system. Suffice it to say as its recommendation that the system insures the curves being truly circular, and greatly economises the labour that is often requisite to drive the curve through a distant given point from which little or no variation can be allowed; which is a case of frequent occurrence, and upon some systems one whose practical execution is very tedious.



"The first principle is, that in circles of the magnitude of those used for railway curves, if a tangent be drawn to them, the offsets from the tangent to the curve increase according to the squares of their distances from the point of contact.

Thus let the junction of a curve and tangent be at 0; then, if equal distances be set off from 0 at the points 1, 2, 3, 4, 5, and 6, which may represent chains, the offset from the tangent to the curve at the 2nd, 3rd, 4th, 5th, and 6th will be respectively 4, 9, 16, 25, and 36 (or 2^2, 3^2, 4^2, 5^2, and 6^2) times the offset at the 1st chain.

"This is one of those close approximations which, though not rigidly correct as an abstract mathematical proposition, is much too near the truth to permit any discrepancy to appear after the most critical examination; it being understood that when the radius is as small as twenty chains, the length of the tangent is restricted to three chains, and when it is three miles radius it is restricted to eight chains, it is between these limits that railway curves are supposed to range.

"In the practical staking out of curves the offsets from the tangent to the circle at each chain length, expressed in inches, or feet and inches, are made use of, and from the preceding paragraph it will be seen that having the offset from the tangent for one chain length given, the succeeding chains will be deduced from it by multiplying by 4, 9, 16, 25, &c.

"It perhaps will not be amiss at this stage to point out a rule for finding these offsets, which is particularly convenient when the radius is some aliquot part of a mile, like the principle enunciated in section 2, to which it is so closely allied, it is practically correct, but not mathematically true. Its somewhat singular phraseology runs thus—from the square of the tangent in *chains* subtract its $\frac{1}{100}$th part; divide the remainder by the diameter of the circle in *miles*, and ten times the quotient is the required offset in *inches*.

A Treatise on the Steam Engine. By the Artizan Club. Parts XXIV. and XXV. Longman: 1846.

As these are the concluding parts of the treatise, we may as well say a few words respecting its general character, notwithstanding that the work has already been frequently noticed in these pages.

Excepting an excellent folio plate giving views of 14 of the most celebrated varieties of direct action marine engines, the present numbers contain little that possesses independent interest, for they are chiefly occupied by the index. We have however the introduction, by the editor, Mr. Bourne, and the character which he gives his own performance is on the whole so nearly correct, that we are content that it should be taken as an expression of our judgment on the work.

"The circumstance of having been published in monthly numbers furnishes, of itself, an explanation of many imperfections; for it can hardly be expected that works produced under the exigencies of periodical publication should be distinguished by the perfections which belong to literary leisure and fastidious elaboration. I have been obliged to confide the greater portion of the theoretical part of the present work to some mathematical assistants, whose algebra has, I fear sometimes risen to a needless luxuriance, and in whose superfine speculations the engineer may perhaps discern the hand of a tyro. In spite, however, of its imperfections I believe that the present Treatise on the Steam Engine is likely to prove the most useful yet published; and it is the only one, I believe, which can be regarded as of a really practical character. Although falling far short of my conceptions of what such a work should be, I believe that it substantially fulfils the promise held out in the prospectus; and having now collected the rough materials, I trust to be able, should another edition be called for, to clear them of the dross by which they are now disfigured, and present them in a form that will in some measure justify the public approbation.

"The preliminary and practical portions of the work have, for the most part, been executed by me, the disquisitions upon the slide valve and parallel motion are taken from the 'Artizan,' and other portions of the work are by various members of the Artizan fraternity. In the practical part of the work I have been able to obtain but little assistance from previous authors, and many of the subjects discussed are now brought for the first time before the public. Mr. Farey's work, though of great merit, gives but little information of any kind touching modern engines; and Tredgold's work is chiefly made up of mathematical sublimities, which have but little relation to practice."

The acknowledgement of the theoretical errors is made in a manner which disarms criticism. As far as we could judge the errors arose from an attempt to combine the theory of De Pambour with that of Tredgold—that is, the true with the false. We have no hesitation in saying that

* The bearings are all by compass.

Tredgold's theory of the steam engine bears the same relation to the truth which the speculations of the old Greek philosophers respecting planetary motion bore. The evaporative power of the boiler as an ingredient of numerical calculation is entirely neglected in Tredgold's theory, and the gross errors of principle with which his work is filled are made ten times worse by Mr. Woolhouse's profession of having corrected them. It is really too late, now that De Pambour's masterly investigations have been for six or seven years before the world, to endeavour to revive Tredgold's exploded views, and we regret that the treatise before us should have been injured by this injudicious attempt. However the reader is, we are very glad to find, put upon his guard in the preface, and it is therefore his own fault if he be deceived.

The great merit of the present work is the vast quantity of information which it affords as to details of construction. In this respect it seems unrivalled. The only thing to be complained of under this head is that a large amount of matter is frequently compressed into so small compass that the reader will often have a difficulty in finding the information for which he is in search. The book is not sufficiently digested—not systematic enough. It contains a vast store of invaluable facts, but these, like other warehoused commodities, are frequently so crowded together that it is difficult to get at them. Mr. Bourne talks of having a new edition; we hope that he may be encouraged to do so, and that he will adopt in it a simple and exact arrangement by which the reader may find "every thing in its place, and a place for every thing."

Hand Book of Mapping and Engineering Drawing. By B. P. Wilme. London: Weale, 1846, quarto. Part 6. Page 69.

This is the concluding part of a practical treatise on engineering drawing, which has been already favourably noticed by us. The present part contains a comparison of the different methods of copying maps, a description of drawing instruments, methods of representing geological strata, &c. There are some useful suggestions respecting the execution of Parliamentary Plans, which will be of interest to some of our readers, and may be quoted as a fair specimen of the character of the book.

"By the standing orders of the House of Commons, engineers and surveyors are required to plot their railway plans at a scale of not less than 20 chains to an inch. The width of railway surveys varies from 5 to 20 chains, at the option of the engineer. One very essential point to be attended to is to carefully survey, plot, and number all houses, fields, &c., within the *limits* of *deviation*. The *limits* of *deviation* are certain lines which mark the space beyond which it is not proposed to take power to deviate the line of railway. The limits of deviation are shown by a strong dotted line,—the proposed railway line is represented by a strong line.

"When railway plans are drawn at a scale of 20 chains to an inch, it is usual (compulsorily) to give enlarged plans of those subdivisions of land into very small allotments, as gardens, houses, &c., subdivisions being often rendered indistinct, from the smallness of the scale. The principal object of these enlarged plans is to enable the draughtsman to sufficiently develop the houses, &c., both by drawing and numbering; a separate number being required for each garden and house, as well as for all fields, roads, rivers, &c. The names of the different parishes through which the line is proposed to be carried must be written, and of late days the *county name* is placed at the top of each sheet. The sheets are numbered 1, 2, 3, &c., and the name of the line of railway is sometimes written over the number of the street, as Elverton, No. 1. The enlarged plan should be placed in each case directly over or under that portion of the small plan to which it refers. By taking care to get the portion of the railway line on each enlarged plan exactly parallel to the corresponding portion of railway line on the small plan, a very pleasing and convenient arrangement will be effected, and we are thus enabled in using the plan to find at once the enlarged portions. I have been induced to say so much for the guidance of the young surveyor, from having frequently noticed the slovenly manner in which some surveyors are in the habit of misplacing the enlarged plans. They are sometimes so jumbled together that it is quite a labour to wade through them. The radii of the curves in miles and furlongs is required to be written in each case where curves occur. When the plan is drawn at a scale of 20 chains to an inch, the enlarged plans are usually plotted at a scale of five chains to an inch.

The scale of six chains to an inch is one frequently adopted for Parliamentary railway plans; but they are seldom drawn to a larger scale than five chains to the inch. The relative merits of the large and small scales may be fairly taken as follows: viz., when the survey has been carefully taken, the scale cannot be too large; but if it be carelessly done, as is too frequently the case, it becomes necessary (as it is technically denominated) to *fudge* it, and in such cases it is frequently plotted or reduced to a 20 chain scale. This is done with a view to obscure, as much as possible, the inaccuracies of the survey. The merits of the large and small scales may also be taken in another light, viz., when there is a sufficiency of time to admit of plans being drawn at a large scale, it is desirable to use it, but if the time be short, the work will be sooner done at a small scale.

"Again, for the duplicate plans; this becomes a consideration. Lithographers charge a less sum for lithographing and printing plans at a small scale, than at a large one. Lithography has of late years become a very favourite medium with engineers and surveyors, for the production of duplicate plans for parliamentary deposit. It certainly has much to recommend it, and in proper hands, it would be a most invaluable medium. It is to be regretted that this art, (as applied to the purpose above named), almost essential to the surveyor, has fallen into the hands of an ignorant class of persons, viz., the picture-copiers and lithographic printers. It were impossible to detail the mischief annually done by persons being intrusted with this class of business, who are totally ignorant of the construction or use of maps. The numerous railway schemes brought before Parliament during the last two sessions have compelled engineers and other persons intrusted with the getting up of plans and sections to employ a miscellaneous collection of persons, who had never before been similarly engaged. A proportionate amount of mischief has been the consequence. It is painful to see even the professed picture-copiers or lithographic artists attempt to copy plans. The most ridiculous blunders are made, as might be expected; but of this no more. The remedy is simple; at least the evil may, to a great extent, be lessened, if not altogether removed. Let surveyors lithograph their own plans, or employ their draughtsmen upon them; much time and expense would thus be saved. The picture-copiers and lithographic artists would no longer have their brains addled with pursuits above their capacity; and the lithographic printers would have the plans put into their hands in a perfect state, instead of being obliged to send them back to the lithographic ignoramus for every alteration of his blunders required to be made by the engineer, on examining proofs. In fact, by the method recommended above, the necessity of proving may be in a great measure dispensed with.

"The principal point to be attended to in getting up such drawings is to draw them accurately. There is seldom time for pains-taking with embellishment, and the plainest style of execution is quite as useful as the most elaborately finished production."

The work is illustrated by excellent plates, and seems to convey detailed information on every point connected with the execution of architectural and engineering drawings.

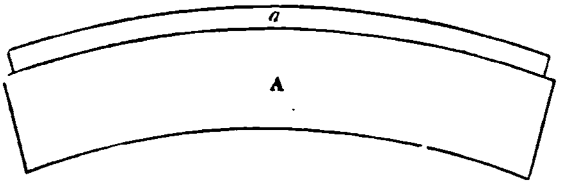
THEORY OF THE STRENGTH OF MATERIALS.

In our last number we published a paper on this subject, by our old correspondent Mr. Byrne, and as some of the arguments on which his views are founded, seem insufficient, we do not hesitate, notwithstanding our respect for Mr. Byrne's scientific attainments, to state where his opinion differs from our own.

The new theory proposed seems to be founded on the idea that there does not exist in deflected beams what is termed a *neutral line*. Now it appears to us that the existence of this line is capable of being proved by several methods which possess the strictness of mathematical demonstration. Before however, detailing these proofs, it may be as well to define what is meant by a neutral line, and to reply to the argument brought to disprove its existence.

The originators of the term "neutral line" stated that when a horizontal beam supports a transverse weight, the upper part of the beam exerts a thrust and the lower part a tension, and since these two portions of the beam exert opposite kinds of action, there must be in the beam some intermediate part which marks the transition from one state to the other—where, therefore, there is neither thrust nor tension. They asserted moreover that the actual position of this neutral line, or rather neutral boundary, depended on the dimensions of the beam, the degree of deflection and the weight supported; and their theory has hitherto been considered incontrovertible. Mr. Byrne however brings forward this argument against it—he says that if a beam be deflected and a slice be taken in the upper part of it (fig. 3, p. 164), this slice has the same form as the whole beam, and consequently there is as much reason for assigning a neutral line to the slice as to the whole beam. The consequent inference would be that the beam has an infinite number of neutral lines, but this absurdity is to be deduced, not from the original theory, but merely from Mr. Byrne's method of stating it. For when he says that the *form* of the thin upper slice is an argument for the existence of a neutral line in it, he makes the neutral line depend merely on the form of the beam and not on its mechanical action and the connection of its parts. If the slice *a* were actually cut off and separated from the remainder A, so as to have no connection with it, then when bent it would no doubt have a neutral line of its own. And if bent, as represented in the figure, while lying upon A, the lower side of *a* would not be so much extended as the upper side of A, but there would be some such difference as that in the diagram.

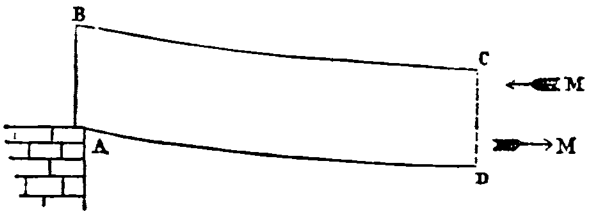
But in an undivided beam owing to the connection between its parts the portion *a* could not assume the form here represented. Its lower surface



must coincide with and be of the same length as the upper side of A, and be much more extended than when separated from it. Consequently no argument taken from the consideration of the slice *a*, in its separated state, will apply to it when considered as an integral portion of the beam.

We proceed now to the direct arguments establishing the actual existence of the neutral boundary.

Whatever may be the degree of deflection of a beam, and however great the load which it bears, it is clear that while the system is in a state of equilibrium, the internal forces of this beam and the external pressures upon it are subject to the ordinary principles of statics. Let A B C D be



one-half of a uniform beam resting on an abutment at A. Then if we suppose for simplicity that the beam is loaded uniformly throughout, the centre of gravity of the system is half way between the two abutments; that is, the pressures on each abutment are equal. Hence the pressure on A is the weight of A B C D, and the load on it. Or if R be the reaction at A, and W the weight of the beam and load together, $R = \frac{1}{2}W$.

Now if we suppose the beam actually cut in half at C D, it is certain that the equilibrium of A B C D will not be altered if we consider the molecular forces which the supplied by the connection with the other half of the beam to be external forces acting at C D. And whatever these forces may be, they are capable of being resolved parallel to three co-ordinate axes, and the resultants may be equated with the remaining forces of the system. Let the axis of *x* be parallel to the length of the beam and horizontal, let the axis of *y* be vertical, and that of *z* perpendicular to the two former. Then if $\Sigma(X)$, $\Sigma(Y)$, $\Sigma(Z)$ be the sums of the corresponding molecular forces we have equating all the forces of the system,

$$\Sigma(X) = 0, \quad \Sigma(Y) + R - \tfrac{1}{2}W = 0, \quad \Sigma(Z) = 0.$$

With respect to the second of these equations we have since $R - \frac{1}{2}W = 0$, $\Sigma(Y) = 0$, and since these forces represented by $\Sigma(Y)$ are all parallel and lie in one plane, they have a single resultant, and this resultant is zero, consequently there is no vertical force at C D. Similar reasoning applies to the forces represented by $\Sigma(Z)$.

With respect however to the longitudinal forces $\Sigma(X)$ the case is different; for these though parallel to each other do not lie all in one plane. Consequently they do not necessarily have a single resultant. The equation $\Sigma(X) = 0$ may be interpreted by supposing it to represent a couple $M, -M$; and if we take moments about A we shall see that this is the correct interpretation, for the moment of $\frac{1}{2}W$ about A must be balanced by some equal and opposite moment, and this can only be supplied by the forces $M, -M$.

The final conclusion is therefore that the resultants of all the molecular forces at C D are two equal and opposite forces $M, -M$, such that if the distance of the centre of gravity of A B C D from A be called *a*, and the distance between the points of application of M and $-M$ at C D be called *b*,

$$M\,b = \tfrac{1}{2}W\,a.$$

It is certain also from the direction in which M acts that it arises from the compression or tendency to compress the upper part of C D, and in the same way $-M$ arises from the extension or tendency to extend the lower part of C D.

We have therefore the upper and lower parts of C D in opposite states of action, and these two portions must be perfectly distinct from each other. It is quite impossible to conceive that the compressed and extended parts can *alternate*, that as we examine successive portion of C D, we shall have first an extended part, then a compressed part, then again an extended part, and so on. The portion of the beam exerting thrust cannot contain any part in a state of tension, and the portion exerting tension cannot contain any part exerting a thrust. Neither can these two portions *overlie* each other, for then we must have some part of the beam exerting both tension and thrust, which is as absurd as to suppose a man can pull and push a thing at one and the same time.

It is clear then that the two parts of the beam in opposite states of action are perfectly distinct from each other, and there must therefore be some boundary which marks the transition from the one state to the other, some place where the one kind of force ceases and the other begins. This place is called the neutral boundary.

It will be observed that this conclusion is deduced from foundamental principles of statics and not from hypotheses respecting the molecular structures of the beam which, however ingenious, are seldom trustworthy. It is a necessary consequence of the existence of a neutral line that the compression of the upper side and the tension of the lower should vary in degree, and gradually diminish towards the neutral boundary, so that there should be no abrupt transition from one state of action to another. It is impossible to imagine that the molecular action can *suddenly* change in any part: from the connection between each two successive laminæ, it is clear that the extension or compression of the one must be affected by the extension or compression of the other. We are therefore perfectly safe in supposing that there is some general law by which these variations of action may be represented, this is, that the amount of molecular force at any point of either side of the beam is a *continuous function* of the distance from some fixed point. Now this function changes its sign in passing through the neutral boundary, for on the upper side of the beam it represents forces contrary in direction to those on the lower side, and therefore, since no continuous function can change its sign without passing through zero or infinity, and since in the present case it is obvious that it cannot pass through infinity, it must pass through zero, and consequently there is no longitudinal action whatever at the neutral boundary.

It is usual to represent the molecular forces as a function of their distances from the neutral boundary. This is perfectly arbitrary and merely corresponds to a convenient choice of co-ordinates, for by properly altering the form of the function we might make the molecular forces depend on their distances from any *other* point of reference.

The determination of the actual position of the neutral boundary may frequently be difficult, but the fact of its existence does not depend on the labour of calculating its place. It fortunately happens however that for the cases which most commonly occur in practice—those in which the deflection of the beam is small —the place of the neutral boundary can be ascertained with quite sufficient accuracy to answer all useful purposes.

It may be as well to point out to those not familiar with the subject that this neutral boundary is not a mere matter of curious speculation, but one of direct practical importance. Every thing depends upon it. Without we know its position, we cannot tell how much of the beam is in a state of compression, and how much in a state of tension—in other words, *we can know nothing about the strength of the beam.*

We have wished to confine attention here to those things only which may be strictly deduced from the fundamental principles of mechanics, an which cannot be controverted without attacking those principles. We therefore do not enter into the consideration of the *form* of the function above alluded to. The assumption usually made accords perfectly well with the results of practice, and there does not seem the least reason for disputing its accuracy. At the same time we must remember that its correctness depends on experiment, and not on independent reasons. When, indeed the beam is perfectly homogeneous, there are good theoretical reasons in favour of the usual assumption, and of this at least we are certain, from both theory and experiment, that the true law must be so near the assumed one, that any error introduced into the calculation by this assumption will be inappreciable in the general result when the deflection of the beam is small.

We have stated our objections fully and freely, because if any mistaken conclusion be here set forth, Mr. Byrne will be able to correct them. If in error, we shall be sincerely obliged to him for setting us right, for we have no other object but the advancement of the truth; but till he does this, we shall confide little on a theory of the strength of beams founded on a denial of the existence of a neutral boundary.

MAGNETIC EXPERIMENTS ON METALS, ALLOYS, AND METALLIC SALTS.

A paper on this subject was lately read by Mr. William Sturgeon, at the *Manchester Literary and Philosophical Society*. After having taken a retrospective view of the labours of other experimentalists in this department of magnetics, the author proceeded to describe a novel apparatus by means of which his own experiments had been made. It consists principally of a powerful magnet and a light wooden lever, delicately suspended by a few silken fibres, the whole being enclosed in a glass case. By means of this apparatus, Mr. S. has found that gold, silver, copper, platinum, antimony, bismuth, lead, tin, and some other metals, when pure, are perfectly neutral to the action of the magnet, but that when some of them are combined they become magnetic in an eminent degree. Some of his earliest experiments, especially those on brass, many specimens of which he found to be magnetic, led him to suppose that their magnetic actions were due to small portions of iron which they contained; for in some of the metals of commerce on which he experimented, iron was absolutely present. In a mass of bismuth, for instance, iron was found in considerable proportions. Mr. S. has discovered that all our silver coinage is magnetic, but in different degrees, according to the dates of its production. Domestic articles of silver, as spoons, &c., are still more magnetic than silver coins. Gold coins are also magnetic, but not so highly as silver ones. The gold of articles of jewellery is more magnetic than gold coins. Mr. S. was still of opinion that these alloys might possibly contain iron, and their magnetism be therefore dependent on that metal, although he had met with some facts which he could not reconcile to that view. Having found much more magnetism in an old half-crown piece of William and Mary than in any other coin, and the historical report being that the silver coinage of that period was in a very base state, he supposed it possible that the high magnetic action of the old half-crown might be due to the extra proportion of copper, which led him to form an alloy of pure silver and pure copper, in which the latter metal formed about one-sixth part of the whole; and what is very remarkable, this alloy was more highly magnetic than any silver article he had previously examined. The copper and silver of this alloy had previously been ascertained to be non-magnetic; they were melted in an earthen crucible, and no iron entered the alloy. This fact, and some others which he subsequently discovered, shook the opinion Mr. Sturgeon had first formed respecting the pre ence of iron in brass, and the other alloys which showed magnetic action. Cavallo had discovered the magnetism of brass, and showed that hammered brass was never more magnetic than when unhammered, which facts corresponded to Mr. Sturgeon's own observations. But the most capital discovery had yet to be made. Mr. S. formed an alloy of iron and zinc in equal parts, and, to his surprise, found that this alloy was almost neutral to the magnet; so much so, that it would not move a magnetic needle at half an inch from the pole. In another alloy of those metals, the iron being about one-eighth of the zinc, magnetism was quite extinct. These novel facts naturally led to the inference, that as zinc is an essential constituent of brass, the magnetism of that alloy could not be owing to its containing iron; and subsequent experiments, both magnetic and chemical, have shown that this is the fact. Antimony has long been known to deteriorate the magnetism of iron, but Mr. S. has ascertained that its neutralising powers are much inferior to those of zinc. An alloy of antimony and iron, in which the latter metal was less than a twentieth part, still showed magnetic action, though in a slight degree. Mr. S. had also discovered that nickel loses all its magnetic powers when alloyed with about ten times its weight of zinc. Antimony also counteracts the magnetism of nickel, but not so powerfully as zinc. German silver, which contains a large proportion of nickel, is slightly magnetic; but in the inferior kinds of this alloy, where nickel is less abundant, no magnetism is perceptible. The neutralising metal in these cases is zinc.

The salts of iron which have been examined are mostly magnetic; but what is remarkable, their magnetism bears no proportion to the proportions of iron they contain. In conforming his theoretical views to the facts thus developed, Mr. S. now considers all bodies to be more or less magnetic, and classes them into two grand divisions—those that are palpably magnetic, and those that are but obscurely magnetic. The former class he calls *sapho-magnetics*, and the latter *asapho magnetics*.

Sapho magnetics are again divided into *mono-magnetics* and *suno-magnetics*, accordingly as they consist of individual or compound bodies respectively. Those bodies which counteract the magnetism of others, Mr. S. calls *katalo-magnetics*, because many of them, if not all, have the power of completely neutralising even the highest powers of *mono-magnetic* bodies.

The *mono magnetics* at present known are iron and nickel, and perhaps cobalt. In the class *suno magnetics*, Mr. S. places alloys of silver and copper, gold and copper, and zinc and copper, under the expectation that many more will soon be added to their number. The *katalo-magnetics* are very numerous, being all those that deteriorate the magnetism of other bodies. Amongst the metallic *katalo-magnetics*, Mr. S. has found zinc, antimony, tin, and lead. Other *katalo magnetics* are sulphur, oxygen, chlorine, cyanogen, and the generality of those bodies which combine with metals.

RAILWAY STATISTICS.

The annual return of the Board of Trade, recently published, contains some very valuable information on the subject of railway statistics. The following information is taken in a condensed form from that return:—

The total number of passengers, as given in the returns for the year ending 30th June, 1844, and for the year ending 30th June, 1845—

	1844.	1845.
1st class	4,875,332½	5,474,163
2nd class	12,23[illegible].686	14,325,825
3rd class	8,588,085½	13,135,820
Mixed	2,069,495½	8 5,445½
	27,763,602½	33,791,253½

The rate of increase of travelling in each class is—

1st class	12 per cent.
2nd class	17 per cent.
3rd class is upwards of . . .	50 per cent.

The amount received for each class is as follows:—

	1843-4.	1844-5.
1st class . . .	£1,432.688	£1,516,805
2nd class . . .	1,375.679	1,598,115
3rd class . . .	483,069	651,903
Mixed . . .	147,858	209,518
Total . .	£3,439,294	£3,976,341

The increase of returns on the year 1844-5 was, therefore, upwards of half a million on passenger traffic alone. On gross receipts from all sources it stood thus:—

1843-4	£5,074,674
1844-5	6,209,714
Increase . .	1,135,040

The rate of fares on the lines included in the above returns, and the reductions in the two years, stand thus at the end of the year 1845:—

	1845 Express. d.	1845 1st Class. d.	1845 2nd Class. d.	1845 3rd Class. d.	Reduction. 1st Class d.	Reduction. 2nd Class d.	Reduction. 3rd Class d.
Great Western . .	3·00	2·74	1 60	1·			
London and Birmingham	2·88	2·45	1·81	1·	·74	·32	·48
Grand Junction . .	2·44	2·08	1·71	1·	·92	·41	·39
Midland . . .		3·21	2 19	1·			·41
Birmingham and Gloucester		3·16	2·37	1·			
Chester and Birkenhead.		2·00	1·60	1·			
Great North of England.	3·46	2 93	2·13	1·	·53	·26	·60
Hull and Selby . .		1·93	1·54	·967			
Lancaster and Preston .		3 30	2 10	1·			
Leeds and Selby . .		2·06	2·00	1·			
Brighton . . .	2 97	2·37	1·78	1·18	·47	·11	
Croydon . . .		1·42	1·14	·85			
South Western . .	2·87	2·48	1·91		·70	·42	·26
Manchester and Birmingham	2·47	2·11	1·62	1·	1·12	·77	
Manchester and Leeds .		2·28	2·00	1·	·94	·23	·41
Newcastle and Darlington	3·23	3·07	2·15	1·	·15	·30	·38
Newcastle and Carlisle .		2 40	1·80	1·			
North Union . .		2 45	1·63	1·	·54	·51	·38
Preston and Wyre .		2 52	1·59	1·			
South Eastern . .	2 45	2·04	1·36	·82	·48	·28	·10
York and North Midland		3·00	2·25	1·	·50	·25	1·00

Cattle, Sheep, &c.—The total number of cattle conveyed in the year 1844-5 is nearly two millions. The gross amounts received range as follows:—

London and Birmingham . . .	£50,000
Great Western	17,000
Midland, and Bristol and Birmingham .	9,000
Eastern Counties	5,300
South Western	4,000
Manchester and Leeds . . .	4,000
York and North Midland . . .	3,200
Great North of England . . .	3,200

Horses.—The number conveyed is as follows:—

Bristol and Birmingham . . .	2,879
Chester and Birkenhead . . .	664
Eastern Counties . . .	2,160
Northern and Eastern	2,796
Grand Junction	4,267
Manchester and Birmingham . . .	785
Great North of England . . .	2,709
Great Western	10,504
London and Birmingham . . .	10,749
London and South Western . . .	5,570
London and South Eastern . . .	2,714
London and Brighton . . .	4,303
Manchester and Leeds . . .	1,409

Midlands	9,595
North Union	989
York and North Midland	4,197

Coal Traffic.—The following shows the gross tonnage and amounts received on the undermentioned lines in the year beginning 1st July, 1844, and ending 30th June, 1845:—

	Tons.	£
Arbroath and Forfar	12,000	1,700
Ardrossan	42,144	2 106
Ballochney	282,622	3,206
Bristol and Birmingham	70,000	3,708
Canterbury and Whitstable	13,000	1,188
Clarence	300,000	20,000
Dunfermline	28,477	3,142
Durham and Sunderland	372,714	22,712
Edinburgh and Dalkeith	118,340	4,800
Glasgow and Ayr	120,000	8,000
Glasgow and Garnkirk	1,761 000	7,600
Great North of England	181,012	13,079
Hartlepool	790,486	32,627
Hayle	20 000	2,400
Leicester and Swannington	178,566	15,827
Liverpool and Manchester	133,396	9,414
Llanelly and Llandilo	92,381	6,067
London and Croydon	6,000	500
London and South Eastern	22,519	
London and Brighton	30,000	2,400
London and South Western	4,000	
Manchester and Bury	49,826	3,332
Maryport and Carlisle	119,375	7,244
Midland	313,854	42,000
Newcastle and Carlisle	205,500	19,476
Newcastle and Darlington	400,000	
Newcastle and North Shields	26,936	1,198
North Union	321,923	
Pontop and South Shields	662,829	49,591
Preston and Wyre	21,538	4,289
St. Helens and Runcorn Gap	229,775	9,762
Sheffield and Manchester	58,668	2,447
Sheffield and Rotherham	16,000	977
Stockton and Darlington	900,000	80,000
Taff Vale	125,986	19,039
Ulster	807	130
Whitby and Pickering	1,708	241
Wishaw and Coltness	390,240	9,969
York and North Midland	47,529	2,419

Rate per mile for toll only, and for total charges:—

	Toll. d.	Total Charges. d.
Canterbury and Whitstable		6·00
Dunfermline and Charlestown		4·29
Bodmin and Wadebridge		4·25
Hayle		4·20
Dundee and Newtyle		3·37
Maryport and Carlisle	1·16	3·33
Arbroath and Forfar		3·30
Monkland and Kirkintilloch		3·00
South Western		3 00
Wishaw and Coltness	2·27	2·90
Manchester and Bury		2·30
London and Croydon	2·00	2·25
South Eastern		2·12
Brighton	·25	2·10
Newcastle and Carlisle		2·00
Leicester and Swannington		1·75
Llanelly and Llandilo	1·00	1·50
Bristol and Birmingham		1·43
Durham and Sunderland		1·40
St. Helens and Runcorn Gap		1·40
Pontop and South Shields	·75	1·30
Garnkirk and Glasgow		1·27
Newcastle and Darlington		1·25
Edinburgh and Dalkeith		1·25
Preston and Wyre		1·25
Taff Vale	·66	1·16
Manchester and Leeds	1·00	
Clarence		·91
Hartlepool	·75	
York and North Midland		·75
Great North of England		·50

The above are not in all cases the average charges, but the maximum charges; as on some lines, a higher rate is charged for going up hill than for going down hill.

VIBRATION OF TRAINS IN TUNNELS.

Report on the vibration produced by trains in passing through the tunnel of Kensal Green. To R. Stephenson, Esq.

Sir—I have the honour to submit to you the results of the series of experiments performed at Kensal Green, with the view of ascertaining to what distance the vibration produced by a train in passing through the tunnel may be sensible.

In these experiments, I employed a basin of quicksilver, which was placed on the ground and fixed as firmly as possible. A lens carrying a set of cross wires was attached, in such manner that the image of the wires could be reflected in the mercury, and therefore any vibration of the mercury could be easily detected by the oscillation of the reflected image. A piece of glass effectually protected the mercury from currents of wind, and the experiments were thereby rendered very satisfactory. In observing the reflected wires, I did not employ a telescope, as a previous trial had convinced me that no material advantage would arise from the use of a telescope, since the sensibility of the eye in detecting the least vibration of the mercury was far greater than I could have expected, and more than sufficiently delicate for the purpose in view.

The situation selected was a field belonging to Mr. Sullon, on the north side of the tunnel. The distances were measured with a land chain from the northern side, as nearly as its position could be ascertained.

April 16th.—The day cloudy, but without rain, a moderate breeze blowing from the eastward.

Distance 60 feet. Down train very great vibration, the reflected image of wires was quite invisible from agitation as the train approached the centre of the tunnel; the vibration commenced immediately the train entered the tunnel, and ceased the moment that it left.

Distance 138 feet. Down train—the vibration began about two seconds after the train entered, and ceased about the same time before it was out of the tunnel; though the amount of oscillation was much less than at 60 feet, it was still considerable.

Distance 300 feet. Down train—the vibration began immediately the train was in the tunnel, and continued about ten seconds after it had left; the train was in the tunnel twenty seconds.

Distance 472 feet. A heavy down train—thirty-two seconds in passing through the tunnel. The vibration was seen about seven seconds after it was in the tunnel, and ceased four seconds before it left. The amount was rather considerable.

Distance 572 feet. Up train—twenty seconds in tunnel. The oscillation of the mercury was sensible five seconds after the train entered, and ceased ten seconds before it emerged from the tunnel. Another up train produced the same effect.

Distance 644 feet. A down train—twenty seconds in the tunnel—produced *not the slightest effect.* The observation very satisfactory.

Distance 609 feet. A down train—twenty-seven seconds in the tunnel. The vibration so excessively small as to be visible only by transient glimpses when the train was fairly in the tunnel. *I consider this to be the distance where the vibration becomes sensible, and beyond it the trains will have no perceptible effect in this locality.*

The following estimated values for the *amount* of vibration, though necessarily very rude approximations, may still be interesting:—

Distance		Amount of vibration
Distance	60 feet.	100
,,	138	40
,,	300	25
,,	472	10
,,	572	5
,,	609	1
,,	644	0

On April 11th, some observations were attempted in a field adjoining that belonging to Mr. Sullon, at a distance from the tunnel of 400 feet, but the perpendicular drawing from the place of observation to the tunnel, would fall not more than 50 feet from the entrance, and this circumstance, in addition to most unfavourable weather, probably prevented my seeing any vibration. An objection being raised on this day against the performance of the experiments on Mr. Sullon's property, I was unable to proceed until the 15th, when that gentleman was kind enough to allow me the use of the field on the north side of the tunnel, a most favourable locality for the purpose.

On April 15th, I made some experiments to ascertain whether a horizontal wire of a transit telescope placed at different distances from the tunnel to bisect a distant object would show the vibration at those distances to be sensible. I very soon found that this method was not sufficiently delicate, as no vibration could be detected even at 60 feet distance from the side of the tunnel. The experiments with mercury on the following day were made under very favourable circumstances, and the results are, I believe, worthy of great confidence.

EXTRACTION OF COPPER FROM ITS ORES BY ELECTRICITY.

The admirable researches of Becquerel upon the chemical actions effected under the influence of weak electrical currents, have opened a path destined to lead metallurgy to results of which we are even now unable to appreciate the full importance.

Having for their object the application of these actions to the extraction of copper from its ores, M. M. Dechaud and Goaltier De Claubry have long been engaged in researches which they now consider sufficiently matured to command attention, being destined to effect a complete tranformation of the existing processes. The following is a brief account of their results, reduced to the simplest form.

The extraction of copper from pyritous ores is divided into two series of operations entirely distinct, the roasting the ore, and the precipitation of the copper.

The Roasting.—This is effected in a reverberatory furnace, either by the direct conversion of the sulphuret into sulphate by the sole action of the air, or else by another reaction of useful application which consists in the transformation of the oxide of copper into sulphate by calcining it with sulphate of iron, at a dull red heat in a current of air, the iron being left in the state of peroxide.

Suitable washing extracts the sulphate of copper, which contains neither arsenic nor antimony, so that the most impure minerals, as the *fahlers*, will afford copper equally pure with the carbonates or oxides of copper which contain no other metal.

The Precipitation.—The precipitation of copper from its solution requires, in the galvano plastic processes, batteries of which the cost is far too great to be employed in metallurgy. It has therefore been attempted to obtain the same effect without the use of exterior batteries. The principle upon which the apparatus depends are these.

If we place, one over the other, two solutions, one of sulphate of copper, very dense, and the other of sulphate of iron, less dense, and in the first we place a plate of metal forming the cathode, and in the sulphate of iron a fragment of cast iron, and then unite these two metals by a conductor, the precipitation of copper commences at once, and is completed in a longer or shorter time according to the temperature, the concentration of the liquids, and the extent of the metallic surfaces. But as M. Becquerel has observed, the physical state of the copper undergoes great change as the liquid becomes weaker. We obviate this great difficulty by turning to profit the observation that after some minutes' action there exists four strata in the liquids; at the bottom we find the dense solution of sulph. copper, then a less dense solution of the same salt which has been deprived of its copper by precipitation; next is sulphate of iron become more dense by the solution of the cast-iron; and last, on the surface, the same salt in its original strength.

If, therefore, at the level of each of these strata we arrange suitable apertures for the addition or removal of the liquids in proportion as the chemical action goes on, we can easily preserve these liquids at uniform states of density, and thus the copper is always pure and in the same physical condition.

In the application of this process to metallurgy, the extent of surface of land required to precipitate a large quantity becomes an important consideration; it is, however, easy to modify the form of apparatus, though preserving the same principle, so as to avoid this objection.

With this object we arrange the liquids in vertical instead of horizontal layers; they are now to be separated by a diaphragm very permeable to electricity but not to liquids. Paste-board answers perfectly for this purpose; it lasts for months without undergoing any alteration, and the quantity of sulphate of iron which penetrates into the sulphate of copper is still too small to effect the operation. The apparatus is therefore arranged in the following manner:—

A chest of wood, lined with lead or some suitable mastic, contains the solution of sulphate of iron; through an opening near the top, we add the liquid until the proper degree of density is attained, while through a lower opening the saturated solution is allowed to escape.

Into this chest we plunge a number of cases, made of a frame having its ends and bottom formed of iron plate coated with lead; the sides are made of a sheet of paste-board. The strong solution of sulphate of copper enters through a pipe near the bottom, and escapes in its weak state through an opening at the top. *In* each case is placed a sheet of *leaded* iron; *between* each case, and outside the end ones, are plates of cast iron. Separate rods connect each plate with the common conductor which is supported above the apparatus. Two large reservoirs, of constant levels, receive the solutions and furnish them continuously. We adjust once for all the densities of the liquids, and then the apparatus works on for whole months without requiring any kind of attention. The most convenient strength of the solution of copper which escapes from the apparatus is from one-fourth to one-half of a saturated solution. The copper is precipitated on both sides of the sheet of metal forming the cathode.

As the paste-board prevents the *immediate* contact of the two liquids, we effect this by making small holes through its upper edge, taking care that they are some distance above the highest part of sheets of metal forming the cathode; the sulphate of iron can thus float above the solution of sulph. copper, and the vertical apparatus now fulfils all the conditions of the horizontal one.

At a temperature of 20 Cent. 68 F. one square metre (10·73 sq. ft.) of surface will receive as much as 1 kilogramme (15444 grs.) of copper in twenty four hours.

The precipitated copper is pure and is always in the same physical condition; the sheets obtained are fit for immediate working under the hammer, or to pass through the rolling mill; four or five passings through this gives the metal a density of 8·95; we therefore avoid all the operations required in the common process to reduce it from the form of bars to that of sheets. The manufacture presents no difficulties, requires no refining, and gives no scoria. In a regular manufacture as much as 75 per cent. of the copper has been obtained in the form of sheets, the remainder being precipitated, partly in pure fragments, and partly in powder of cementation. The authors consider, as a metallurgical result, at the lowest, 50 per cent. of the copper in sheets, 25 per cent. in fragments which only require fusion to be reduced into bars or plates; and 25 per cent. in powder requiring subsequent refining.

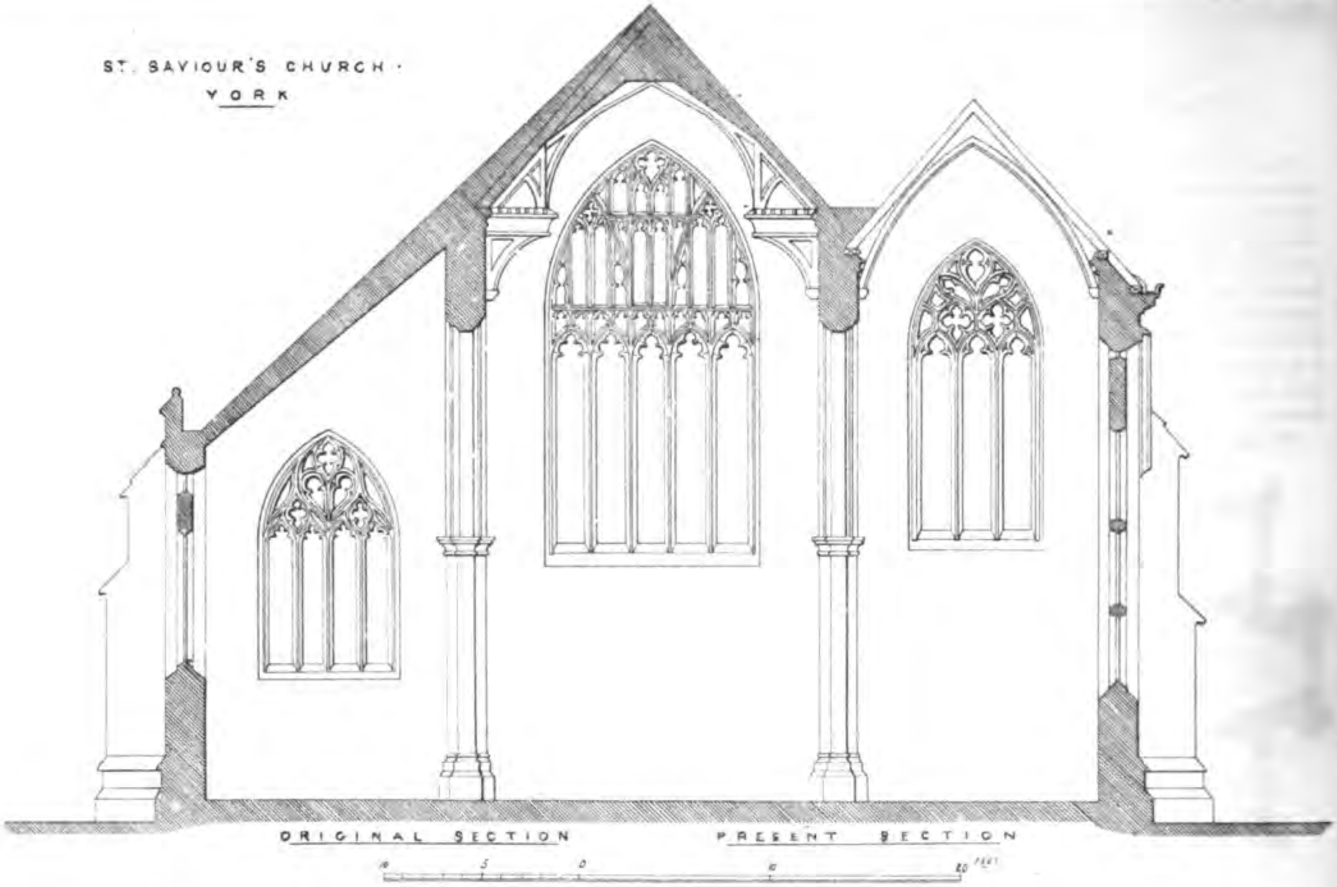
The question as to the applicability of galvanic action to the extraction of copper, appears to be reduced to the simplest possible form. It is hardly necessary to remark that electrotypes on the largest scale can be thus obtained.—*Journal of Franklin Institute.*

THE LEANING TOWER OF PISA.

"The moon was shining when we approached Pisa; and for a long time we could see, behind the wall, the leaning Tower, all awry in the uncertain light,—the shadowy original of the old pictures in school-books, setting forth 'The Wonders of the World.' Like most things connected in their first associations with school-books and school-times, it was too small. I felt it keenly. It was nothing like so high above the wall as I had hoped. It was another of the many deceptions practised by Mr. Harris, bookseller, at the corner of St. Paul's Churchyard, London. *His* Tower was a fiction, but this was reality—and, by comparison, a short reality. Still, it looked very well, and very strange; and was quite as much out of the perpendicular as Harris had represented it to be. The quiet air of Pisa too; the big guardhouse at the gate, with only two little soldiers in it; the streets, with scarcely any show of people in them; and the Arno, flowing quaintly through the centre of the town; were excellent. So, I bore no malice in my heart against Mr. Harris (remembering his good intentions), but forgave him, before dinner; and went out, full of confidence, to see the Tower, next morning. I might have known better; but, somehow, I had expected to see it casting its long shadow on a public street where people came and went all day. It was a surprise to me to find it in a grave retired place, apart from the general resort, and carpeted with smooth green turf. But, the group of buildings clustered on and about this verdant carpet—comprising the Tower, the Baptistery, the Cathedral, and the Church of the Campo Santo—is perhaps the most remarkable and beautiful in the whole world; and from being clustered there, together, away from the ordinary transactions and details of the town, they have a singularly venerable and impressive character. It is the architectural essence of a rich old city, with all its common life and common habitations pressed out, and filtered away. Sismondi compares the Tower to the usual pictorial representations, in children's books, of the Tower of Babel. It is a happy simile, and conveys a better idea of the building than chapters of laboured description. Nothing can exceed the grace and lightness of the structure; nothing can be more remarkable than its general appearance. In the course of the ascent to the top (which is by an easy staircase,) the inclination is not very apparent; but, at the summit, it becomes so; and gives one the sensation of being in a ship that has heeled over, through the action of an ebb-tide. The effect *upon the low side*, so to speak—looking over from the gallery, and seeing the shaft recede from its base—is very startling; and I saw a nervous traveller bold on to the Tower involuntarily, after glancing down, as if he had some idea of propping it up. The view within, from the ground—looking up, as through a slanted tube—is also very curious. It certainly inclines as much as the most sanguine tourist could desire. The natural impulse of ninety-nine people out of a hundred, who were about to recline upon the grass below it, to rest, and contemplate the adjacent buildings, would probably be not to take up their position under the leaning side, —it is so very much aslant."—*Dickens' Pictures from Italy.*

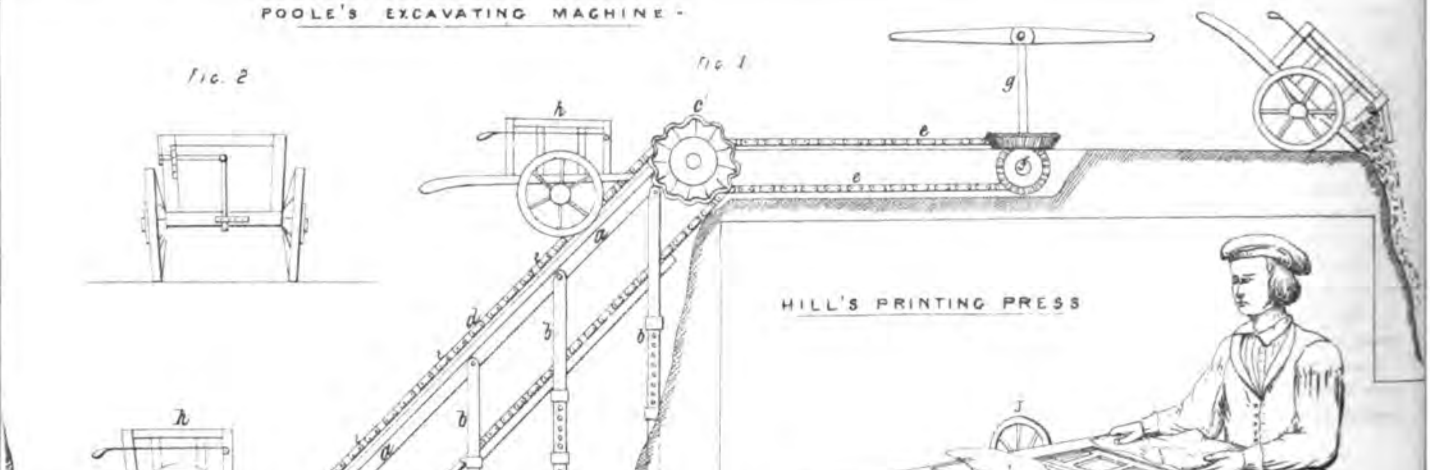
Steam Factory in America.—The central part of the Portsmouth steam factory, which is 204 feet long, is now two-thirds up. The centre part is to be six stories high, the wings five stories. Height of the lower story 13 feet, of the other stories 12 feet. The length of the front will be 504 feet, or about a tenth of a mile. There will be about four acres of flooring in the factory. Number of spindles, 50,000; number of operatives, 1,200 to 1,500. In the rear, two parallel buildings, two stories high, will be extended 100 feet back from the junction of the main building with the wings; and between those buildings, 50 feet from the main structure, the boiler-house is to be erected. The foundation of the chimney, which is to be 140 feet high, is laid, and is in progress of erection. A gentleman who has been travelling the last year in pursuit of information respecting manufacturing establishments, and who has visited more than a thousand factories, informs us that the largest factory building he has seen or heard of is at Manchester in this State, which is 440 feet in length. There is no factory in England to compare with it for size.—"American Paper."

ST. SAVIOUR'S CHURCH · YORK



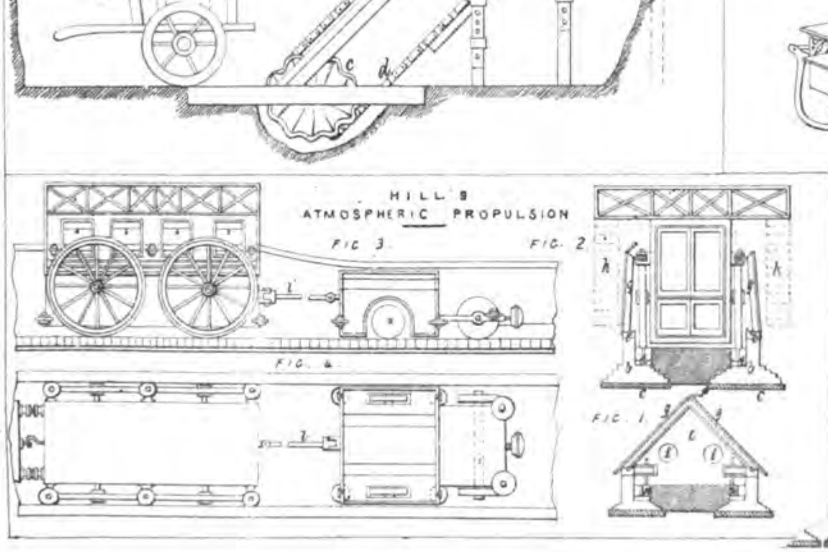
R. H. SHARP – ARCHT. —

POOLE'S EXCAVATING MACHINE ·



HILL'S PRINTING PRESS

HILL'S ATMOSPHERIC PROPULSION

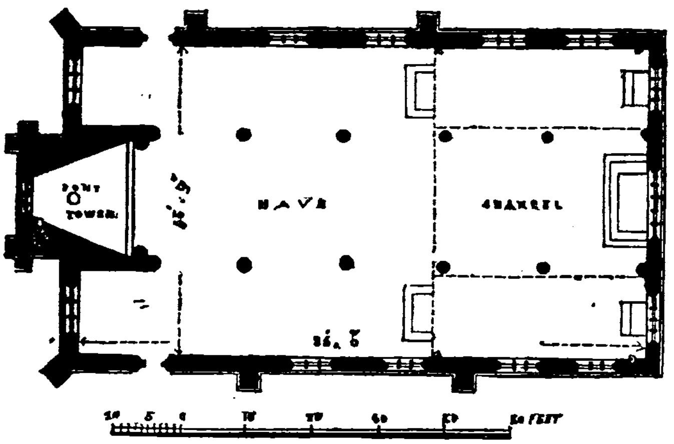


RESTORATION OF ST. SAVIOUR'S CHURCH, YORK.

(With an Engraving, Plate XI.)

The ruinous condition of this church having excited very serious apprehensions, a subscription was raised in 1843 under the patronage of the Archbishop of York, for the restoration of the decayed portions of the edifice. The work was assigned to Mr. Sharp, architect, who generously offered to superintend the restoration gratuitously. The church now affords accommodation for 1000 persons, of whom 423 have seats in the galleries. The report of the subscription committee expresses a regret that the funds raised did not suffice for the restoration of the tower and east wall of the chancel. A well-deserved compliment is also paid to Mr. Sharp for his liberal exertions, and the ability with which he has drawn up the report, which appears below.

The plan and section of the church here given are taken from drawings



sent by Mr. Sharp. We avail ourselves of his permission to print those portions of the letter sent with the drawings, which are of a public nature.

"Sir—Having received much gratification from able papers in your later numbers on Church Architecture, I am tempted to send you a "slip" of some observations I had occasion to offer to the Restoration Committee of one of our old churches in York, not so much from the importance of the work done, as that the opinions contained in the notes seem to harmonize with those of your talented correspondents . . . .

My only object in these communications is to answer the call that has been several times made on architects to supply notices of their works, and if I may be allowed to do so, to hint that letterpress of late usurps the place which we should all like to see filled with drawings.

After forty years study and practice of the profession of architecture, praise and censure are alike indifferent to me.

I send at the same time a carefully reduced plan and section of St. Saviour's church, the one side showing the former condition, and the other the present state. I am, Sir, with great respect,

Your obedient humble servant,

Richard Hey Sharp, Architect."

The total receipts and disbursements for the restoration amounted to £1300. At a meeting of subscribers recently held, it was agreed that a committee should be formed for considering the best method of presenting a testimonial to Mr. Sharp, in acknowledgment of his services.

The Architect's Report.

It would appear that the edifice lately restored was erected about the year 1420, at a time when the perpendicular style of Gothic architecture had superseded the decorated or flowery style. Traces, however, of this last remained in a beautiful four-light window, at the east end of the north aisle, which retained its painted glass. This circumstance prompted the retention of the flowery or undulatory style of tracery in the present eastern windows. Whatever merits the perpendicular style had over the earlier one, it is unquestionable that it was inferior in the adornment of the windows. A much earlier edifice, probably of the twelfth century, existed on the spot, the materials of which, including several gravestones, had been very unceremoniously employed in the walls of the later building. It is not unreasonable to suppose that the extreme badness of the foundation (the church is styled St. Saviour's in the Marsh) caused the premature ruin of the earlier building. Even in the later one, the south-west angle had sunk very considerably. On digging down to obtain a more secure foundation, the cause of the failure was plain enough. After passing through what appeared to be Roman rubbish, at the depth of 14 feet below the floor of the church, several rude coffins were found, which may not unreasonably be referred to a British æra: they were made of slabs of oak, 2½ inches thick, fastened by wooden pins or dowells, and contained skeletons in a very perfect state, but perfectly black from the infiltration of water from the bog in which they were laid. One of these coffins was directly across the angular buttress, so that there is no wonder that it should have sunk. The coffins were too much decayed to admit of removal, and the bones were laid in some of the vaults which the excavation had laid open. The usual methods of rubble foundation, now called concrete, were resorted to, and the corner is now perhaps more secure than the rest of the fabric. The eastern end of the church, as far as the chancel extended, had declined about eight inches, and it became a matter of urgent consideration with the architect, whether to take up the whole of this wall, and to refound it in the same manner; but as the settlement was of ancient occurrence, and did not appear to have increased of late, it was thought that the old foundation might be trusted to, and the more so as the new weight to be borne would not materially exceed the old one, which had been supported for so long a time without increase. The event has justified the opinion of the architect, as no settlement has become visible. As a measure of precaution, however, this half of the south wall was bound together by an iron tie-bar, ending in a stout anchor, which may be seen at the east end. A similar one is placed in the north wall, but the anchor is concealed within the buttress. These bars are connected with the large stones forming the window sills in what is thought to be a novel manner. What may be termed double lewises are inserted into the middle joints of the stone sills, and run with lead so as to connect them firmly together, the chain bars before mentioned are then secured by single or ordinary lewises. In this manner a powerful and permanent bond or connection is obtained. This detail is entered into, as the method may be useful in similar cases, or in new works.

A satisfactory foundation having been obtained, the main walls were carried up in a solid manner, and the windows inserted. This part of the work, and one of the most important, is executed in a very satisfactory manner, and is highly creditable to the contractor. The settlement before mentioned had extended to the arcades separating the aisles, which, when the plastering was removed, exposed cracks of an alarming character. Relying on the foregoing considerations, it was thought sufficient to wedge them up with solid oak, we believe from the Minster, and the result has been equally satisfactory. The paramount consideration of economy doubtless pressed on the architect's mind throughout all the operations. The next main point was the roof. It appears probable that the church had originally three roofs as at present, but at the time of important repairs, in the time of Charles 1st, the roof, whatever may have been its pristine form, was reduced to an uniform plane from the ridge to the eaves. In order to obtain this plane surface, the depth or thickness of the timbers was from 18 inches to 2 feet about half way up, the outer roof being separated from the lower and original one. The existence of several churches in York, All Saints, North-street, St. Sampson, and others, corroborates the notion of the triplicate roof. Indeed, so long as side galleries are demanded of the architect, this is perhaps the best form that can be given to a church, as it affords the requisite height to the side walls. It is to be hoped, however, that these abominable contrivances will either be abandoned, or that the Gothic style of building with which they are wholly irreconcileable, will be relinquished for the churches of Queen Anne, with which they are in perfect harmony.

Sufficient sound oak timber was obtained to frame the new roofs in a substantial manner; the old tiles were re-employed as more in character than slating, and as in lapse of time the defective tiles have perished, the remainder, although not very sightly, promise to endure for a very considerable period. An opportunity offered of procuring some excellent slates from the Minster, which were used in the inside roofs.

The main constructive points being obtained, the roof was lined with thin wood, the ribs intended to strengthen the roof added to the beams, which the safety of the church did not allow us to remove, and some ornamental work added.

In uncovering the old pews, which had been suffered to remain all this while, by reason of the uncertainty of obtaining the funds necessary for the repewing, a discovery of the original pews was made, and to the great gratification of the architect they were found to be almost identical with his design for the new ones, and for which the contract was made. It is not pretended that these fittings were the furniture of the church of 1400, or 1420. No doubt that edifice was prepared for the Roman Catholic service in a very different manner. Screens, or parcloses, doubtless then separated nearly one half the church from the people. The altar of the Saviour would occupy the eastern end of the nave, that of the Virgin Mary the end of the north, an of St. John Baptist of the south aisle. Near the second pillar from the east end screens, or reredos, would be placed across the aisles, against which stood altars belonging to the chantries, founded in the church by individuals. A piscina still remaining in the south walls confirms this opinion. Another, much defaced, existed in the north wall, and there were traces of others near the eastern walls. The particulars of these chantries are added below, but the business of the architect is not with them. The seven chantry priests presided over by the rector, would form a choir sufficiently numerous to occupy the middle chancel, and it would be for their use that the stalls, of which two have been preserved, were doubtless provided. Each of these priests had an equal endowment with the rector, and if these emoluments, properly reformed, had been continued to the church throughout the land, how different might the present state of things have been.

All these decorations had probably disappeared when, in the time of Charles I., the church was thoroughly repaired and fitted for the Protestant service. Many churches in York felt the benefit of similar, and as it often happens, simultaneous efforts. In St. Cuthbert's we have the date 1636 on pews of a character precisely similar, and others might be named. At that period York was often the residence of the Court, and would partake in the advantages of it. The architect decided that it was fruitless, with the extremely limited means at his disposal, to attempt any decorations of the fifteenth century, and that it was in better taste to adhere to the Protestant model of the first Charles. The lectern or reading desk now placed by the font is of this time. The font is of the time of the restoration, when the clergy exerted themselves, it has been said, with more zeal than taste to repair the ravages of the Puritans. The altar pieces of Belfry's, of St. Martin's, Coneystreet, and St. Martin's, Micklegate, are of this epoch, and, although out of place, are very handsome in themselves. The style, however, of the time preceding the rebellion retains enough of the Gothic character as not to shock the eye, and may therefore, it is conceived, be employed where circumstances forbid recourse to an infinitely more elaborate ornament. Of the fittings up of the Norman and early English styles we have in this country at least very scanty remains: the fifteenth century seems to have been the time of a general refurnishing, so to speak, of sacred edifices, in a manner more suitable to the greatly increased luxury and wealth of the age. In the more important edifices this change was not confined to the wood work; in Gloucester Cathedral the vaulting and pannelling are "spread like a network of embroidery over the old Norman work"

Before fixing the pews, precautions were taken to ensure dryness, and to prevent the ascent of noxious gases from the ground beneath. Means have since been employed to give sufficient warmth to the church.

It now only remains to the architect to acknowledge very thankfully the obligations he feels under to the restoration committee in general, and to the church-wardens in particular, for the great confidence they have been pleased to have in him during the progress of this tedious, and somewhat difficult work, without the succour of which trust his efforts would have been unequal to cope with the discouragements inseparable from such undertakings, where the funds are necessarily precarious.

It should have been noticed that considerable expense has been incurred in rebuilding the church-yard walls. The public spirit of the Improvement Commissioners came to the aid of the committee to carry out the very desirable object of insulating the church, and at the same time affording a double width to Hungate. A substantial wall and railing have been carried along St. Saviourgate and west end of the church, and although it is difficult in such matters to reconcile old ideas with modern ones, yet recourse has been had to Lincoln Minster for the pattern of the iron work. The external drainage of the church has been thoroughly completed. When it is remembered that the earth on three sides reached up to the place where the new works begins, about three feet above the floor, it is no wonder that damp and rottenness should have prevailed within.

To complete the perfect restoration of the church there remains only the tower, some parts of which are in a state of rapid decay. To remove the unsightly roof, to repair the mouldering stone work, to renew the dilapidated windows would be a most desirable thing, and after what has been done, it is surely worth an effort to accomplish it. Another work, hardly less desirable, is to remove the hideous vestry to a situation on the north side of the church, insulated from the church, but connected by a passage, where its being constructed in a plain manner would be of less importance; to renew the very beautiful eastern window, and so restore to this elevation its very handsome former appearance which has not, it is hoped, been injured by the elevation of the side aisles. Without having entered into a minute estimate, it is thought that £300 would suffice to carry out all these objects, and it is worthy of consideration by the benevolent persons who have already done so much to the restoration of an interesting and highly useful structure.

Richard Hey Sharp, Architect, York.

There were formerly no less than seven chantries belonging to this church, all of them of considerable value. The first was a very ancient chantry, founded at the altar of St. Mary, in this church, for the soul of Robert Verdenell, whose tomb-stone is under the present floor in the north aisle of the chancel. There was another chantry founded in this church, at the altar of St. John the Evangelist, for the souls of John de Hathelsey and Emma his wife. In 1468, this chantry was united to another chantry in the same church, founded for the souls of William Burton and Ivetta his wife, at the altar of St. James the Apostle and St. Lawrence. William Burton, of York, founded another chantry in this church, at the altar of St. Anne, for his soul and the soul of Ivetta his wife. There was another chantry founded in this church, at the altar of St. Thomas the martyr, for the soul of Adam de Spiriden; also one founded by Richard Watters, of great value; a chantry founded by William Frost, alderman, and Isabella his wife, in 1399; a chantry founded by William Gilliot. Besides these chantries there was also a gild or fraternity of St. Martin in this church, which was founded by letters patents from Henry VI.

DECISION OF THE BOARD OF TRADE ON THE GAUGE QUESTION.

The Minute of the Board of Trade, containing their lordships' deliverance on the Report of the Gauge Commissioners, is dated the 6th of June, 1846. It commences by stating that—

"My lords fully and entirely concur in the general conclusions at which the commissioners have arrived with respect to the advantages of uniformity of gauge for the conveyance of the internal traffic of the country. They are of opinion that the facts set forth in the report, and the evidence by which they are supported, incontestably establish the conclusion, that a 'break of gauge is a very serious evil,' and they see no reason to doubt the soundness of the opinion the commissioners have expressed, that none of the mechanical contrivances, or other methods proposed for mitigating the evil, 'are calculated to remedy, in any important degree, the inconveniences attending a break of gauge.'"

The Minute then quotes at length the conclusions and recommendations of the commissioners. The recommendations are in substance:—1st. That equitable means should be found of producing entire uniformity of gauge, by reducing the broad gauge lines to the narrow gauge. 2nd. That all public railways now under construction, or hereafter to be constructed in Great Britain, shall be formed on the narrow gauge. With respect to these proposals, the Minute remarks:—

"After long and anxious deliberation, my lords are unable altogether to concur with the commissioners in the full extent of these recommendations.

"Adverting to the vast expense which must be involved in an entire alteration of the broad gauge, and having regard to the circumstances under which the companies employing this gauge were established, and to the interests they have acquired, my lords cannot feel themselves justified in recommending that it should be proposed to parliament to compel the entire reduction of the 7 feet gauge. They feel, with the commissioners, that 'they cannot recommend the legislature to sanction such an expense from the public moneys, nor do they think that the companies to which the broad gauge railways belong can be called upon to incur such an expense themselves (having made all their works with the authority of parliament), nor even the more limited expense of laying down intermediate rails for narrow gauge traffic.

"Still less can they feel themselves justified in proposing that the expense of such alteration should be defrayed by a contribution levied, as has sometimes been suggested, on the rest of the railway companies in Great Britain: and they are unable to suggest any other equitable or practicable means by which the desired uniformity of gauge could be obtained.

"The conclusion to which my lords have come respecting the reduction of the broad gauge on existing lines necessarily affects their opinion with regard to the future gauge lines now in course of construction."

The Minute goes on to state that all that seems now possible is to prevent the further extension of the evils arising from different gauges, and reduce the inconvenience inflicted on goods and passenger traffic within the narrowest possible limits. To this end it is recommended that

"The lines for which acts have been obtained, but which have not yet been completed to the south of the line from London to Bristol, should be permitted to be constructed on the broad gauge, as originally intended. They have had some difficulty in coming to a conclusive opinion on the case of the South Wales line. They are aware that strong arguments may be adduced in favour of requiring this line to be constructed on the narrow gauge; but, adverting to the great public importance of a continuous line of communication with the south of Ireland, and of a second line of railway communication from Lonon to Ireland generally; and having regard to the value of a continuous line to Milford Haven, &c., for the furtherance of the public service; they are of opinion that, on the whole, it would be advisable that the South Wales line, together with its branch to Monmouth and Hereford, should, as originally sanctioned, be formed on the broad gauge."

The districts to which the Board of Trade has directed most of its attention are those which are to be supplied with railway accommodation by the Rugby and Oxford, and by the Oxford, Worcester, and Wolverhampton lines.

1. *Rugby and Oxford lines.*

"In the last session of parliament an act was obtained for forming a line of railway from Rugby to Oxford. The act contained the following clause:—

"'Cap. 188, sec. 35. That as a commission has been appointed for inquiring whether provision ought to be made for securing a uniform gauge in the construction of railways, and for other purposes in reference to the mode of obviating impediments to the internal traffic of the country; if, in conformity with the report of the said commission, it shall appear to the Board of Trade expedient that rails of the same gauge as the rails of the London and Birmingham Railway should be laid down on the line hereby authorised between Oxford and Rugby, it shall be lawful for the said board to order and require that such railway upon the said gauge shall be laid down and maintained, and that the company hereby incorporated shall thereupon proceed with reasonable despatch to execute the same to the satisfaction of the Inspector-General of Railways for the time being. Provided always, that nothing herein contained shall prevent the said company from laying down and maintaining, on the whole or any portion of the said line, rails of the same gauge as those now laid on the line of the Great Western Railway.'

"It is their lordships' intention, in the exercise of the powers granted to them by this clause, to require that the narrow gauge rails shall be laid down from Rugby to Oxford forthwith. They would, therefore, submit that it is not necessary to interfere with the construction of the line on the broad gauge, as authorised by the act. In order to complete the general chain of narrow gauge communication from the north of England to the southern coast, they beg to repeat with a slight variation the suggestion of the commissioners, that 'any suitable measure should be promoted to form a narrow gauge line from Oxford to Basingstoke,' or by any shorter route connecting the proposed Oxford and Rugby line with the South-Western Railway. With the same view they beg to suggest that any suitable measure should be promoted for forming a narrow gauge link from Gloucester to Bristol, and so completing the general chain of narrow gauge communication between the manufacturing districts, the centre and north of England, and the port of Bristol."

2. *Oxford, Worcester, and Wolverhampton line.*

"In the act by which the company was incorporated in last session the following clause was inserted:—

"'That the said company hereby incorporated shall, and they are hereby required to lay down and maintain upon the whole extent of the railway hereby authorised, between the point of junction thereof with the said Birmingham and Gloucester Railway at Abbotswood, and the point of junction thereof with the said Grand Junction Railway near Wolverhampton, as well as on the said branch railways by this act authorised to Kingswinford and Stoke Prior aforesaid, such additional rails, adapted to the gauge or the said Birmingham and Gloucester and Grand Junction Railways respectively, as may be requisite for allowing the free and uninterrupted passage, as aforesaid, of carriages, wagons, and trucks passing to or from the said Birmingham and Gloucester, and the said Grand Junction Railways respectively, or from the last-mentioned railway to the said Birmingham and Gloucester Railway, or passing from one portion of the said Birmingham and Gloucester Railway to another portion thereof, or to or from any intermediate place between the two said railways to the one or the other of them; and such additional rails shall be laid down, and maintained and used, to the satisfaction and approval of the Board of Trade, and all necessary facilities and accommodations shall be afforded by the company hereby incorporated, or their lessees, for the convenient use thereof; and it shall be lawful for the said board at any time, on complaint made by any company or person interested in the question that such additional rails have not been laid, or that such facilities or accommodations are not afforded, to order and direct the said company hereby incorporated, or their lessees as aforesaid, to adopt such regulations as they may see fit to require with reference to the laying down of such additional rails, or to the use of the said additional rails and other conveniences as aforesaid, and for the purpose of securing such free and uninterrupted passage thereon as aforesaid.'

"It is their lordships' intention to exercise the power given to them in this instance, as in the case of the Oxford and Rugby line; and on the same grounds they would submit that it is not necessary to interfere with the construction of this portion of the line on the broad gauge in the manner authorized by the act. And, since they regard the break of gauge as a most serious evil, more especially in the conveyance of goods, they conceive that a continuous and a second line of communication between London and the district of Staffordshire, &c., must be regarded as of great value and importance. They accordingly submit that the line from Worcester to Oxford should be made as proposed on the broad gauge. They regret that the provision for the formation of a second line of rails was not inserted in the act affecting the portion of the line between Oxford and Worcester, in the terms of the clause regulating the portion lying between the Birmingham and Gloucester line and Wolverhampton; and they would recommend, that if it should hereafter appear that there is a traffic requiring accommodation on the narrow gauge between the Staffordshire districts and the southern coasts, any suitable measure should be promoted by Parliament to form a narrow gauge link from the Birmingham and Gloucester line to Oxford, on the same grounds and in the same manner as the commissioners have recommended that it should be formed between Oxford and the South Western Railway."

The Board of Trade declines to give an opinion on the merits of the 4 feet 8½ inches gauge. They do not think that its adoption by the legislature as a national gauge—recommended by the commissioners—ought to be positive and final. They would leave an opening to adopt what may be recommended by the experience of Ireland or foreign countries.

"With this explanation, my lords beg to recommend, that no line shall hereafter be formed on any other than the 4 feet 8½ inches gauge, excepting lines to the south of the existing line from London to Bristol, and excepting small branch lines of a few miles in extent, joining the Great Western Railway, and conveying to it the traffic of places in its immediate vicinity; and they further recommend, that no bill for any such line as above excepted shall be passed by parliament, unless a special report shall have been made by the committee on the bill, setting forth the particular reason which have led the committee to advise that such line should be formed on any other than the 4 feet 8½ inches gauge. They concur, also with the commissioners in recommending that, unless by the consent of the legislature, it shall not be permitted to the directors of any railway company to alter the gauge of such railway."

The suggestions of the board, recapitulated in a condensed form at the close of the minute, are as follow:

"1. That no line shall hereafter be formed on any other than the 4 feet 8½ inches gauge, excepting lines to the south of the existing line from London to Bristol, and excepting small branches of a few miles in length, in immediate connection with the Great Western Railway; but that no such line, as above excepted, shall be sanctioned by Parliament unless a special report shall have been made by the committee on the bill, setting forth the reasons which have lead the committee to advise that such line should be formed on any other than the 4 feet 8½ inches gauge.

"2. That, unless by the consent of the legislature, it shall not be permitted to the directors of any railway company to alter the gauge of such railway.

"3. That, in order to complete the general chain of narrow gauge communication from the north of England to the southern coasts, and to the port of Bristol, any suitable measures should be promoted to form a narrow gauge link from Gloucester to Bristol, and also from Oxford to Basingstoke, or by any shorter route connecting the proposed Rugby and Oxford line with the South-Western Railway.

"4. That the South Wales line, and its branches to Monmouth and Hereford, should be permitted to be formed on the broad gauge, as sanctioned by their act.

"5. That the Rugby and Oxford line, and the Oxford, Worcester, and Wolverhampton line, should be permitted to be formed on the broad gauge, as sanctioned by their acts; that the Lords of the Committee of Privy Council for Trade shall exercise the powers conferred upon them by the several acts, and shall require that additional narrow gauge rails shall forthwith be laid down from Rugby to Oxford, and from Wolverhampton to the junction with the Birmingham and Gloucester line; and that if it should hereafter appear that there is a traffic requiring accommodation on the narrow gauge from the Staffordshire districts to the southern coast, any suitable measure shall be promoted by Parliament to form a narrow gauge link from Oxford to the line of the Birmingham and Gloucester Railway."

THE GAUGE COMMISSION.

Analysis of Evidence given before the Royal Commissioners appointed to investigate the subject of the diversity of Railway Gauges.

(*Continued from page 183.*)

MR. JAMES EDWARD M'CONNELL: Is, and has been for upwards of four years, superintendent of the locomotive department on the Birmingham and Gloucester Railway, now part of the Bristol and Birmingham. If as large an amount can be got of evaporating space, compared with the weight of the engine, on the narrow as on the broad, they would be equal in that respect.

Dimensions of Mr. M'Connell's Locomotive Engine at Bromsgrove.

The dimensions of the Great Britain Locomotive Engine, constructed at Bromsgrove Station, and now employed to work the heavy goods trains upon the Lickey Incline on the Bristol and Birmingham Railway, are as follow, viz.:—

	Ft.	In.		Ft.	In.
Diameter of cylinders	0	18	Diameter of pump rams	0	2½
Length of stroke	0	26	Breadth of shell of fire-box	4	4½
Diameter of each of the six wheels	0	46	Length of ditto, outside	3	11
Distance from centre to centre of front wheels	6	9½	Height from bottom to top	6	3
Distance from centre to centre of hind wheels	6	11	Height of lower edge of cylinder	2	0
Length of boiler	12	0	Length of chimney	6	9
Length of tank over boiler	11	9	Circumference of ditto	3	6
Breadth of ditto	3	7	Total weight of engine	30 tons	
Depth of ditto	2	7	Weight on front wheels	9 tons	
Distance from centre to centre of cylinders	6	2	Weight on centre wheels	12 tons	
Length of tubes, No. 134.	12	6	Weight on hind wheels	9 tons	
Diameter of ditto	0	2	Height of smoke-box	6	1½
Diameter of piston rods	0	3	Width of ditto	4	10
			Diameter of boiler cylinder vertically	3	10
			Ditto ditto horizontally	3	9

The Lickey incline is one in thirty-seven, which is a very steep gradient, and has always been worked by a locomotive engine. For the last four years, engines were of so light a construction that they had not sufficient adhesion on the driving wheels; in order to test the relative economy of a heavy and light engine in working this steep gradient, witness made an engine which has been at work now the last two months, with a cylinder 18 inches diameter, stroke 26 inches, and the driving-wheels 46 inches diameter, six wheels, all coupled. The engine carries its water in a tank on the top of a boiler, so as to give it the advantage of all the weight possible to increase the adhesion of the wheels, and it weighs in working order somewhere about 30 tons. There is a great variety in the weight of the engines on the two lines, from 10½ up to 30 tons; the average weight of the 30-inch cylinder passenger-engines is about 12½ tons, with 5 feet driving wheels. Four have 5ft. 6in. wheels, for mail and express trains, and weigh about 13 tons. The average speed of express trains about 30 miles an hour, with 15 tons load. The luggage van is about half a ton lighter than the passenger carriages, and is placed next the engine. For the last three years, the van has been placed there, on the recommendation of the Board of Trade, for public safety, and if they had two, or any empty carriages, they would be placed there to prevent risk to passengers. Is aware that the lighter the carriage with high velocity, the greater is the tendency to run off the rails, but thinks when the luggage-van is loaded, the weight is sufficient; and the empty carriage is about as heavy as the loaded van; should not place an empty van there; would place two loaded vans if he had them. The relative speed of heavy goods trains on the two lines averages on the broad 8¾ miles and 13 on the narrow. The broad gauge wagons do not load more heavily than the narrow; that is the result of the regular working of the traffic. 135 wagons upon the narrow gauge carried 138 tons net; and that on the broad gauge, 135 wagons carried 134 tons net. On one occasion, the gross load upon the broad gauge conveyed by Mr. Slaughter's engine was 235 tons 2 cwt.; the tare was 137 tons 12 cwt.; the net was 97 tons 10 cwt. On the narrow gauge the gross load was 254 tons 9 cwt., the tare 101 tons 17 cwt., and the net 152 tons 12 cwt. The wagons were taken and loaded expressly, that there should be as little dead weight as there possibly could; and this is a further proof of the comparative net and tare upon the two gauges. There were 36 wagons upon the narrow gauge, and 25 wagons upon the broad gauge. On the latter the gross load was 235; on the former 254. With 35 tons 15 cwt. less tare, there was on the narrow gauge 55 tons 2 cwt. more net. Went up two inclines of 1 in 100 at a speed of 8 miles an hour. On other portions of the line, that is, on level portions of the line, and slight inclinations, our maximum speed was 25 miles an hour. Size of the engine on the broad gauge: cylinder 16 inches diameter, stroke 24 inches, wheel 54 inches, gross weight of engine and tender 23 tons. Size of engine on the narrow gauge: cylinder 15 inches diameter, stroke 24 inches, wheel 54 inches, weight of engine and tender 27 tons. All six wheels were coupled in both cases, so as to get the utmost adhesion to the engine. The Birmingham and Gloucester is laid with longitudinal bearings, thinks the Bristol and Gloucester is also laid with them. An increase of the boilers would increase the weight of the machine, and thinks that, at a high velocity, a very heavy engine would act very injuriously on the rails; so far as it is safe for the rails, the increase of the weight and power of the engines to produce speed, can be got on the narrow as well as on the broad gauge. The consumption of coke, consequent upon the generation of more steam, would be greater, but thinks it is cheaper to work with one large powerful engine, than with two small: has an engine on the narrow gauge capable of taking 600 to 700 tons, and his engine will take 1000 tons on lines of easy gradients, at 10 or 12 miles an hour. Thinks the injury to the rails and permanent way would be very much increased by increased weight and speed. Believes the injury to the permanent way on both gauges is more caused by high velocity than increase of weight. Has observed that the shocks received from the fast trains appear to affect the rails more than the slow, and the contractors for the repairs do not like fast trains so well as heavy ones at slow speed.

Has not seen the fractures of axles on the broad gauge; has seen them on the narrow. A very extraordinary change takes place in axles from the constant blows the wheels receive; it amounts to what is called cold swedging on the anvil, and renders them more brittle, which must exist to the same extent on the broad gauge; on the narrow, axles have broken that had worked three or four years, and though at first they might be fibrous in their texture, yet on fracture they appeared as if broken up into small crystals; considers the breakage of axles must arise generally from this, and the greatest care is required to get them of the best manufacture, and of the toughest and strongest iron. Prefers those of the patent axle company, near Wednesbury, with radial bars all welded together, and finds them, from experience, superior to the Low Moor. The elasticity of the long bearing of the axle would affect the wheel, throw it out of the perpendicular, tend to injure the railway, and force it out of gauge; on curves, an objection arises again to the broad gauge, as one wheel has to travel over greater surface than the other, there is either a straining of the wheel, or a twisting of the axle; the axle will be strained and deteriorated in this manner more on the broad gauge than on the narrow.

100 miles is a fair day's work for an engine, but he sees no objection to doing more; thinks that by seeing that the engines are in good order, and changing them once a fortnight, there is economy in working as much as 150 miles; the steam being raised in fewer engines would save fuel. Is aware that the London and Birmingham Company change their engines at Wolverton; they make a trip each way, being 120 miles a-day, without putting out the fire. If the gauge were uniform at Gloucester, one-third of the present staff of porters could do the goods trade; at present they are kept for lifting goods from one wagon, and repacking them in another, which requires five to six hours from their arrival. The guards' returns show, during the month of August, an average detention of 16 minutes for passenger trains. The detention to goods trains by transhipment from one gauge to another cannot be estimated at less than from 4½ to 5 hours. Thinks the alteration of gauge matter of necessity, and that the cost would form a very small practical part of the ultimate profit. Supposing the cost to be £5,000 a mile, has no doubt the increased profit would more than cover the interest of the outlay, but thinks £5,000 is very much too high a sum for the alteration, for this reason—with respect to the wagon-stock, it would take for instance for 50 miles of railway a certain number of wagons, but for 100 miles of railway it does not take a double number of wagons, because if the wagons work through, a small addition, comparatively speaking, would work the 100 miles beyond what is required for the 50. And so with respect to all the carrying stock. Having the carrying stock for the Birmingham and Gloucester portion, it would require a very small addition for working the other portion of the line, comparatively speaking. To lay down the broad gauge to Birmingham would amount to a complete demolition of the present works; the bridges and tunnels are too narrow, and the stations must be removed. Imagines the expense would be very great, almost a re-making of the line. The largest goods train he ever knew to arrive from the north at Gloucester was 320 or 330 tons gross weight, but thinks only a small quantity was transhipped to the broad gauge, as it consisted chiefly of salt shipped at Gloucester. In many cases, a day is occupied in transhipping. Recollects 40 or 50 loaded goods wagons waiting at Gloucester a fortnight for broad gauge wagons to come up, and that may occur either way. No mechanical arrangement at Gloucester for transferring goods, but manual labour and cranes. At first, shifting on low trucks was proposed, but on inquiry, they did not go to this expense. Goods wagons placed on additional trucks would not pass under the narrow gauge bridges, but they could on the broad. The weight of the additional trucks on the broad gauge would be about 3 tons 5 cwt. Although mechanical arrangements may work well experimentally, believes they will be found in practise totally unfit for every day traffic. The strength of the railway carriage and body is increased by their being united, and being exposed to rough usage, a separation would be a constant cause of damage to the carriage and the goods in it. Thinks that detaching the bodies of passenger carriages from the wheels and frames would be highly objectionable. High velocities would not increase the expense on the narrow as much as on the broad, the lighter machine on the narrow having less tendency to damage the rails. The permanent way on both lines is kept up by contract, and the expense on the Birmingham and Gloucester is about £100 per mile. The rails on the latter were originally too light, and the timbers and cross sleepers of the embankments not sufficiently seasoned, nor put into the Kyanizing process, so that the expense of repair has thus been increased. A line well made would be kept up at a very low expense. Believes that 75 lb. rails are now adopted on all lines, and they are to be substituted for those on the Birmingham and Gloucester.

Description of the improvements on the narrow gauge engines with six wheels.—The general features of both are as follows: Mr. Robert Stephenson has always advocated the six-wheel engine, and has made it; he has improved it very much; he has simplified the arrangement and construction of the engine; he has adopted the outside cylinder to his passenger engines, with a framing rivetted to the boiler plates; and he works his slide valves in a vertical direction. He has very much increased the length of the boiler. The average length, before it was varied by Mr. Stephenson, was from 8 to 10 feet, and now Mr. Stephenson has adopted the 12 feet tube and upwards, thereby safely calculating that a very great economy is effected in the consumption of fuel, that is, that a less proportion of heat is allowed to escape unprofitably up the chimney. This engine is found to answer in practice exceedingly well, inasmuch as it gives a greater length of engine on the rails, and increases very much its steadiness at a high speed. He has also a patent for placing the whole six wheels between the fire-box and the smoke-box, whereby he is enabled to distribute the weight more equally on the wheels. In working the engine he also uses what is termed the expansive motion, the link motion. It enables the driver of the engine to regulate the supply of steam to the cylinder in proportion to the load. There are various plans of doing so. There is a plan proposed and patented by a Mr. Bodmer of Manchester and Mr. Myers of Mulhausen on the Continent for doing the same thing, all tending to the saving of steam, and providing the quantity of steam requisite to overcome the load. The size of the engine is increased. At one time it was considered that from 12 to 13 inch cylinders was a good average size for working railways. Now we find from experience that economy of working is very much assisted by taking the train by one heavy engine instead of two light ones: that is to say, you save the wages of two men; and the expense of repairs is very much reduced, and materials, for instance, oil and tallow, &c., and the consumption of coke in the one engine is not at all equal to the consumption of the two, which would only do the same amount of work. The practice has become general on narrow gauge railways to adopt 15 inch cylinders instead of 12 inch, and even higher than that. There are at present engines being made at Messrs. Sharp's manufactory at Manchester with 18 inch cylinders of nearly the same size as the one at work at Bromsgrove, but with 24 inch stroke, 4 feet 6 inches driving wheels. They are intended for the Sheffield and Manchester Railway and the Manchester and Birmingham, and it is calculated they will be of very great service with heavy goods trains, and enable them to carry at a very low cost indeed. Those engines will be equal to take 800 tons, and travel with ease when they are at work; proving that, so far as the power of an engine is concerned, the power of getting machinery on the narrow gauge is sufficient to take any load; it will be quite equal to produce it, at least as far as it can be properly adopted without increasing the weight of the machine to the injury of the permanent way. Our power is increased more than it would be warrantable to increase the weight of the machine, of which the engine at work at Bromsgrove is an instance; for although it is 30 tons in weight, the whole six wheels can be made to spin round and slip with the six wheels coupled. That settles the point completely that we can get sufficient power on the narrow gauge, without at all injuring the construction of the engine, or rendering it objectionable. With respect to those engines that are in construction by Messrs. Sharp at present with the 18 inch cylinder, it is a most remarkable thing that the cylinders are not placed outside the wheels, but inside, so that there is room for two 18 inch cylinders in the narrow gauge to be constructed inside the wheels, working with the crank shaft. That does not much affect the centre of gravity; the cylinder is kept low; the valves are underneath in this case. The principal objection is the crank shaft, to get room for the boiler; but on the drawing and on the elevation of the engine, the centre of gravity does not seem to be at all too high. Those engines have four eccentrics, and are to be worked with the link motion. Thinks a speed of from 12 to 20 miles an hour with a goods train, as great as would be safe with this weight of engine on either gauge. These engines not used for passenger trains, the wheels being only 4 feet 6 inches in diameter, and wanting adhesion as well as power.

Description of the improvements on narrow gauge engines of the second kind, namely, those with four wheels.—Mr. Bury has always been a maker and supporter of the four-wheel locomotive engine. They are in use on the London and Birmingham Railway and several other railways. They also have been much improved; the boilers have been lengthened to about 11 feet; they have been increased in size with 15 inch cylinders and 2 feet stroke. The interval between the fore and hind axle is somewhere about 6 to 7 feet; in those of Mr. Stephenson's the distance is rather less than 12 feet; they are all in the space between the fire-box and the smoke-box. A plan is adopted on the London and Birmingham, of attaching the engine to the tender by a draw spring, rendering it an 8-wheeled machine. Believes, with the inside bearings adopted by Mr. Bury, that the engine would go on with the axle broken. Has seen them going 12 or 14 miles an hour with the axle cut through. Has known the axle broken, and not discovered till the train was at the station. The breaking of the axle takes place close to the journal, and sometimes at the corner of the crank, the iron being cross there, and not so strong. Prefers the straight axle with outside cylinders for safety. The chief objection to the crank axle is liability to give way.

John Urpeth Rastrick, Esq.: The largest engine on the London and Brighton Railway is one of 15-inch cylinder. Gives a preference to the cross over the longitudinal sleeper, as it is much more easily rectified and kept in order. At the time the extension of the Greenwich Railway (that is, the widening out of it where the Croydon, Dover, and Brighton Railways run over it,) was proposed to be done, the Directors of the Greenwich Railway Company desired their engineers (Colonel Landmann and Mr. Miller) to make a report upon the sort of rails they ought to use in the laying down of those two lines. Each of those gentlemen made out a report; one recommended rails to be laid of the same size as those that are laid on the Croydon Railway, which is a rail that has got a flat top to it; it is rather a low rail, with a wide flange at the bottom, and a narrow rib between the top and the flanch, and that was to be laid on longitudinal bearers. The other gentleman recommended that the rails should be made about 75 lb. per yard (these are called the H rails), and fixed in cast-iron chairs with wooden keys. The Directors of the Greenwich Railway Company did not think proper to take upon themselves to decide which of those rails should be laid down, and they sent the reports that had been made to them, to witness (of course not putting the names of the engineers to the reports, but merely stating that they were the reports of their engineers), and requested an opinion as to which of these methods they ought to adopt. Advised them to adopt neither of the rails, as the Croydon rail seemed (that is the light rail, and the light longitudinal bearer,) altogether too weak, and the other was not so well adapted for a viaduct as it would be if laid on longitudinal bearers, but a stronger rail; therefore recommended them, instead of making use of a cross sleeper, with a 75 lb. rail, to make use of a bridge rail of 80 lb. per yard, which had got a wide flange at the bottom. The rail was about 2¼ inches wide at the top. The flange was half-an-inch thick, and the outside width of the flange was six inches, and each of those sides was three-quarters thick; these rails were screwed to the timber; screw pins went through the longitudinal timbers, and underneath there were bars into which the screw-pins were screwed. By placing an auger-spanner on the top of the pins, the rails can be screwed down most securely. The rail laid down on the viaduct of the Brighton Railway was found to answer so well that witness recommended its adoption to the Greenwich Railway, and those rails are now laid down there. The nut keeps its hold and will run back, because it can at any time be screwed up; they have nothing to do but to apply an auger-spanner on it. Is laying down a railway from Hastings to Lewes, and likewise from the Chichester line, from Shoreham to Chichester, with rails of that description, but on cross bearers with this addition, that to each of them, at the joints, there is a wrought-iron plate into which the two rails slip. There is a wrought-iron plate about 10 inches long, turned up on the edges, so as to form grooves; the two rails come together into this wrought-iron plate; the rails cannot separate, and of course that part which turns down on the upper flange of the rail keeps the one rail from rising above the other. In laying down these rails on the Greenwich Railway, we had no provision of that sort, and consequently they are liable in some degree to rise one above the other, unless the screws are kept tight; but even if the screws are all slack where these wrought-iron joint plates are used, they cannot rise one above the other. The rails were laid on cross sleepers; did not use the screw-pins at all, but merely a parallel bolt five-eighths of an inch in diameter, which holds better than screws or any other contrivance. We bore a hole half an inch in diameter, and then drive in the bolt; in fact, they hold so very fast, that in endeavouring to get them out sometimes on the Brighton Railway when a chair has broken, we have had to bend the pin backwards and forwards considerably before we could pull it out.

The velocity of the express trains on the Brighton is about 34 miles an hour, with one stoppage at Red Hill. There is very little oscillation if the road is in good order. Outside cylinders do not produce any yawing motion; it is impossible any such motion can be produced, unless there is a play in the framing itself. Considers the outside cylinders to be very much preferable to the inside, and they run a great deal steadier.

Mr. Henry Pringle Bruyeres: Is superintendent of the London and Birmingham Railway, and controls the general arrangements both of passengers and goods. Average speed of express trains on London and Birmingham line between station and station, exclusive of stoppages, rather more than 40 miles an hour, making no allowance for slacking and regaining speed. Including the stoppages at stations, the speed is 37 miles an hour. Does not think the greatest speed at any time exceeds 45 miles an hour for any distance. Passenger carriages on London and Birmingham line greatly improved. The improvement in the first class carriages is, as respects the construction, making the under framework stronger, and making it solid instead of open, as it was originally; in point of comfort to the passengers, in making the carriages larger altogether; each compartment being longer, to give more room for the legs, and higher. The carriages the company now build are in size proportionate to those on the Great Western Railway, with the exception that they may be three or four inches less in height. The reason of having them less in height is to allow of the luggage being conveyed on the roof; however, ample room is given, even for a tall person with his hat on inside. The luggage placed upon the tops of the carriages is principally "through" luggage, belonging to passengers that are going a long distance, so that when they arrive at the end of their journey, instead of having to seek their luggage at the forward part of the train, it is over their heads, and if they can only divest themselves of the idea that they are in a crowd upon their arrival, and remain stationary on getting out of the carriage, they will find their luggage immediately before them. All inside cylinders, and only one six-wheeled engine. The Company are now building six-wheeled engines. The engine and tender are tightly screwed together. Probable expense of London and Birmingham goods wagons into loose boxes for transfer on to broad gauge, about £50 per wagon. The London and Birmingham line now so consolidated, that the rains have little effect upon it; subsidence of the ballast does not take place upon the embankments.

The area of the Rugby Station is about 12 acres, including the portion used by the Midland Railway, as well as the London and Birmingham.

Dimensions of old and of new carriages.—They consist of three compartments, holding six persons each; the old carriage was in length, that is between the persons, face to face, 4 feet 11; the new are 5 feet 9, being an increase of 10 inches; the width of the old carriage was 6 feet, and the new is 6 feet 6, giving 2 inches more in width to each seat. The height of the old carriage was 5 feet, and the new ones are 5 feet 7, giving an extra height of 7 inches, that is between the floor and the ceiling, and taking it at the centre of the ceiling; the roof is curved about 2 inches, and is 5 feet 5 at the two sides. The outside length of the old carriages was 15 feet 6, and of the new, are 17 feet 6. That is the entire body. The width was 6 feet 6 in the old, and is 7 feet in the new. The height, allowing for the curve mentioned before, would be 5 feet 2 the old, and 5 feet 8 the new. The total height above the rail of the top of the carriage is 8 feet 9 the old, and 8 feet 10 the new. The additional height inside has been obtained by lowering the floor.

At present, if the Great Western Company require engines from the North of England, when not carried by water, they come up upon the London and Birmingham, and are transferred from Euston-square to Paddington, and run down the Great Western line. This has frequently been the case; they are brought up on trucks. The comparative dead and net weight carried by the down express train for the month of August, 1845, is as follows: number of passengers, 1,613; carriages, including luggage van, 132; weight of passengers, at ten to a ton, 161 tons; weight of carriages, 556 tons.

Cononel George Landmann: Was engineer of the London and Greenwich Railway and the projector of that scheme. When the line was constructed, used a very light rail, of 50 pounds to the yard. Subsequently changed those rails for others of a heavier description, weighing 65 pounds; the first rails did not reverse; the present rails do reverse; the new part is upon the Great Western principle, upon longitudinal sleepers; in the first instance, used stone blocks, which were afterwards changed to transverse sleepers. The widened portion of the line, from London to the separation of the Croydon, and the portion from Deptford to Greenwich, originally laid upon longitudinal sleepers, with the same form of rail as the Great Western; that rail was 60 pounds to the yard, whilst the Great Western was 43 pounds. The longitudinal sleepers between Deptford and Greenwich are 12 inches wide by 6½ deep; those upon the widened part are the whole size of the baulk; 12 and 13 inches, with ties across the same depth, to preserve the gauge. The longitudinal sleepers of the Greenwich line, extending from Deptford to Greenwich, rest upon transverse sleepers, 10 inches by 6, by 6 to 7 feet long, and placed at distances of about 4 feet apart, and to which the longitudinal sleepers are spiked; these sleepers were all Kyanized, and, as far as witness has been able to discover, are still quite sound. With longitudinal sleepers a lighter rail might be used than would be required where there is a space between the supports; and if the ground be properly made at first under longitudinal sleepers, is of opinion that that would be the best mode of constructing a line; objects to the mode adopted under Mr. Rastrick's direction of laying the rails upon the widened portion of the Greenwich Railway. Witness's design was to have transverse sleepers, with the longitudinal sleepers upon them; it now entirely rests bedded upon earth; if it had had fixed points to rest upon, it would have been much more secure. Should rely entirely upon the bearing upon the transverse sleepers. It is not found too elastic upon the Great Western; the longitudinal sleeper is only 7 inches thick; they have no transverse sleepers. The engines on the Greenwich line weigh about 14 tons with the water. Some are six and some are four-wheeled engines; four-wheel engines are going out of use as fast as they become destroyed; upon a portion of the line (the Brighton and South Eastern line) they run with much heavier engines, weighing 16 or 17 tons.

CHARLES VIGNOLES, Esq.: Laid out the Eastern Counties with Mr. Braithwaite, but that gentleman executed it; a question as to the gauge arose; was then very desirous of making the gauge wide; Mr. Braithwaite's view of having a 5-feet gauge was adopted; should have preferred a 6-feet gauge. Intended the Dublin and Kingstown Railway to have been a 6-feet gauge; but the Directors overruled his opinion, on the plea that so short a line might, if necessary, have its gauge altered without inconvenience; they had to obtain all their first carriages and engines from England, where 4 feet 8½ was the prevailing gauge, and they were very unwilling to depart from it; he has been consulted in laying out many principal lines, and also on the gauges of many; the Edinburgh and Glasgow was laid out, though not executed by him; as it was likely to connect ultimately with lines coming from the south, on the 4 feet 8½ principle, that gauge was adopted; some Scotch lines already executed are on rather a narrow gauge; thinks one coal line, the Forfar, was 5 feet 6 inches; but the general feeling was strong that connection with south lines should be kept in view; most of the lines mentioned were previously to the introduction of the broad gauge by Mr. Brunel. On the Continent, as the engines and carriages were obtained from England, they were unwilling to deviate from the fixed rule; the first railway in Brunswick was about 30 miles to the foot of the Hartz mountains, and the English gauge was adopted; the latest large operation of his on the Continent was laying out the Würtemberg railways; there the question of gauge was greatly discussed, and is not yet settled; they are intended to unite the railways in Baden, which run parallel to the Rhine, and those in Bavaria, which run from the Danube; the gauge of the Baden railways is 5 feet, or 5 feet 6, and that of the Bavarian 4 feet 8½; under all the circumstances, he recommended that 4 feet 8½ should be adopted; as all the railways in connection with Bavaria, and all the Saxon and Austrian, are 4 feet 8½, and as a great transit trade was coming from those countries, he considered that the larger amount of traffic would be from those of 4 feet 8½, and that the length of rail on the Baden side, next the Rhine, would be short in comparison; he thought Baden would ultimately be obliged to change, and bring it to the gauge of the others on the Continent; however, Baden and Bavaria persist in not changing, and it is a question at what point the transit shall take place, whether on the eastern or western frontiers of Würtemburg; thinks the probability is, that they will ultimately adopt the 4 feet 8½ gauge throughout Würtemburg.

As to the cost of the carriage-frame, thinks it would increase as the squares of the gauges, but with a certain additional amount of accommodation; one great advantage of a large carriage is, that you get less gross weight in proportion to the net; does not know whether that has been realized in practice, but thinks it ought to be so. As regards increase of speed, does not think on that alone the Great Western have an advantage; the trains travel very fast on it, but much more is due to the gradients, which are very flat, than to the gauge; with respect to economy of working, the expense on the Great Western and the London and Birmingham is as near as possible the same. With respect to safety, as far as it is connected with steadiness, is quite satisfied that at very high velocities the trains travel more steadily on the Great Western than on the London and Birmingham, taking the gradients as they occur. In the abstract, is quite satisfied there is greater steadiness of motion on the broad gauge at high velocities. If the road happens to be out of order, or the springs of a carriage stiff, or if it is not loaded or overloaded, or a little slack in the coupling up, or too tight—all those will affect it, particularly at high velocities; has not made a series of experiments, but is quite satisfied that it is steadier with the broad than with the narrow gauge at a high velocity. It is impossible to write on the London and Birmingham at a high speed; he could read in their express trains very well where the road was in good order, but when bad could not.

Used to be, and is still, very partial to the longitudinal sleeper; but some facts have come to his knowledge to shake his views, in particular, on a foggy morning on the North Union, when an engine comes to the longitudinal sleepers she invariably slips, which does not take place on the cross-sleepers; cannot account for it. It may be owing to a dampness that remains on the longitudinal sleepers which may impart to the rail a moisture which converts dust to mud, and produces greasiness. The soil is chiefly sand, with probably a little clay in that portion of it; but still, wherever the longitudinal sleepers are, the engine has a great tendency to slip. Has often calculated the relative cost of laying rails on the longitudinal and cross-sleepers; it was very much in favour of the longitudinal in the first instance, where a slighter baulk was used; but as it is now necessary to have the whole, or at all events a three-quarter baulk, the balance is against the longitudinal as the more expensive; a very heavy rail, with a cross-sleeper without the chair, answers very well, and is the most economical mode. The first Liverpool and Manchester rails were 35 lb., and the 42 lb. rail on the Dublin and Kingtown is still in use. On the lower part of the North Union the 42 lb. rails have been taken up and replaced by 63 lb. On that line the passenger trains are light, but the merchandize and coal excessively heavy. The lengths of bearings are 3 feet 9 inches and 4 feet; four to a rail.

Should the Grand Junction Company alter to the broad gauge, it would be practicable to alter the North Union too, as the bridges and tunnels are sufficient for the purpose; none of the bridges are less than 30 feet span, and those of the Great Western are not more. His practice is to make bridges about 30 feet. The tunnels are about 27 feet. On the Midland Counties the bridges are all 30 feet; the viaduct at Rugby is 27, which would admit of the broad gauge by corbelling out the parapet; the Great Ribble Bridge on the North Union is 27 or 28 feet wide, and the tunnel into Preston, the only one, is nearly 30 feet. With less than 30 feet there would not be room for a man with safety; it would be better to have recesses built in the tunnels. Thinks, by a judicious system of transfer of bodies, the packing and unpacking at Gloucester might be avoided. The passenger carriage-bodies may be transferred, as at Rouen, to the frame of the railway carriage, without any risk or difficulty. Has ridden in one of those carriages, and been lifted up with it, without any practical inconvenience. It is bolted down, and is as perfect as if it were the railway carriage itself. A carriage put together in that way is as strong as a usual one, in case of collision; it is strong enough to be lifted, and, being required for the road, is stronger than the railway carriage. Considers the 7-feet gauge wider than is necessary; the wider the gauge, the more the effect of curves is felt; does not think the gradient at all enters into the question. The Great Western have large driving-wheels, not with regard to gauge, but velocity; there is no necessary connexion between the diameter of the wheel and the gauge. Would not adopt the 7-feet wheel on the narrow gauge; but that is a proof that it must be steadier on the broad. A great number of things were proposed in adopting the broad gauge, which have not yet been carried out with effect. Were he the engineer of a broad gauge line, should avail himself of the increased space to make engines more powerful. The necessity of increasing the engine is every day apparent, and to have engines so far above the work that there can be no question about their power. The driving-wheel of the engine will regulate the velocity; one of the Great Western engines, with the large driving-wheel, would give the same amount of speed, whether on the broad or the narrow gauge. The diameter of the driving-wheel is quite a different question from that of gauge, except as regards the increased steadiness arising from the wider gauge.

(To be continued.)

VENTILATION OF THE HOUSES OF PARLIAMENT.

The second Report from the Lords' Select Committee to inquire into the Progress of the Building of the Houses of Parliament.

That the Committee have again met, and having examined Mr. Goldsworthy Gurney as to the best system of ventilation for the new Houses of Parliament, are of opinion that further inquiries and experiments should be made, under the direction of her Majesty's Commissioners of Woods and Forests, before the final adoption of any plan hitherto proposed for that purpose. And the Committee have directed the evidence of the said Mr. Goldsworthy Gurney, taken before them, to be laid before your lordships.

[We select from the appendix the following extracts from the evidence of Mr. GOLDSWORTHY GURNEY.]

Are you aware of all the plans proposed by Dr. Reid, for ventilating the new Houses of Parliament?—No.

Therefore you do not know what his scheme is, and how he proposes to force a due diffusion of air over all parts of the building?—Except from hearsay. I have no accurate information.

In what manner do you understand that he intends to do it?—By a large upcast shaft, the base of which is to communicate by air passages to the various apartments in the building.

Do you suppose that that is to be assisted by any power either of furnaces or steam power?—I suppose it must be assisted by a blowing cylinder, or a centrifugal fan. Those adjuvants would be unnecessary if the upcast shaft had sufficient power. They are always objectionable, in consequence of involving machinery, and being liable to get deranged. Yet some mechanical assistance must be had; for if this extensive building is to be ventilated by the upcast shaft it must fail. The size of a shaft would be inadmissible, for it will be evident to your lordships that the whole of the air drawn from the whole extent of the building ventilated must pass through it. This is not all; the whole of the air drawn out of the different apartments, and passing through the shaft, must be raised to the temperature of 500° of Fahrenheit, otherwise it will have no power. That is a very important point; one to which I wish to fix your attention, and explain as clearly as possible. Suppose the buildings of the new houses extend over ten acres of ground; suppose five acres—one half only—occupied by rooms, the sectional area of the five acres of rooms will be, in round numbers, 200,000 feet, accurately 217,600 feet square, which is about the square surface of five acres of ground. Suppose the movement of air to be at the rate of 11 feet a minute, which it must be for good ventilation, the quantity of air discharged must be 2,393,000 cubic feet per minute. Now the whole of this 2,000,000 cubic feet of air must be heated sufficiently high to produce an available power, by the difference in the weight or balance of the internal and external columns. A temperature of 500 degrees Fah. believe, is necessary to produce any available pressure. The whole of the air must, therefore, be passed up the chimney, and then raised to a temperature of 500 degrees of heat as it passes. This appears to be impracticable. But supposing it possible, the quantity of fuel burnt could never be suffered. On referring to experiments made by myself some years since, I find a pound of charcoal will heat 1,000 cubic feet of air from 60 degrees only to a temperature of 500 degrees. Therefore, if we take this as sufficiently accurate and favourable data, we shall find that we require at least 2,000 lb. of fuel per minute. The impossibility of being able to consume this quantity of fuel is evident; it is not possible to burn this quantity of fuel. To produce practically a discharge of that quantity of hot air, or effect an available power, it must be borne in mind that air raised from 60 degrees to 500 degrees doubles its volume.

You object, also, to the system of ventilating from the floors or sides of the room instead of from the upper portion of the apartments?

Yes; there is a practical objection to this direction, which will be seen by looking at the subject carefully. These retrograde currents produced from air entering at a low level into a room are practically very objectionable; they produce an increased rate of evaporation upon the skin, which produces a sensation of cold. Although the temperature of the air in motion itself may be warm—say 70 or 80 degrees—it will produce a temperature very considerably lower on evaporating surfaces. The skin of the human body is essentially an evaporating surface, and suffers much from this law. The feeling of cold in the parts of a room where retrograde or direct currents act is not due to the actual temperature of the currents, but to the increased rate of evaporation produced by them. Evaporation produced by retrograde currents rapidly absorbs heat. A person cannot get out of the influence of the direct or retrograde currents if they enter near the floor or at a low level, but if the openings are made in the ceiling or at a high level, then they are mixed with the atmosphere of the room above, and cease or become destroyed before they can possibly reach any one standing on the floor.]

Although not evinced by the common thermometer?

Not by the common thermometer, but instantly by an evaporating thermometer.

It does not depend upon temperature, but evaporation?

It is entirely due to the increased rate of evaporation produced by a current of air passing over the surface. It is said, "If you cover the skin with ether, or some other rapidly evaporating substance, you may freeze a man to death in the height of summer." A current moving at the rate of three miles an hour, acting on highly alcoholic ether placed on the surface of a thermometer, will occasion the mercury soon to fall to the freezing point, notwithstanding the current of air may be at 80°. Evaporation where there are partial currents goes on unequally; there is a feeling of heat out of the currents, and a feeling of disagreeable cold when in them. You cannot get out of them if the entering current is anywhere where it impinges upon the person. There is a great objection to air for ventilation entering a room anywhere at a low level; it must necessarily impigne upon the person.

Will you state what force you propose to apply to set the atmosphere in motion?—I prefer the *vis à tergo* arising from the escapage of high-pressure steam; through proper sized air passages it furnishes a power capable of being managed so as to produce at will any rate of current down to almost an insensible breathing. I prefer it, also, in consequence of its great capability of management. When I state that in some experiments which I made ten years since, I raised a column of mercury nine inches by the force of the current of air produced by it, the Committee may see from that fact that it is capable of producing a force which never can be required for ventilation. M. Arago, in some experiments within the last few months, has raised by a current of air thus produced a column of mercury 15 inches. Therefore these facts prove that we have abundant power so as to overcome every opposition arising from wire-drawing or other resistance, and to compel air to pass with uniformity wherever it may be necessary. It is simple in application, and its economy great, though that is not of so much consequence as the former; it is capable of being passed easily and independently to any part of the building separately. You may act by this principle upon groups of rooms, or upon single rooms, or anywhere where it may be convenient; by that means, you prevent the necessity of cutting up the building, or the making of large communications. Another advantage which it will produce, and which though last may not be the least, is, that it is capable of passing a sufficient quantity of air, as much as can be required to produce ventilation, through small passages, which passages may be secured against the communication of flame, in case of fire, on the principle of the safety lamp. This is a circumstance of great importance where a building is to be made fire-proof. Supposing there are several rooms connected together by ventilating flues, all would be rendered safe and perfectly independent of each other as to fire by the intervention of diaphrims of wire gauze, upon the principle of Sir Humphrey Davy's safety lamp. Wire gauze cannot be introduced unless you have great command of power, because you offer by it a strangulation difficulty in the passage of air, which cannot be overcome by the ordinary means of ventilation.

You consider this principle perfectly applicable to fire-proof buildings—that it does not affect the fire-proof quality of the buildings in any way?—Not at all; but if there should be any doubt as to the safety of a wire gauze disc, or layers in succession, each room may be ventilated independently of any communication made between them; in that case it must be self-evident that there can be no danger from fire.

So that the system may be applicable either to single rooms or to an entire building?—Yes; the power is sufficient to produce ventilation for the entire building.

You are aware that Dr. Reid's view of taking the air, by which the houses are to be supplied, f om the top of this great tower, when completed, is for the purpose of getting a purer atmosphere than he thinks he can get down near the river, where it is, in a degree, vitiated by sewers and smoke; do you think that it would be advantageous to get your air from such a source for the general ventilation of the buildings?—The sewers I know little about; but in regard to smoke, the most deleterious and injurious products of combustion in London from the chimneys I believe are those which are invisible. The visible smoke—the unburnt carbon—we need not be much afraid of; it blackens our faces, but I believe does no harm to our lungs. The most serious injury is from the sulphurous acid formations, and from some of the volatilized metallic oxides: but this is a question of great difficulty, a question that much better chymists than I am must answer.

Do you mean to imply that you doubt whether air two or three hundred feet high is not likely to be loaded with much greater impurities than the lower atmosphere, which appears to be coarser?—Yes; I should have some doubt about it.

You are aware that Dr. Reid has a plan for collecting the smoke of every fire in the building, and conveying it all through one shaft?—I have heard so.

Do you believe that can be done?—I think it is very difficult.

SUBSTITUTE FOR RAILWAY SLEEPERS.

The following suggestion occurs in the Engineer's eleventh report to the Georgia Central Railroad Company, (America):—

During the past year, I have made an experiment of substituting iron cross ties for our present wooden sleepers. In renewing the sleepers as they decay we use no other timber than cypress—this is not to be obtained near the road above the Ogechee river, and we are obliged to transport the sleepers from the lower portions of the road, which increases the labour and expense.

I have long entertained the opinion that a much smoother track could be attained by removing entirely the sleepers, which support the string pieces at intervals, so as to give the string piece a continuous and uninterrupted bed of earth. I am now convinced of the correctness of this opinion. The plan is as follows:—

The string pieces (6 by 12 inches) are laid on an even, well rammed surface, and in length of from 30 to 60 feet—at the joinings, a bolster piece of the same scantling as the string piece and three feet long, is placed lengthwise immediately under the joint, and the string piece pinned to it. The iron rails, of the ordinary ⊥ pattern, are laid along the centre of the string piece, and the track is kept in gauge by the iron tie, a piece of flat bar iron, half an inch thick by two inches wide; this tie is let flatwise into the string piece, flush with its upper surface under the rail, and the ends, bent into the form of a hook, grasp the outside of the bottom web of the rail at the joint. The rail is confined in other respects as usual with the ordinary hook spikes. The track is filled even with the top surface of the string pieces. We have laid about seven hundred feet in the manner above described, on a portion of the road where the earth was springy and it was difficult to keep the track in adjustment. It has borne the transit of the trains for several months past, and keeps in much better order than with the wooden sleepers. The following statement shows the comparative expense of a mile of road with iron cross ties, as above described, and with wooden sleepers, for twenty years:—

With Iron Cross Ties for one mile.

352 iron bars, 18 lb. each, at 4 cents per lb.,	253·44 dollars
Bending the ends and preparing them, at 4 cents each	14·08 „
330 bolster pieces under the joinings of string pieces (6 by 12 inches, and 3 feet long), at 7 dollars per thousand feet, B.M., to be renewed three times in 20 years	166·32 „
Putting in 352 ties	57·12 „
Amount	490·26 dollars

With Wooden Sleepers for one mile.

660 cypress sleepers, allowing them to be left sound at the end of 20 years, will have to be renewed three times; then 1980 ties at 25 cents each	495·00 dollars
Putting in 1980 ties	471·24 „
Amount	966·24 dollars
Difference in favour of iron cross ties in a period of twenty years, per mile	475·98 „

The first cost for substituting the iron for the wood is, per mile	379·00 ,,
First cost of renewing the wooden sleepers	322·00 ,,
Difference. . . .	57·00 dollars

You will thus perceive that in a period of twenty years, a saving of four hundred and seventy-five dollars would be effected, while the additional first cost is only fifty-seven dollars per mile. The cost of putting in the ties, both of iron and wood, is estimated from actual experiment.

I have said nothing in the above estimate, of the saving which would be made in the labour of keeping the track in adjustment; this would not be less than 10 dollars per mile per annum, and would swell the difference in favour of the iron ties to nearly 700 dollars per mile in the period of twenty years.

SMELTING WITH ANTHRACITE COAL.

The following particulars respecting the first discovery of the applicability of anthracite coal for smelting iron are communicated to the Journal of the Franklin Institute, by Mr. S. W. Roberts. He states the original inventor of this important application of anthracite was Mr. Crane, who superintended the Yniscedwin works, in Breconshire. When Mr. Crane took charge of the works, and for a long time after, the smelting of the iron ore found in the vicinity was carried on with coke made from bituminous coal; but, as an extensive field of anthracite coal existed in the neighbourhood, which was considered useless for smelting purposes, his attention was early turned to the importance of bringing that fuel into use; and at different periods, during fourteen years, he had, at a large outlay, tried a variety of plans to effect the object.

Though repeatedly baffled he still persevered, and his efforts at length were crowned with complete success. Finding that the use of this hard and refractory fuel caused his furnace to chill, he resolved to try the effect of heating the blast to a temperature sufficient to melt lead, upon the plan so successfully introduced by Mr. Nielson, for increasing the yield of furnaces worked with bituminous coal.—Having made the necessary preparations, he began the experiment with the hot blast on the 7th of February 1837, in a furnace forty-one feet high and eleven feet in diameter at the boshes. From that date until the 12th of March the furnace was worked with roasted anthracite as the only fuel, and thenceforward exclusively with raw anthracite as it came from the mine without any preliminary preparation. In all respects Mr. Crane's success was complete; his furnace worked well, the yield was better than with coke, and the iron was of superior quality. He felt that the problem to which so many experimenters had turned their attention, both in Europe and America, and to which he had devoted so much of his time, was triumphantly solved. He had accomplished the object on an extensive working scale, with continued and increasing success; and from this period dates the establishment of a new and important manufacture, from which the iron trade, both of Great Britain and the United Sates, is now deriving great advantages. The writer of this notice, who was at that time sojourning among the iron works in Wales, visited Mr. Crane's establishment in May, 1837, for the purpose of seeing the process and of satisfying himself that the materials used were similar to those which exist so abundantly in Pennsylvania. Finding that the great object was accomplished, and that the results were highly gratifying, he communicated the fact to his friends in Philadelphia, by whom it was shortly after made public through the newspapers. At that time there was no blast furnace in Pennsylvania working with anthracite coal; their number in the State is now twenty-seven, and there are several in New Jersey.

At the meeting of the British Association for the Advancement of Science, held in Liverpool, in September, 1837, Mr. Crane attended and presented a paper descriptive of his process, which is printed in the sixth volume of the proceedings of that association. He had secured a patent in Great Britain and had applied for one in the United States, the issue of which was for some time delayed, owing to obstacles which grew out of the premature publication of his process. His patent was infringed, and he became involved in a tedious and expensive litigation which some of his friends feared might end in his ruin. At length, however, the question as to the validity of his British patent was decided in his favour, and thenceforward it became a source of much profit to him. He extended his works at Yniscedwin by the erection of several additional furnaces, and his concerns became highly prosperous.

ORNAMENTAL FLOORS.

At the *Decorative Art Society, May* 13, a paper "On Ornamental Floors," was read by Mr. Laugher. The subject was treated principally with regard to modern appliances, and more particularly to the use of parquetry (or inlaid wood), in our principal apartments. Some observations, however, were made respecting the pavements and floors of antiquity; of which several familiar imitations were referred to in the painted floor-cloths of the present day. Subsequently to the introduction of Canadian timber into this country, stone floors were said to have become nearly universal; and also that, for upper rooms, plaster was generally adopted. It was observed that boarded floors (usually of oak) were considered a very distinctive appurtenance to the English mansion in the seventeenth century; and that they received increased attention to ornamental effect in the early part of the eighteenth, at which period the parquet floor had obtained considerable favour, and was constructed at great cost. Carpets of home manufacture then began to enter into competition with them; and the use of foreign deals (which, from their shrinking, rendered carpeting more essential to comfort) tended to the disuse of this superior kind of flooring. It was remarked that at present there was a revival in the feeling towards parquetry; and explanations were given of several applications of steam and machinery (by Messrs. Steinitz and Co.) for accelerating, not only the production of the geometric forms of the component parts, but ulterior processes of framing and construction, whereby considerable economy in time, labour, and cost resulted. Several observations were made upon the relative cost of parquetry; and it was said that its price, when laid down marginally in dining-rooms, does not now exceed four times that of its imitation on painted cloths, and than for drawing-rooms it is not more expensive than the richer kinds of carpet. The superior results arising from having an inlaid margin of hard polished wood were enumerated.

DAMPNESS IN BUILDINGS.

ITS CAUSES AND CONSEQUENCES, AND THE MEANS OF PREVENTING IT.

In our last number (page 187) we gave part of a translation from the *Magazin Pittoresque*, of an abstract of a prize-essay, by M. Vandoyer, on the prevention and cure of damp. When we commenced this paper we were not aware of Professor Donaldson's intention of reading before the Royal Institute of British Architects a translation of the original essay. He has however since done this, and we gladly avail ourselves of a translation which, being prepared by one of the best French scholars in England, would in all probability be far superior to our own. In order however to avoid repetition of part already published, we have ventured to omit some portions of Mr. Donaldson's paper.

According to physical laws, the damp of the soil tends to penetrate, in one direction or another, the hygrometric bodies with which it meets. It hence results, that the walls of buildings will absorb from the soil a certain dose of humidity at all the points immediately in contact with it. That is to say, if there be an underground basement, the outside walls will absorb by their footings, and by one of their faces, and the division walls by the footings alone. If there be no underground basement, the division and outer walls will be under precisely the same conditions, with respect to those parts of them below the level of the exterior surface of the soil. But are these the only causes of humidity ordinarily regarded in lower parts of buildings? Certainly not; and it is easy to prove that, with regard to external walls, there are other causes, which, although less constant, are notwithstanding not less immediate;—we mean the rain-water, which the wind drives upon the faces of walls, by which the lower part is wetted; as well by that driven directly on the surface as by that which rebounds from the ground, or by that which falls down the face of the wall. In the case of dripping eaves, without gutters, it may be easily imagined the abundance of wet which the walls receive at the lower parts from the drips of water, and from stacks of rain-water pipes without shoes.

If the lower floor of a building be covered, whether it be by any pavement whatever, or by a planking, immediately upon the soil itself, it is certain that the ground under the floor contains, first its own humidity, as also the damp which traverses the foundations of the outer walls; so that there will exist always a constant humidity throughout the whole extent of the *lowermost* floor, susceptible of exercising its influence upon all bodies immediately in contact with the surface of the soil.

The paving the outer surface next the building, or its being unpaved, materially affects the dryness of the inside; and the construction of numerous and full-sized sewers and drains in large towns, also carries off a great portion of the surface waters; and again, an isolated building is more exposed than one contiguous to another; and also when a house is on the slope of a hill, with one part against a bank, through which the waters may flow, it is necessary to adopt precautions to prevent their penetrating the solid constructions.

No reliance can be placed on the impenetrability by humidity, of any material—wood, bricks, ordinary stones of every quality, marble, nay granite itself, are more or less hygrometric—that is to say, that plunged in water or kept in a humid atmosphere, after having been previously weighed in their dry state, there is not one which will not have acquired some addition of weight. Thus, if the base of a column be immersed in water, it will gradually rise up the shaft, and the damp never quits a body into which it has once penetrated, unless it be absorbed by the air or heat. If the upper part be dried by exposure, as soon as it ceases to be acted upon, the humidity of the lower portion will again rise to the dry part.

A wall, therefore, constructed of brick or stone of any quality whatever, will be subject to the damp which exists in the soil, and which will enter in all directions and in all parts, where the wall is in immediate contact with the ground. The extent to which this damp will penetrate, cannot be determined, and it may rise to a very great height above the level of the soil; and if it be arrested more or less, that will be caused by the influence of the neutralising power of the temperature of the atmosphere; so that a wall, which may be very damp at the beginning of summer will be much less so at the end of the dry season, and particularly so if immediately exposed to the sun, but the following winter the damp will return, unless the original causes of humidity be subdued.

It is desirable in all and every class of soil, to have a substratum of concrete under the footings. For the purposes of damp this need not be very deep, perhaps not exceeding a foot high. As soon as the footings and lower part of the wall are carried as high as the level of the ground inside, it will be well to introduce a thin sheet of lead the whole thickness of the wall, or a layer of bituminous substance as thin as possible, so as to penetrate the brick and stone and fill the pores, or a double course of thick slate set in cement.

The purpose of the sheet of lead and of the bituminous substance, and the slating, is to prevent the wet from rising up from the footings. But other precautions are necessary to prevent the access of damp from the surface of the ground next the outside face of the wall. A facing of stone is the best remedy. It need not be very thick, but it is well for it to be at least two or three feet high; and if a small interval between this facing slab and outside surface of the wall, so much the better, providing a circulation of air be kept up in the space. By this provision neither the rain beating against this part of the wall, nor the water returning from the pavement or ground, will be able to reach the main substance of the wall; for although the facing slabs may be temporarily damped, they will soon be dried without communicating the damp to the body of the wall.

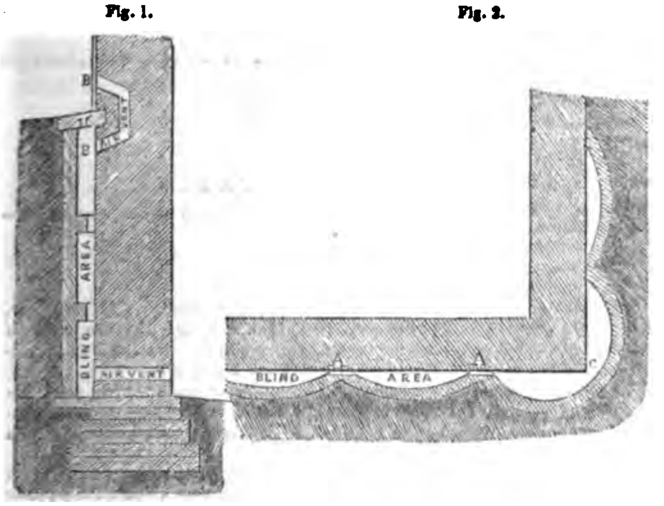
The inside of external walls should never have the plastering applied immediately on the face. They should be battened by means of long narrow slips of wood, attached by hold-fasts to the inside face of the wall. These slips or battens receive the laths upon which the plastering is applied. The space formed by the battens between the wall and the lathing effectually keeps out the humidity.

No impervious covering should be laid on wooden floors in the lowermost story, such as oil-cloth, for instance; a certain moist air always rises from the ground, and escapes through the joints of the boards, but if this be intercepted by an oil-cloth, the air will rot the boards and oil-cloth in a very few months.

But it is important to keep the damp from the floor which come upon the ground, that is, the floors of the lowermost story. It is evident that the timber of stone slabs should not be in immediate contact with the soil; for this purpose, let a stratum of concrete be laid over the whole surface of the house, six or nine inches thick at the least. Upon this form sleeper walls or piers up to the necessary height, and on them lay the plates or paving slabs; as an additional precaution, a thin sheet of lead might be laid under each pier on the bed of the sleeper walls. In palaces, as a greater precaution, and in buildings where expense is a secondary object, a thickness of asphalte might be laid on the concrete. In the dwellings of the poor it is expedient at all events, to have the sleeper walls or piers, which need be only half brick wide, and one course high, without the cement, and generally that will be a sufficient precaution; where stone paving forms the floor, bricks must be laid under all the joints. Thus will the humidity be more or less prevented from reaching the floors.

But of all precautions to prevent damp entering by the face of the wall, the best remedy is have an area, which, by keeping the soil at a distance, preclude its fatal effects on the wall. There areas may be three or more feet wide, and may serve as a passage all round the building, and afford access to cellars outside, as in the London houses; or if this, from want of space or the expense, be impracticable, it will be sufficient to have what

Fig. 1. Fig. 2.



are called blind areas, with convex walls against the earth, the points of contact with the outer wall of the house being as small as possible, to diminish the possibility of the communication of damp. Care must be taken to leave openings at A A A (fig. 2), so as to maintain a draft or circulation of air throughout the several areas; and to render this circulation perfect it will be requisite to form in the wall three or four shafts, as B B (fig. 1), to keep up a communication with the outer air. It is necessary to leave the angle C, quite free and clear, for the angle at C being a solid mass, requires the greater exposure, that it may throw off the damp, which it originally acquired by exposure to the atmosphere, as it tends to make it evaporate. The top of the areas must be covered by stone slabs, which it is desirable to keep above the surface, and the face of the wall immediately above should be rendered with cement. If it be necessary to have the covering slabs below the earth, the face of the wall must be rendered with cement, or the damp will undoubtedly penetrate through the wall from the slightest depth of ground next to it.

Another precaution must always be taken in regard to floors, and that is, to insert in the outer walls iron gratings, with channels in the wall, say 9×6, so as to let air pass into the floor from the outside; and in order to exclude the air from the floor in winter time, or the event of damp weather, it is well to prepare a sliding plate in the skirting, which may shut it off or open the holes for the re-admission of the air, as the one or the other effect may be desired.

Dripping eaves and rain-water shoots or gurgoils, without standard pipes, should always be avoided; for the water, which falls from the eaves, or gushes from the projecting spouts or shoots, is driven against the face of the wall ere it falls a few feet, and keeps the brick or stone-work saturated at times with the water. Hence eaves-gutters and standard rain-water pipes are always indispensable, and a proper shoe at the foot of the pipe should never be omitted, otherwise the force of the water causes it to undermine the wall, producing the most disastrous results, whereas a shoe keeps the water from the wall, and turns it into a drain prepared to receive it.

ROYAL INSTITUTE OF BRITISH ARCHITECTS.

June 8.—W. Tite, V.P., in the Chair.

Sir T. Deane, of Cork, made some observations on the drawings which he exhibited of the Abbey Church of the Holy Cross at Tipperary.

An address *on Ventilation* was delivered by J. Toynbee, Esq., F.R.S., Surgeon to the St. George's and St. James's General Dispensary. He introduced the subject, by stating that during the whole of his professional career he had almost constantly been attached to public medical institutions; and that he had slowly become aware of the existence of an enormous amount of disease in the human race. A large share of this disease was incurable when once produced; but he was in a position to prove that much of it could be wholly prevented. He, therefore, felt that it was the duty of medical men, while they devoted themselves to the cure and palliation of disease, also to exert themselves in behalf of preventive measures. In the performance of this duty, he had investigated the sources of disease; and he found that one of the most fertile was the want of a due supply of air in dwellings and public buildings. In speaking on the *Necessity for Ventilation*, it was shown that 10 cubic feet of air, or a volume double the size of the person, is required for the purposes of respiration and transpiration each minute. The circulation of the blood was described as the process of carbonization—respiration as the process of decarbonization, in the 170,000,000 of air cells, forming a surface 30 times as large as that of the skin. In the process of transpiration, the so-called insensible perspiration was continually given off; which, together with the vapour expelled from the lungs, amounted to two fluid ounces per hour. Thus, 500 people in a church during two hours give off fifteen gallons of water into the air; which, if not carried away, saturates everything in the building, after it has been breathed over and over again, in conjunction with the impurities it contains collected from each individual. The use of lamps, gas, and oil, was shown to deteriorate the air, and to add much moisture to it. The effects of neglect for carrying out plans for ventilation are shown in the production of three of the most formidable and frequent diseases which affect the human race,—fever, scrofula, and consumption. Numerous facts were adduced in proof of this view; and the way in which these diseases was produced was pointed out. Thus, it was shown that all those who were among the victims in the Black Hole of Calcutta, and did not perish from immediate suffocation, died, in a short time afterwards, of putrid fever. The proportion of people dying of consumption who follow in-door occupations is double that of those who work out of doors; and it increases as the space for labour is more contracted. Dr. Guy has shown that it is more common in the upper parts of large establishments, as printing-houses, &c., where the air is most vitiated. The inhabitants of towns exposed to the wind are much less liable to consumption than those which are well protected and sheltered; and the goître afflicting the inhabitants of the valleys of the Rhone is produced by a stagnation of air. Instances were cited of schools in which the mass of the children were scrofulous, and to whom an increased diet, warmer clothing, &c., was not productive of any benefit—and by the aid of proper plans of ventilation the disease disappeared entirely. The same result has taken place in the Zoological Gardens, Regent's Park, since the new dens opened to the air have been in use. It was then shown that hitherto there had been a total absence of plans for the suppy of pure air, in a sufficient quantity, to the abodes of human beings. Towns are erected in localities wholly unadapted for residences. They are constructed so as effectually to exclude the air, and often increase to so large a size as to be rendered, from that cause alone, most unhealthy.—The last portion of the address was devoted to the consideration of the means to be adopted for securing an efficient ventilation. The example set by nature ought to be followed; and the gentle changes produced by the wind should be as much as possible imitated. The great principle is to admit into rooms and houses a *large quantity of air at a moderate temperature* (60° to 65°); and that there should be an outlet for the vitiated air; the pure air to be admitted within 3 or 4 feet of the floor, and to be warmed by aid of the fire-place. The various plans for warming the fresh air were examined; and their errors were found to have been, that a small quantity was admitted through a narrow channel, and at a temperature much too high, so that its nature was deteriorated. The subject of warming abodes was also alluded to; and it was shown that, from the bad mode of construction of stoves and fire-places, and from improper materials being used, the smoke was not consumed, ventilation was rendered impossible, and the greater part of the heat dispersed up the chimney. Mr. Toynbee was happy to say that he had recently examined some plans about to be patented by a gentleman who had devoted a long life to the subject, and brought it to great chemical and practical knowledge—in which these evils would be remedied, and important advantages gained. In speaking of the means for insuring the egress of the vitiated air, it was stated that, as its temperature, on escaping from the mouth, is between 80° and 90°, it rises to the upper part of the room,—from which there should always be a means of escape. Dr. Arnott's valve had been generally used for this purpose; and thousands of people will be indebted to its use for their lives and health. If it were the custom of this country to erect statues in memory of those who, like Jenner, saved the lives of thousands of their fellow men, Dr. Arnott, in manifold ways, had earned for himself this distinction. A modification of Dr. Arnott's chimney-valve, by Daw, a working man, was alluded to and displayed,—having the advantage of always remaining open, unless voluntarily closed. Various suggestions were made, showing how plans of ventilation may be carried out; and Mr. Toynbee concluded by appealing to the architects to adopt efficient plans in the construction of buildings—by doing which, they would confer unbounded good upon the public, by the improvement of the public health.

Dr. Buckland and R. A. Slaney, Esq., a member of the Health of Towns Commission, offered some remarks on the ill effects arising from badly ventilated apartments, and from the effluvia escaping out of the gratings in the streets, which are connected with the sewers by means of a gas-light burning within lofty air shafts.

Models were exhibited by Mr. Stedall, of his patent Scolecothic Ventilator; adapted for the cure of smoky chimneys, and for the admission of fresh air into the engine-rooms and other confined parts of vessels.

SIR JOHN RENNIE'S CONVERSAZIONI.

The first of a series of four conversazioni held by Sir John Rennie, as President of the Institution of Civil Engineers, took place last month, and were very numerously attended by many noblemen, members of parliament, architects, artists, engineers and celebrated men of science. In the rooms were exhibited a large number of models and specimens of new manufactures, among the former were Mr. Maclean's proposed method for conveying Railway trains across the River Dee, by means of a platform travelling upon rails fixed on piles across the river.—A model of the President's design for the improvement of the Great Wash, in Lincolnshire, by which an area, almost equal to a new county, will be recovered from the sea; the model showed on one side the present state of the outfall, and on the other the embankments and works as they will appear when completed. —The St. Katherine's Point and Menai Lighthouses.—A model of Hallett's atmospheric railway.—Plans of Mr. G. Rennie's proposed harbour of refuge, at Dover.—Model's of Mr. R. Stephenson's long boiler engine, and the new Great Western engine.—Mr. Ricardo's instrument for showing the velocity of railway trains.

Mr. Rand's machine for making collapsible tubes excited a good deal of attention, as a skilful adaptation of a known property of tin, that when subject a high pressure it may be molded to any form without being melted. In the machine exhibited the pressure was about five tons. A flat capsule of tin being struck by a solid cylindrical punch sprung up, and embracing the punch closely, took the form of a perfect tin tube. These tubes are intended to hold some fluid substances (such as artist's colours), which it is difficult to extract from common bottles.

Specimens of wood carved by machinery, by Taylor, Williams, and Jordan, were exhibited. There was also a model of Mr. Oldham's machine for numbering and paging registers at the Bank of England.

The assembly rooms, which last year were built temporarily of wood, have this year been constructed more substantially, and were elegantly decorated in polychromic, by Sang. Suleiman Pacha was among the remarkable persons present.

FRENCH ARCHÆOLOGICAL CONGRESS.

At the annual meeting of the Congress, held at Metz, several subjects of great interest were proposed for discussion. The *Athenæum* gives the following list of questions:—Is it not possible to ascertain in churches of pointed architecture the numerical relation of the several portions, and a geometrical deduction of their architectonic forms?—Do not the ecclesiastical monuments of the Middle Ages prove the existence of an architectonic hierarchy, by which all cathedrals, and abbatial and parochial churches, and even private chapels, were severally built according to certain dispositions and dimensions?—Is not the pointed or *ogival* style better indicated by the presence of pinnacles than by pointed arches?—May we not trace the progress of the styles of Gothic architecture by the technical terms employed in architectural documents of different epochs?—What are the distinctive characters between the pointed styles of France and those of Germany? and is not the cathedral at Metz an example of transition between two varieties of that style?—Was there not in each of the dioceses of Metz, Trèves, Strasbourg, and Verdun, a special architectonic school? and if so, what were their distinctive characters?—What were the monuments which served as the prototypes of those churches with a choir at each end, so frequently met with in Germany?—If, as supposed, there was some absolute rule for building churches due east and west, how can we explain the numerous exceptions to such rule observable in Lorraine and about Metz?—What is the origin of the little gallery so commonly found on the outside of Germano-Romanesque churches?—In the architectonic decoration of Gothic churches, should not the disposition of their statuary be under the architect's control, and considered as an integral part of his original design?—What kind of pavement was employed in the civil and ecclesiastical edifices of the Middle Ages?—What were the innovations in castellated buildings brought into Western Europe after the first Crusades?—What is now the most expedient form of church-building, whether considered artistically or economically?—What is the most fitting style of decoration for churches in the pointed style of architecture?—In what cases may we venture to repair ancient monuments, and according to what general rules should such repairs be conducted?—In what proportion, and to what kind of edifices should be restricted the employment of coloured glass as church ornament?

RAILWAY GEOLOGY.

At the Geological Society, *May* 6, a communication was read: "On a disturbance in the Hastings sand and Weald clay, exhibited in a cutting on the Tunbridge Wells Railway," by Messrs. J. Prestwich, jun., and J. Morris. The principal object of the authors was to give an account of the upper beds of the Wealden series as seen on the northern side of the great Wealden elevation. It is known that sections in this part are very rare, and the sequence of the beds is somewhat obscure. In the direction along which the railway cutting is excavated the beds are repeated by a fault, and disturbed by a singular flexure, the existence of which was conjectured by Mr. Hopkins from the physical conditions of one of the lines of disturbance in the districts. The section near Tunbridge exhibits the lower part of the Wealden clay with the upper beds of Hastings sand, but does not extend to the lowest greensand. The uppermost beds seen consist of 30 feet of brownish laminated clay, to which succeed 20 feet of dark-coloured laminated clay and slate; the clay generally of dark bluish grey colour, and containing impure beds of limestone with various species of cypris, cyrena, and paludina. Other clays, and some light-coloured sandstones, which then appear, are afterwards succeeded by an important bed, in the upper part argillaceous and in the lower part sandy; and this again by a band of lignite. The fossils throughout are few, and chiefly confined to the upper beds.

REGISTER OF NEW PATENTS.

If additional information be required respecting any patent, it may be obtained at the office of this Journal.

ATMOSPHERIC PROPULSION.

John Reid Hill, of Upper Stamford-street, Lambeth, civil engineer, for "*certain Improvements in atmospheric propulsion, applicable to water as well as land carriages.* (A communication.)—Granted Oct. 2, 1845; Enrolled April 2, 1846. With an Engraving, see Plate XI.

The improvements relate—Firstly, to the mode of constructing pneumatic mains for the conveyance of goods and passengers by atmospheric propulsion, combined with the description of carriages and pistons herein described.

Secondly, to the removal of the air through the piston or piston-carriages of the mains, and also through the pistons of metallic cylinders, as now used, by means of tubes communicating with the external carriages through the openings of the longitudinal valve.

Thirdly, to giving motion to carriages, in the manner hereafter described, without the aid of a pneumatic main.

And Fourthly, to the mode of applying this power to the propulsion of passage-boats or other vessel on water, by placing the mains herein described on the banks of canals.

Fig. 1 Plate XI, is a transverse section of the main closed, with the piston-carriage, *c*, and air-tubes *f f*, for the removal of the air from the main, the apparatus for that purpose being attached to the piston-carriage. *g g*, the valves, or roof of the main, to be lined at the points where they close with soft leather, cloth, or other elastic material, attached to thin boards or other flexible materials, and covered, as indicated, with a flexible cap. *a a*, wood-paving, with iron edge-rails between the blocks, level with the surface. Fig. 2 is a transverse section, with the main open, and carriages passing through it. *h h*, steps for ascending to the roof or top of the carriage. *b*, dwarf walls. *c*, concrete foundations, or ballast. *d*, planking or sleepers. *e*, wall-plate and hinges. Fig. 3, longitudinal section. The piston carriage, in its practical application, is to be placed at a greater distance a-head of the first carriage of the train than is represented, as indicated by the break in the connecting-bar; a train of carriages for heavy goods may be continued from the piston to the passenger carriage, instead of this connecting-bar, if preferable. Fig. 4 is a ground-plan.

The engraving shows a main of sufficient width to admit of trains moving inside, each carriage is provided with rollers to throw open the upper sides; if the mains are not of sufficient size for that purpose, the carriage is to move inside, at a certain distance behind the piston, in order to throw open these valves by means of such horizontal wheels or rollers attached to the upper parts of the side of the carriage, which carriage should also serve to connect the trains to the piston when moving outside, or to connect barges on water, by such mains being laid on the bank of the canals, and this power substituted for horse-power for the purpose of towing such barges. The roof, or valves, are to be composed of a series of rafters, attached by axles or hinges to a wall plate bedded on the dwarf walls, and covered inside and outside with asphalted felt, or other flexible materials, rendered impervious to air and water, and of sufficient strength to resist the atmospheric pressure; a covering of india-rubber, or other impervious material, should likewise extend to the dwarf walls, in order to render the joints air-tight. A communication is also intended to be made between the roof of the carriages, thus represented, and the interior, by means of stairs, or a step-ladder, to enable passengers to ascend or descend as from the deck of a ship to the cabin. It is proposed, also, to convey goods and passengers by means of pistons moving on wheels, as thus described, and propelled by atmospheric pressure through close tunnels or galleries, somewhat similarly constructed, but with arched roofs, and the side-walls of greater elevation, in order to afford sufficient carriage room; and such tunnels or galleries may be illuminated by artificial lights when necessary, or by daylight through strong glass, and provided with doors in the sides for the admission of passengers, placed at any convenient distances, opening outwards, so constructed as to exclude the external air and resist the atmospheric pressure. It is likewise proposed to put carriages in motion by means of rapid currents of air thus driven through cylinders, traversing such carriages from front to rear, without the aid of a pneumatic main; the apparatus for such purpose being placed in such carriages, and the velocity with which such carriages can be moved will be in proportion to the amount of power applied to the area of the cylinders, and the rapidity with which the air is propelled through such cylinders or other channels, which should traverse these carriages from front to rear.

HILL'S PATENT PRINTING PRESS.

John Reed Hill, of Stamford-street.—Granted August 2, 1844; Enrolled September 2, 1845. (*See Engraving, Plate XI.*)

This is a very ingenious invention, by which, by means of hand labour, and without the aid of steam power, a hand printer is enabled to produce impressions with a rapidity far beyond anything that the hand-press, or any press not worked by steam, has hitherto produced. The simplicity of construction is also a great advantage, for it has neither tooth wheels, rack, or pinions for giving motion; neither has it the tapes for conveying the paper. A strong lad can work off from 1,200 to 1,500 impressions per hour with less labour and exertion than is required by the common hand-presses to work off 300 impression."

We are indebted to our contemporary the Mechanic's Magazine, for the following description.

A A are the side-standards of the machine; B B horizontal frame for support of type-table; C C type-table running on wheels or rollers; D, printing cylinder, revolving on horizontal axis; E E, inking rollers; F, distributing rollers; G ink trough and supplying roller; H treadle for foot motion; I fly-wheel for rendering the motion uniform; J grooved wheel for driving the machine; K K lever for throwing off the printed sheets; L receiver for sheets when printed; M register plate for receiving or "laying on" the sheets to be printed; N part of top of machine, forming a table when in use, but which is turned up to afford access to the type-table.

Motion is given to the machine by means of a treadle, which the pressman works with his foot, whilst his hands are employed in laying on the sheets; but this is an arrangement intended to be confined to presses for small work: in presses of larger dimensions it is proposed to use hand-wheels.

Originality cannot of course be claimed, either for producing the impressions by cylindrical pressure, or for the mode of working the cylinders, in both of which respects Mr. Hill's press differs in little, if anything, from the (now) common steam-press. The chief novelties in this press we conceive to be these; *first*, the peculiar arrangement for moving the type-table; and *second*, the apparatus for taking off the sheets when printed. In both of these respects the simplicity of construction and working efficiency of the machine are such as apparently leave nothing more in the shape of improvement to be desired.

The manner in which impressions are taken is as follows:—The form of types being fixed and made ready for printing, and motion being given to the wheel, the pressman connects the motion of the wheel to the axis of the printing cylinder by a sliding clutch; he then lays a sheet on the register-plate, with its front-edge and one of its ends in contact with a guide, and on the printing cylinder arriving at a certain position of its revolution the front edge of the sheet is secured to the cylinder by claws, which carry it round to meet the types and receive the impression. By the time the impression is completed, the cylinder has brought the front edge of the sheet within the claws of the removing arm, which claws then close, and secure the sheet; and simultaneously, beneath, the cylinder claws open and allows the sheet to pass from the cylinder by the removing claws, and to be deposited on a shelf ready for being removed by hand.

On the end of the cylinder spindle outside the frame, there is a crank-arm which pushes back the type-table after an impression has been taken, and on its arriving at its most backward position, the crank-arm quits its connection with the table, and a connection takes place between the end of the printing cylinder and the edge of the type-table, by which means a firm contact takes place between the two surfaces, which produces the forward motion of the tables and types to produce the impression.

The supply and distribution of ink are effected by the table and types running under the inking rollers in the ordinary manner of steam printing machines.

EXCAVATING MACHINE.

Moses Poole, of the Patent Bill Office, London, for "*Improvements in raising and transporting earth and other heavy bodies.*" A communication. Granted Nov. 18, 1845; Enrolled May 18, 1846. (*With an Engraving, see Plate XI.*)

This invention, for improvements in raising and transporting earth and other heavy bodies, consists in the application of certain mechanical arrangements or combination of parts for facilitating the removal of earth, stone, and other matters, when constructing or forming cuttings for railways, canals, and other similar works, which will be understood by the following description, reference being had to the drawing, which shows a section of the earthwork and side elevation of the apparatus forming the subject of this patent, and consists in the application of endless pitch-chains in the following manner:—*a a* is a framework of wood or other suitable material, forming an inclined rail or tram road, and supported by props or standards *b b b*, capable of being lengthened or shortened at pleasure. At the top and bottom of the incline there is a wheel *c c'*, round which is made to pass an endless chain *d d*. *e e* is also an endless chain passing round a wheel fixed on the axis of the wheel *c'*, and also round a wheel keyed upon an horizontal shaft *f*. *g* is a vertical shaft, which may be driven by a horse or other suitable power, and gives motion to the shaft *f* and pitch chains by means of a pair of bevil wheels. *h h* are the carts which are drawn up by means of the chain *d d*, which is provided with a number of hooks that take into an eye or link attached to the tail part of the cart. When the carts arrive at the top of the incline, they are allowed a little fall on to the horizontal rail, which, together with the velocity they have acquired in coming up, has the effect of liberating them from the hook. Fig. 2 is a back end view of one of the carts, showing the arrangement of levers for disconnecting the hind part of the cart, which is effected by pulling a string which passes over a small pulley and along the side to the front part of the cart.

SLUICE COCKS.

William Henry Waller, of Vauxhall Water Works, Upper Kennington-lane, Lambeth, in the county of Surrey, engineer, for "*improvements in sluice-cocks.*"—Granted October 31, 1845; Enrolled April 31, 1846.

The improvement consists in applying moveable bushes or facings to sluice-cocks, and in constructing them in such a manner that they shall be harder, fit more truly, and be more readily applied, and replaced when worn. Fig. 1, is a vertical section of the improved sluice cock; fig. 2, a vertical section, taken transversely to the last figure. A is the case of the cock, bored out at the points, and recesses, and the backs of the bushes *b b*, are turned in a lathe, so as to fit the recesses thus formed. The inventor prefers making the bushes of cast-iron, the working surfaces are chilled in the act of casting, and are ground with emery in a lathe. The bushes are coated on their backs with marine glue, or similar material, previously to introducing them into the cock; and after the bushes have been introduced into the cock, they are moved back in the recesses before mentioned, into a proper working position, by forcing down the valve *c*, into its place. The patentee does not confine himself to the particular shape here described, as that may be varied. *d* is a screw for raising and lowering the valve *e*; a screw-nut, *f*, formed on the interior of the upper part of the cock; and *g* corresponding ribs on the outer surface of the upper part of the valve; the ribs are to guide the valve in its movement up and down. The surfaces of the valve are chilled in the act of casting, and ground with

Fig. 1.

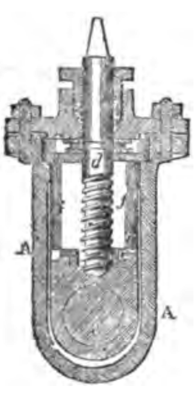


Fig. 2.

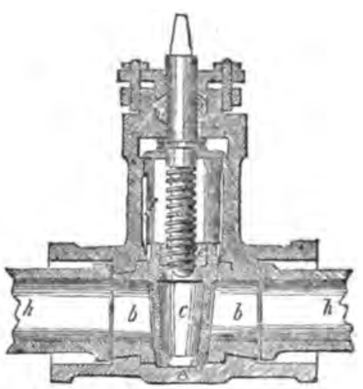


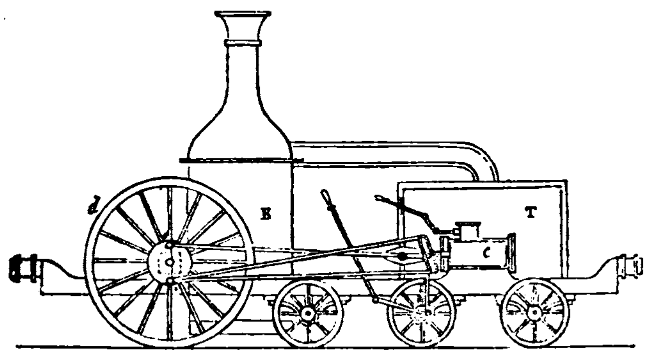
emery. *h h*, are portions of two pipes let into the sockets of the cock. For sluice-cocks without moveable bushes, the surface against which the valve works is to be chilled in the act of casting the body of the cock, so as to make it more durable; and afterwards ground true by a revolving tool and emery.

LOCOMOTIVE ENGINES.

Thomas Russell Crampton, of Southwark-square, London, engineer, for "*Improvements in locomotive engines and railways.*"—Granted Oct. 6, 1845; Enrolled April 6, 1846.

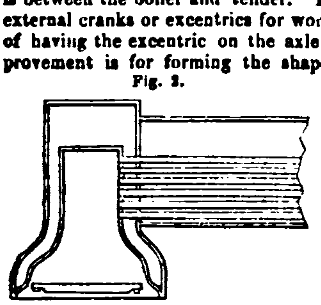
The first claim is for arranging a locomotive engine so as to include the tender on the same carriage or frame; this is effected as shown in fig. 1,

Fig. 1.



where B is an upright tubular boiler, supported on the same framing that carries the tender T with the coke and water; *c* the cylinder fixed on the side of the tender, and *d* the driving wheels; the stage for the engine driver is between the boiler and tender. The second improvement relates to using external cranks or excentrics for working the slides, as shown at *e e*, instead of having the excentric on the axle between the wheels. The third improvement is for forming the shape of the fire box, so as to increase the length of the tubes and the area of the fire grate, as shown in fig. 2. The fourth improvement or claim is for the combination of wooden rails with iron rails; the wooden rail is fixed on the outside of the ordinary iron rail, and the top is about one-fourth of an inch above the top of the iron by this arrangement the wheels of the locomotive engine may travel upon the wooden rail, and obtain greater adhesiveness, and the wheels of the carriages run upon the rails as at present.

Fig. 2.



ELECTRIC LIGHT.

Edward Augustin King, of Warwick-street, in the county of Middlesex, gentleman, for "*improvements in obtaining light by electricity.*" Being a communication. Granted November 4, 1845; Enrolled May 4, 1846.

This invention consists in the application of continuous metallic and carbon conductors (intensely heated by the passage of a current of electricity, to the purposes of illumination.

The metal to be used is that which, while it requires a very high temperature for its fusion, has only a slight affinity for oxygen, and offers a great resistance to the passage of an electric current. Platinum, though not so infusible as iridium, has but little affinity for oxygen, and offers a great resistance to the passage of the current, and as it is abundant and easily worked, appears to be preferable to any other metal. It should be reduced to very thin sheets known as leaf platinum, so thin that, on holding it before a printed page, the letters can be distinguished through it. A strip is to be cut from the platinum leaf of a width proportionate to the quantity of the current (which, with Grove's cells, having platinum plates three inches long and two inches wide, is about one-fourth of an inch), and of a length proportionate to the intensity (which, of course, varies with the number of cells); care being taken to cut the strip of an equal width throughout, and with a clean edge, as otherwise it will be unequally heated, and will be fused in one part before the other parts have attained a sufficiently high temperature to produce a brilliant light.

Fig. 1

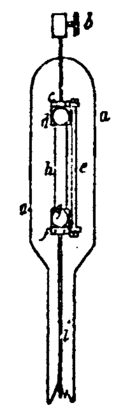


Fig. 2.

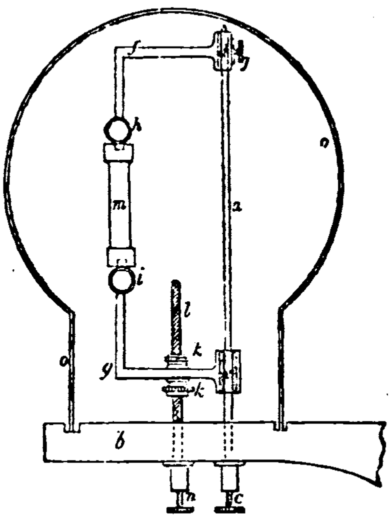

The strip of platinum is to be suspended between two forceps in the apparatus represented in vertical section at fig. 1, *a* is a square brass bar, fixed on the wooden stand *b*, and having a binding-screw *c*, at it lower end; upon this bar two sockets *d e*, slide, carrying the arms *f g*, which are terminated by broad forceps, tipped with platinum, and opened or closed by milled screws *h i*. The upper arm *f*, is fixed at the top of the bar *a*, by means of the screw *j*; and the position of the lower arm *g*, is adjusted by turning the nuts *k k*, upon the screwed rod *l*, which passes through the arm *g*: the socket *e*, of the arm *g*, is lined with ivory or other non-conducting substance, to prevent any metallic communication between that arm and the bar *a*. *m*, is the platinum leaf, which is held by the two forceps, and is included in the electric circuit by attaching one of the wires from the battery or other apparatus to the binding-screw *c*, at the bottom of the bar *a*, and the other wire to the binding screw *n*, at the bottom of the rod *l* The current should be one of considerable intensity, and the distance between the forceps should be sufficient to prevent the platinum from being fused. *o*, is a glass shade, which serves to screen the platinum from currents of air, dust, &c

When carbon is used, it becomes necessary, on account of the affinity this substance has for oxygen at a high temperature, to exclude air and moisture from it, which is best effected by inclosing it in a Torricellian vacuum. Fig. 2. is a vertical section of the apparatus employed for this purpose. *a*, is a glass tube, similar to those used for barometers, except that its upper end is enlarged into a cylindrical bulb, and a stout platinum wire sealed in at the top. The upper end of the wire is furnished with a binding screw *b*, and the lower end is screwed into the iron piece *c*, to which the forceps *d*, is attached; the piece *c*, is connected, by a porcelain rod *e*, with a similar piece *f*, that carries the forceps *g*; and the piece of carbon *h*, is held between the forceps *d*, and *g*;—*i*, is a copper wire, which is attached to the piece *f*, and extends to the bottom of the tube. The tube is filled with mercury in the same manner as a barometer (the air being carefully expelled, as usual); its length, independent of the bulb, should be about thirty inches, so that a vacuum will be formed in the bulb when the tube is inverted in a cup of mercury. The instrument is included in the electric circuit by connecting one of the wires from the battery or other apparatus with the binding-screw *b*, and the other with a wire which enters the mercury in the cup at the bottom of the tube. The circuit is thus completed by the column of mercury; and when it is depressed in the tube, by the formation of vapour of mercury in the bulb, the connection is preserved by the wire *i*. That form of carbon found in coal-gas retorts which have been long used, is well suited for the purposes of this invention, and may be worked into the form of small pencils or thin plates, by the aid of the saw and file. As carbon will bear a very high temperature without fusion or volatilization, it may be employed when a very intense light is required.

If an intermitting light be required, for light-houses or other purposes, it may be obtained by breaking the circuit at intervals by clock-work.

When the apparatus is suitably sealed, it may be applied to submarine lighting, and to the illumination of places where it is necessary to guard against the inflammation of highly combustible or explosive compounds, as in powder magazines, mines, &c. When the current is of sufficient intensity, two or more lights may be made in the same circuit; care being taken to regulate the power, by increasing or diminishing the number of armatures (if a magneto-electric machine be employed), or the number of cells (if a voltaic battery be used), so that the united resistance of the strips of platinum or carbon shall be sufficient to prevent the passage of such a quantity of electricity as would destroy them.

The patentee claims the application of continuous metallic and carbon conductors, intensely heated by the passage of a suitably regulated current of electricity, to the purposes of illumination, as above described.

SHIP PROPELLERS.

Thomas Samuel Parlour, of Park road, Holloway, in the county of Middlesex, gentleman, for "*improvements in propelling vessels.*"—Granted November 20, 1845; Enrolled May 20, 1846.

Fig. 1.

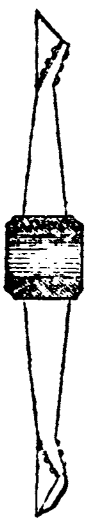

Fig. 2.

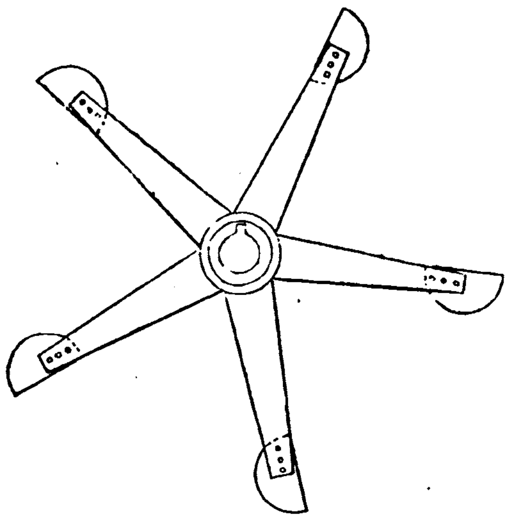

The improvements relate to the form of the propeller, fig. 1 is a side view, and fig. 2, a vertical section of the propeller. "The propeller is formed by taking a hollow cone, of sufficient thickness, and cutting it through the vertex at right angles to the plane of its base, so that the two parts may be equal; these are affixed to arms, as represented in the drawing; and these arms are affixed to a boss; which boss has a hole through it, for the purpose of securing it to the shaft. The number of half cones forming the propeller may vary. The angle also of the vertex of the cone may vary; but the most satisfactory results have hitherto been obtained by taking a half-cone, whose angle at the plane of the base was thirty-two degrees. By extending the surface of the half-cone, a greater propelling surface is obtained.

FIRE ENGINES.

John White, of Salford, Lancaster, engineer, for "*certain improvements in engines, machinery, or apparatus for raising and forcing water.*" Granted Nov. 27, 1845; Enrolled May 27, 1846.

This invention is for certain improvements in engines commonly called fire-engines, the object of the inventor being to construct such apparatus with a greater number of pumps of considerably less calibre than those hitherto employed. The mode of arranging the pumps according to this invention is shown at fig. 1, which represents a plan of a fire engine; *a a* is the edge of a circular tank or reservoir, from which the pumps are supplied. This tank is mounted upon wheels in the ordinary manner, to facilitate its removal from place to place; *b b* are force-pumps, twelve in number, each of which is worked with a separate handle *c*, moving upon a fulcrum or fixed axis at *c'*. In the drawing only one handle is shown, which is sufficient to explain the construction of the engine, as each of the pumps are worked in the same manner, namely with a separate handle or lever. The several pumps discharge their contents into the air-vessel *d*, which is fixed in the centre of the machine, and over the air-vessel there is fixed a platform for the firemen to stand upon. We have not thought it necessary to give a sectional elevation of the machine, as it will be evident that each of the pumps must be provided with two valves and a channel or passage leading to the air-vessel and are the same in construction as ordinary force pumps.

The advantages of a fire engine constructed as above are stated to be, that the engine can be worked before a sufficient quantity of men arrive, that is to say, it can be partially worked; another advantage is stated to be that it will be easy to detect those men who are not doing their duty; also, a greater pressure per square inch will be obtained upon the surface of the water; and lastly, the pumps may be worked alternately, whereby a more regular supply of water will be obtained.

Fig. 1.

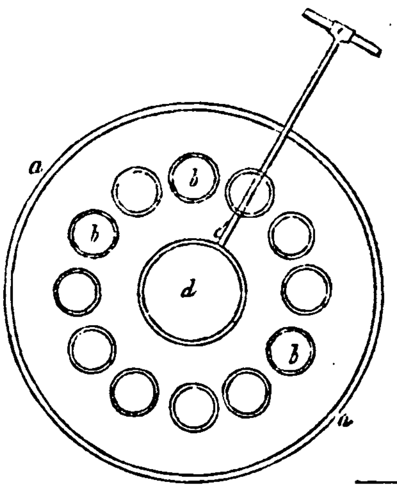

Fig. 2.

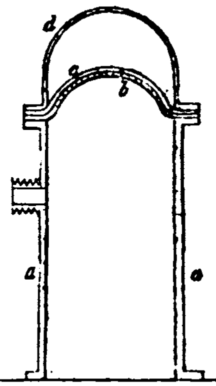
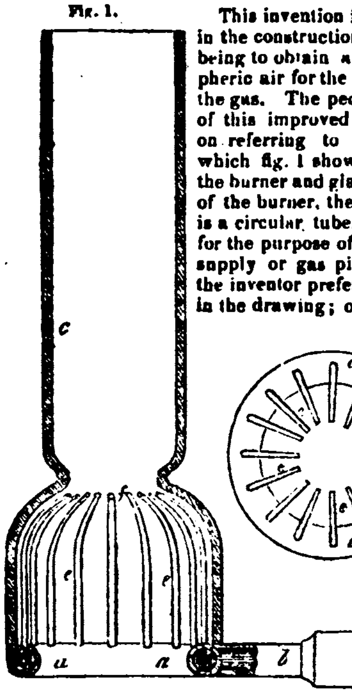


Another part of this invention consists in the construction of air-vessels for regulating the flow of water through the pipe. Fig. 2 shows a sectional elevation of one of these improved vessels, in which *a a* represents the vessel, on the top of which there is a perforated plate *b*, and on the top of this plate there is stretched a piece of vulcanized india-rubber *c*; *d* is an hemispherical vessel forming a cover to the whole, which are firmly bolted together; within this last vessel the inventor proposes to compress atmospheric air to about two atmospheres, or thirty pounds, which forms a resistance or elastic cushion for the water to press against. By this arrangement it will be seen that the water in the aforesaid vessel does not mix with the air; the consequence of which is, that the air cannot pass off from the vessel through the pipe and form the crackling noise which is so frequently heard when working engines of the ordinary construction, the air in the air-vessel being kept entirely distinct from the water.

GAS BURNERS.

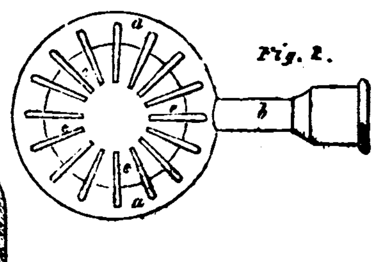
John Leslie, of Conduit-street, Hanover-square, tailor, for "*Improvements in the combustion of gas.*" Granted, Dec. 4, 1845; Enrolled, June 4, 1846.

Fig. 1.



This invention is for certain improvements in the construction of gas burners, the object being to obtain a greater supply of atmospheric air for the more perfect combustion of the gas. The peculiar form or construction of this improved burner will be clearly seen on referring to the annexed drawing, in which fig. 1 shows a sectional elevation of the burner and glass, and fig. 2 is a plan view of the burner, the glass being removed. *a a* is a circular tube, having a branch pipe *b* for the purpose of fixing the burner on the supply or gas pipe; *c* is the glass, which the inventor prefers to be of the form shown in the drawing; on the top side of the circular tube, *a a*, is fixed a number of small bent tubes *e e e*, through which the gas passes, the point of ignition being at *f*, just below the projecting or bent part of the glass, as shown in the drawing.

Fig. 2.

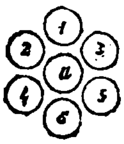


FILTERER.

Josiah Wilkinson, of Lincoln's Inn-fields, gent., for "*certain Improvements in filtering water and other fluids.*" A communication. Granted Dec. 8, 1845; Enrolled June 8, 1846.

This invention consists in a peculiar mode of arranging a series of perforated metal or wooden tubes filled with sponge, animal charcoal, sand, or other suitable material. The mode of constructing this improved filter is as follows:—Fig 1 shows a plan, and fig. 2 an elevation, of a series of

Fig. 1.



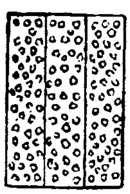


Fig. 2.

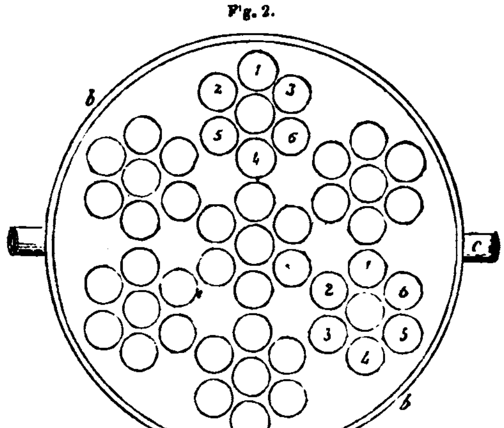


perforated metal or other tubes, arranged as shown in the plan, the centre tube *a* being perforated at those parts only which come in contact with the tubes marked 1, 2, 3, 4, 5, 6, so that a communication is formed between the latter tubes and the central one. Each of the tubes, 1, 2, 3, &c., the inventor proposes to fill with sponge, the tube *a* being filled with sand, charcoal, or other suitable filtering matter. Fig. 3 shows a plan of the interior of a filter when complete, which consists of an arrangement of seven groups or series of tubes, as above described, in all, forty-nine tubes, which are enclosed in an outer vessel or case *b b*, having a pipe *c*, leading from a vessel placed in an elevated position and containing the turbid water to be filtered, which, by the hydraulic pressure, is forced through the perforated vessels or tubes 1, 2, 3, 4, 5, 6, containing sponge, into each of the centre tubes, which latter are provided with a branch pipe, leading to an outlet pipe situate above the filter and in the centre thereof, which outlet is common to all. At the lower part of the vessel there is a pipe *d*, provided with a stop-cock, for the purpose of cleaning out the filter, which may be effected by stopping the outlet pipe, opening the stop-cock, and forcing water through it. The inventor, in conclusion, states that he does not confine himself to sponge as a substance to be used in filtering, but afterwards distinctly claims the mode of filtering by means of sponge. He also claims the mode of filtering be hydraulic pressure.

NOTES OF THE MONTH.

It is with extreme regret that we have to record the melancholy death of Mr. Benjamin Robert Haydon, the artist, which took place on Monday, the 22nd ult., at his residence, Burwood-place, Edgware-road. He contributed several valuable articles to this Journal, and to him we were indebted for the interesting extract from Sir Joshua Reynolds' Diary. Next month we will endeavour to collect some information respecting the life and works of this artist.

The *Augsburg Gazette* informs us that Cornelius has completed and exhibited at Rome his cartoon for the mausoleum of the royal family of Prussia. It is made the subject of the following piece of magniloquence—"The cartoon represents the four powers described in the Apocalypse, which are to appear at the end of the world. They ride through the air on horses that seem more intimately connected with them than the centaur with the animal of which he forms a part. In the van is a Tartar chieftain, who sends from his twanging bow-string, like unto Homer's Apollo, the shaft of Pestilence before him. Hunger follows. Corn is so dear that it must be weighed in the scales which he holds on high, while a figure to the left with horrid mimicry proclaims the high price to which all food has risen. Now follows War; a youth of exceeding beauty, swinging the bloody sword of battle above his head, with the united strength of both arms; and lastly comes Death, mowing down all that the others have left him. A chorus of the departed accompany the dreadful host with cries of woe, whose tones seem to sound from out the picture and become audible to the spiritual sense. The tone preserved in this part of the painting is, it is said, indescribably beautiful. Eleven figures, three of whom are children, represent the perishing human race. And yet in this group is contained a representation of all the horrors which the imagination of man can take in at a glance. In more than one figure we see the celebrated motive of Timanthes employed, who, in the sacrifice of Iphigenia, represented Agamemnon veiled. But what is not expressed by the gestures, by the figure of a youth who, amid the agonising struggles of death, covers his eyes with convulsively-closed hands! What name might be given to the suffering expressed on the countenances of the women, who, imploring mercy and pity, fling themselves on their knees before the mighty band! But above all is Anguish, represented with a wonderfully deep knowledge of the human soul in the two little children, invested as they are with a sublime beauty. The young too, the age of innocence, all is unsparingly swept away. Despair is foreign to such tender souls; but in the countenance of the man, who with clasped hands has fallen to the ground, we behold it in all its horror; and this figure forms the centre of the picture." From this description it may be concluded that the German school has exceeded even itself. Cornelius seems to have painted with a thousand horse power, and prepared a rich treat for the admirers of the "intense and convulsive."

A letter from Cairo (May 17), written by an intelligent traveller, informs us that the temple of Dendera had been completely cleared of all the rubbish with which it was encumbered, and was now to be seen as one of the most perfect of the Egyptian temples.

The architects at Hamburgh appear to have imbibed the taste for the chromatic style. Bülan, the architect, in his buildings, does not use stucco, but introduces ornamental bricks of different colours.

A fine mosaic pavement has been discovered in the church of St. Paul, at Nimes. It represents a warrior in his car driving his fiery coursers at full speed, with the body of a man fastened to the tail of the car, and is supposed to represent the triumph of Achilles.

The *Academie des Sciences* at Paris has elected M. Jacobi, of Berlin, one of its foreign members, to supply the loss occasioned by the death of the astronomer, Bessel.

Through the exertions of Sir Stratford Canning, England is likely to possess the treasures discovered by Mr. Austen Layard, at Nimroud. The *Times* gives us the following particulars of these antiquities:—"The discoveries of M. Botta, at Horsabad, are well known to the learned world. Those in which M. Layard is now engaged at Nimroud promise to be much more interesting and extensive. The mound is eight or ten times larger than that which was excavated by the French. It contains the remains of a palace, a part of which, like that at Horsabad, appears to have been burnt. There is a vast series of chambers, all built with marble, and covered with sculptures and inscriptions. The inscriptions are in the cuneiform character, of the class usually termed Babylonian. It is possible that this edifice was built at an epoch prior to the overthrow of the Assyrian empire by the Medes and Babylonians under Cyaxares,—but whether under the first or second Assyrian dynasty is doubtful. Many of the sculptures discovered by Mr. Layard are, even in the smallest details, as sharp and fresh as though they had been chiselled yesterday. Amongst them is a pair of winged lions with human heads, which are about twelve feet high. They form the entrance to a temple. The execution of these two figures is admirable, and gives the highest idea of the knowledge and civilization of the Assyrians. There are many monsters of this kind, lions and bulls. The other reliefs consist of various divinities; some with eagles' heads,—others entirely human, but winged,—with battle-pieces and sieges, as at Horsabad."

A letter from Alexandria states that the barrage of the Nile is proceeding with great vigour, and the men are made to work both night and day in order to take every possible advantage of the present low state of the water. The Pasha's frigates are employed in bringing cargoes of timber from the coast of Caramania; these are immediately squared and sent up to the site of the barrage with all possible speed. 15,000 men, comprising soldiers and country people, are at present employed at the barrage, and, owing to the great fatigue and privations of these poor people, the deaths are very numerous.

The Cathedral of Durham is now undergoing various repairs and restorations. Among other sacred edifices that have suffered by the hand of the despoiler, this venerable cathedral has not been exempt, and any one who visited it a few years ago must have been greatly offended at the disfigurements which would meet his view at almost every step. For some time the Dean and Chapter have devoted themselves to the task of restoring the interior to something like its original beauty. A highly valuable and important restoration is being made in the Chapter-house. When in its original state, the Chapter-house of Durham was justly described as the finest in the kingdom. It was built by Bishop Rufus, 1133-43, and the only subsequent additions were some buttresses at the end, a large perpendicular window above the doorway, formerly full of stained glass and tracery, with stained glass in the east window. Its whole length was 77 feet, width 34 feet 11 inches, and the height at the western arch of the groining 45 feet. The east end was of a semi-circular form, and when in its original state, with its fine columnar work and beautiful tracery, must have been an object of great interest.

On removing the oak stalls from the chancel of St. Mary's church, Nottingham, preparatory to repairing the roof, a sculptured tablet of marble was discovered, buried with its face downwards, which probably has been lying there since the Reformation. It is said to be a spirited and well-executed *bas relief*, consisting of eight figures, and represents the Pope seated on a canopied and elevated throne, consecrating a bishop. Beside the Pope are two cardinals wearing their hats. The bishop is attended by his apparitor, bearing the crozier, and three other attendant figures evaplete the group. The tablet is above two feet in height and one in width, and has been curiously painted and illuminated, the traces of colour being still visible.

Laboratories of the Royal College of Chemistry.—On the 16th of June the first stone of these buildings was laid by Prince Albert on the north side of Hanover-square. The show front of the structure will appear in Oxford-street, and will combine the usual absurdities of modern debased architecture—a rusticated basement and columns hoisted to the first floor. Really there are so many instances of columns thus elevated out of their places, that it is surprising that architects do not now and then, for the sake of mere novelty *alone*, and irrespectively of all sense of propriety, exhibit designs with the columns in their right places.

St. John's Gate, Clerkenwell.—The restoration of this ancient monument is commenced; the owners have consented to case the building with stone and cover the roof with lead. The restitution of the decorative parts is to be effected by public subscription.

Botanic Gardens at Cambridge.—A proposition to levy a small tax on the members of the University, to raise a sum for forming the new Botanic Gardens, has been rejected by the senate.

Booksellers' Provident Institution.—The "Retreat" of the aged and destitute belonging to this institution is progressing; the first portion of the building is nearly finished.

The new College at Galway.—The design selected by the Board of Trade is stated to be that of a magnificent edifice in the style of Henry the Eight's time

Scott's Monument in Edinburgh.—Mr. Steel's colossal statue of Sir Walter Scott will, it is expected, be erected in its place in the monument in Princes-street on the anniversary of Scott's birthday—the 15th of August. In England we have an invariable rule of elevating honorary statues *out of* sight: we trust that our northern neighbours will not disregard this sage and venerable custom.

Victoria Fountain at Brighton.—A new fountain has been erected on the Steyne at a cost of £1000. The design is apparently very unsatisfactory. It has the appearance of being designed by an upholsterer, it is deficient of solidity, and looks as if it were made of zinc or tin bronzed over.

The Brighton and Chichester Railway is now open. The drawbridge over the Arun, described at length in a former number of this Journal, acts quite successfully.

Conversion of the Regent's Canal into a Railway is abandoned, the required amount of capital not having been subscribed.

The Eastern Union Railway is opened. The fares between London and Ipswich are 15s., 10s., and 5s. 8d.

A long-boiler engine of Mr. Stephenson's construction lately ran from Birmingham to Wolverton, 52½ miles, in 70 minutes, drawing 100 tons of goods. At Ackemon bridge, the funnel of the engine was struck down, it being six inches higher than the arch.

FOREIGN NOTES.

Embankment of the bed of the Adige in Tyrol.—The floods of this river have of late caused such damage in the south of the Tyrol, that its embankment has been decided upon—the more important, as its valley is one of the connecting links between Italy and Germany. The court councillor Dassetti has just completed his report, which is accompanied by an instructive lithographed map of the valley of the Adige, from Meran to Boschetta. After the completion of the cut at Ischia Peratti, another more expensive will be commenced at Ischia Lidoruo. The plans for damming up the Noce, one of the most impetuous and mischievous Alpine torrents, are also to be commenced. The expenses will be very great—but only apparently so, as, by the regulation of this mighty Alpine stream, 8,800,000 square klafter (cubits) of boggy land will be restored to its pristine fertility, an equal area preserved from the destroying influence of floods, and the air improved for about 50,000 people, who have, hitherto, constantly suffered from fevers and other diseases inherent in damp localities.

Public Baths on the Continent.—These are now being established very extensively in almost every town. At Amsterdam a huge swimming basin has been laid out on the Y.; at Paris the old established and extensive salle de natation de l'ile St. Louis has been much improved.

General Canal constructions in France.—Never before has any legislative session been taken up by so many subjects relating to constructions, for the improvement of the working classes, &c. The following is extracted from the *Journal des Travaux Publics*,—"The original plan for the maritime canal of Caen is still carried out with energy; 2,800,000 francs have been alone expended in the erection of one of the four walls of the basin, a new bed for the Orme 2,700 mètres long, and the two yettier of Oysterham. Some angry observations have been made on account of the opening of the Orme having cost 800,000 francs, while the original estimates amounted only to 280 000. 1,200,000 francs have been voted for improving the navigation of the Vilaine in the environs of Rennes, comprising earthwork, excavations, aqueducts, bridges, &c. Now a credit of 15,000,000 francs is asked for the completing of the branch canal to the Garonne, between Toulouse and Casteris." The allusions made by M. Adolphe Beaumont to English canals, in the Chamber of Deputies, are not without interest. "In England," said he, "canals give way to railroads. I have spoken in London of our proposed canals, but no one would believe me. The canal from London to Birmingham, which yields 4 per ct. is merely an adventitious exception, because their has sprung up on its banks manufactories, which are its main support. The only remedy against the monopoly of railroads are the railroads themselves. The expense of 15,000,000 of francs for a canal at the present time is an anachronism."

Submarine Vessel.—Some experiments have been, of late, made with a boat constructed after the plan of Dr. Payerne, and called by him *bateaû cloche* (bell-ship). It is made of iron, and to be seen near the Pont Royal at Paris, where it is now moored. On its last experimental trip, eleven persons were on board, and the craft passed (invisibly to the public) through the space between the Pont Royal and that of La Concorde. None of the passengers felt the least inconvenience, although there was a sort of telegraph established for communicating with those above water.

Completion of E. Gerhard's work on Ancient Sculptures hitherto unpublished.—This work, which was formed after those of Winkelman's "Monumenti Inediti," and that of Zoega, has, at length, reached its concluding parts, not without many a sacrifice on the part of the author and publisher. The plates are folio lithographs, the letter-press royal 8vo. They contain a rich harvest of sculptures collected by M. Gerhard in his many peregrinations through Italy. The publication extended over the period from 1828 to 1844. M. Gerhard was one of the contributors to the splendid work on Ancient Rome, in which Chevalier Bunsen also took a share.

Supply of Water to the City of Madrid.—This metropolis is very scantily supplied with water, which the poorer classes have to purchase. An extensive contract (*subasta*) has just been entered upon for supplying it with water for drink and irrigation. The contractor has to furnish the town with 10,000 reals of water (the standard Spanish measure), which is to be available even to the highest parts. The adjudication amounts to the great sum of 71½ millions of reals, and the works are to be completed within the term of two years. If we compare this projected supply with the present which is only 500 reals, it may be easily imagined what a boon will be conferred on the comfort and healthfulness of the humble classes.

The New Post-office of Hamburgh.—The judicious grandeur with which every part of the destroyed city, especially its public edifices, are re-constructed, becomes every day more conspicuous. The Post-office, which combines the *locale* of four especial post departments, erecting after the designs of M. Charles Teauneuf, has next the street a length of 275 feet by a depth of 87 feet, including the courts 27 feet broad. The front is faced with sandstone and ornamented with cornices; has a height of 65 feet above the pavement; the roofs will be covered with thick lead plates. On the east side of the edifice will be erected the new telegraph tower, 150 feet above the pavement, or 169 feet above the average height of the Elbe, not including the signal staff. Immediately below the roof will be the observation room, of an octagon form with a window at each end. The building will include the dwelling of the Director, printing and other offices. The clock will be at an elevation of 150 feet, lighted in the night by a Bude light: each of the two dials will be of the diameter of 6½ feet. All the rooms in the lower story of the Post-office will be vaulted. Besides spacious halls for the public, there will be a general room for those who wish to read their letters. The building will be in some parts three, in other four, stories high, and contain altogether 110 rooms. The paving along the main front will be 17 feet wide.

New Galvanic Telegraph.—German journals speak of a new discovery of M. Leonhard, watchmaker, at Berlin, relating to the above subject. At present, it has been only executed between Berlin and Potsdam, but it is to be prolonged successively to Brandenburg and Magdeburg. The outer form of the machine is simply that of a writing desk; on these, two dials are to be seen. A hand indicates the letter or sign which has been made at the other station. Both machines are connected by metal wire chains, and have been hitherto placed on wooden blocks, but will hereafter be conducted under ground. M. Leonhard is also said to have discovered a new system of railway telegraphs.

The great Danube Docks at Alt-Ofen executed by English Engineers.—The extent of the Danube Steam Navigation Company is such, that they possess at present thirty-seven boats for passengers, and two barges for the conveyance of goods, both combined of 3,926 horse-power. The docks of Alt-Ofen, since they have been under the direction of M. Massjohn, who studied in England, have assumed the shape of a real manufacturing colony. Since 1844 alone, there have been built at this place ten boats of 1306 horse-power. Thirty iron barges, each of the burthen of 5,000 cwt., are in preparation or nearly ready, besides four iron coal barges, and eight for merely conveying pigs and other cattle, one gun-boat for the Austrian government, and twenty moveable piers with the boats appertaining thereto. The establishment is now in a position to manufacture in its own workshop all the requisite parts of a steam boat of from 200 to 250 horse-power, and even all the tools for ship construction, which hitherto they were obliged to obtain from England. The greatest part of the hitherto wooden building has been replaced by M. Massjohn by fire proof structures, and boats and machinery have been much improved. The passenger boats now ascend the Danube from Pesth to Vienna in 18 hours, and from Vienna to Linz in 17 hours,—a considerable saving on former voyages. Boats of 4,000 to 5,000 cwt. burthen do not draw more than 4 feet water, and can, therefore, safely pass over the sand shoals, which formerly much impeded the navigation of this river. M. Massjohn has also established a superior mode of discipline and order amongst the 1,200 men who constantly work at these docks. Still, the Austrian railroads consume a great quantity of iron, which has had the effect, that the above number of steamboats is only half of what would have been otherwise made.

Lately, the dykes around the docks have been heightened for protecting them against the floods, &c. Besides M. Massjohn, both the shipbuilders and chief machinist, Messrs. Pretious and Bissacker are Englishmen.

Supply of Water to the City of Lyons.—It is an inconceivable anomaly that Lyons, situated between two rivers, should have been, hitherto, entirely deficient of an adequate supply of water for its numerous manufacturing and working population. After many sham proposals of projectors and contractors, the Town Council are about to take the subject in their own hands, beginning with a complete canalization of the city, and execute the works on a grand scale, letting the public reap the profit of the undertaking.

Inauguration of French Railways.—The present season is, without doubt, the most important for the many new lines which have been opened in France. On the 8th of June took place that between Paris and Sceaux, a short line, it is true, but one on which the system *Arnoux* has been first tried with sucess. The Great North Line (Lille) has also been opened with great festivities.

Embellishments of Paris.—The great work of a general paving of the Boulevards are nearly completed. The next will be the approach to the bridge de la Concorde and the levelling of the earth which is now in work. The paving of the Place du Carousel will be completely remodelled in a very short time.

Deepest Artesian Well in Europe.—In the Duchy of Luxembourg, a well is being sunk, the depth of which surpasses all others of the kind. Its present depth is 2,336 feet, nearly 984 feet more than that of la Grenelle, near Paris. It is said, that this immense work has been undertaken for working a large stratum of rock salt.

EMBANKMENTS.

Sir—Having been a subscriber to your valuable Journal from its commencement, I have read with considerable interest and profit several of the communications and papers therein. I am at present in search of information respecting the construction of embankments for reservoirs or water dams, in the formation of which there is little or no material to work upon excepting peat or bog earth, and a small portion of clay, with stones sufficient for the formation of 14 inches of breastwork.

I observe in your Journal, vol. 5, page 26, that at a meeting of the Institution of Civil Engineers, on the 29th June, there was read a paper containing a "Description of the Bann Reservoirs, County Down, Ireland," by John Frederick Bateman, M. Inst. C.E.; and also in your Journal, vol 6, page 426, that at a meeting held on the 13th June, a paper was read "On the Formation of Embankments for Reservoirs to retain Water," by Robert Thom, M. Inst. C.E.

I should feel much obliged by your informing me, in your next number, whether either of the above mentioned papers have been published in a separate form, and by whom, or how I can procure a larger knowledge of their contents than is given in your Journal.

Should you have any knowledge of any other treatise on the subject of Water Dams, or can give me any reference to any parties practically acquainted with the subject, I shall esteem it a favour if you will refer me thereto.

I am, Sir, your most obedient servant,

J. B.

Middleton, in Teesdale, June 5, 1846.

The abstracts of Mr. Bateman's paper, and that by Mr. Thom, given in this Journal, contained the whole of the information afforded by the original. No fuller accounts have been published. If our correspondent will send us full particulars of the dimensions and form of his reservoir, we will tell him the pressure the sides will have to resist.

LIST OF NEW PATENTS.

(From Messrs. Robertson's List.)

GRANTED IN ENGLAND FROM MAY 26, 1846, TO JUNE 24, 1846.

Six Months allowed for Enrolment, unless otherwise expressed.

Nathan Defries, of Saint Martin's-lane, engineer, for "Improvements in gas meters."—Sealed May 27.

John Hyde, of Manchester, engineer, for "certain Improvements in looms and apparatus, connected with looms for weaving."—May 27.

Charles Heard de Boissimon, of Leicester-place, in the county of Middlesex, merchant, for "Improvements in manufacturing corks and bungs." (A communication.)—May 27.

John Aston, of Birmingham, for "Improvements in buttons and in ornaments for dress."—May 27.

Alexander Southwood Stocker, of Camden road-villas, gentleman, for "Improvements in the manufacture of bottles and other similar vessels, also in stopping and covering the same, and in the manufacture and application to the whole or part of the articles to be used."—May 27.

John Blyth, of St. Anne, Limehouse, engineer, for "an Improved mode of closing the orifices of bottles or other vessels applicable to inkholders."—May 28.

Richard Marvin, of Portsea, Southampton, gentleman, and William Henry Moore, of Southsea, in the same county, gentleman, for "Improvements in gratings of metal or wood for the fronts of houses and general purposes for the admission of light and ventilation."—May 28.

Henry Seymour Westmacott, of John street, Bedford-row, gentleman, for "an Improvement in the construction of rotatory steam engines."—May 30.

Moses Poole, of the Bill Office, gentleman, for "Improvements in making fabrics from fibrous materials." (A communication.)—June 2.

William Carter Stafford Percy, of Manchester, upholder, for "certain Improvements in the manufacture of bricks, tiles, chimney pots, and other similar articles."—June 2.

Henry Lawrence Tobias Tschudy Von Uster, of the College for Civil Engineers, Putney, for "Improvements in apparatus or machinery for measuring and indicating the distance travelled by wheel carriages."—June 2.

John Webster Cochran, of Paris, engineer, for "certain Improvements in machinery for cutting and shaping wood for ship-building and other purposes."—June 2.

William Stubbs, and John Isaiah Grylls, both of Llanelly, South Wales, engineers, for "Improvements in locomotive and other engines and carriages."—June 2.

Joseph Clinton Robertson, of Fleet street, London, civil engineer, for "certain Improvements in railways and railway carriages." (A communication.)—June 4.

George Lowe, of Finsbury-circus, civil engineer, of an extension of a patent for the term of five years, from the 8th June, 1848, for increasing the illuminating power of such coal gas as is usually produced in gas works, also for converting the refuse products from the manufacture of coal gas into an article of commerce not heretofore produced therefrom, and also of a new mode of conducting the process of condensation in the manufacture of gas for illumination."—June 4.

John Taylor, of Carlisle, miller, for "certain Improvements in flour mills, and in machinery connected therewith."—June 6.

Robert Rettie, of Glasgow, civil engineer, for "certain Improvements in the manufacture of fuel, parts of which improvements are applicable for the purposes of purifying, compressing, or extracting vegetable and other substances, and fluids, and in the machinery or apparatus to be used for the same."—June 12.

Edward Cottam, of St. John's-wood, for "Improvements in bedsteads."—June 16.

Frederic Handell Burkinyoung, of Baker street, Middlesex, gentleman, for "Improvements in piano fortes."—June 16.

Benjamin Fothergill, of Manchester, machine-maker, and Richard Johnson, of Clitheroe, in the same county, cotton-spinner, for improvements in certain parts of machinery used in the preparation for spinning, and in the spinning and doubling of cotton, wool, and other fibrous substances."—June 16.

Robert Reyburn, of Brown-street, Glasgow, chemist, for "Improvements in making extracts from animal and vegetable substances."—June 17.

William Cormack, of Thames-street, Greenwich, chemist, for "Improvements in obtaining motive power."—June 17.

Alfred Richard Johnson, of the firm of Messrs. Johnson and Co., of Regent-street, and Messrs. Griffiths and Johnson, of Old Bond-street, hatters, for "certain Improvements in hats, caps, and bonnets"—June 18.

John Simson, of Riches court, Lime-street, merchant, for "certain Improvements in machinery for preparing and spinning flax, and other fibrous materials."—June 20.

Henry Austin and Thomas Webster Rammell, of 10, Walbrook, City, civil engineer, for "Improvements in wood, mosaic, and tessellated work."—June 22.

Spencer Thomas Garrett, of Cliff-bank Lodge, Stoke-upon-Trent, Esq., for "certain Improvements in cements, bricks, tiles, quarries, slabs, and artificial stones."—June 22.

Bennet Woodcroft, of Manchester, consulting engineer, for "an Improved mode of printing certain colours in calico and other fabrics."—June 22.

Thomas Walker, of Birmingham, stove-maker, for "Improvements in ships'-logs and in sounding machines."—June 22.

John Mercer, of Oakenshaw, chemist, and John Greenwood, of Church, in the same county chemist, for "certain Improvements in dyeing and printing Turkey red, and other colours."—June 22.

William Mathers Hall, of Leeds, brass-founder, for "a certain improvement, or certain improvements in, and applicable to sliding gas pendants, lamps, lustres, and chandeliers."—June 22.

Joseph Renshaw, of Salford, Lancashire, mechanic, for "certain Improvements in machinery, or apparatus, for finishing velvets and other piled goods or fabrics."—June 22.

William Cotton, of Loughborough, manufacturer, for "certain Improvements in knitting machinery."—June 22.

John Gillett, of Brailes, Warwick, agricultural implement maker, for "an Improved apparatus for protecting property by sounding alarums, or giving signals."—

Joseph George, of Chelsea, Middlesex, coal and twine master, for "Improvements in the construction of houses, buildings, and other erections."—June 22.

Thomas Jones, of Salford, Lancaster, machine-maker, for "certain Improvements in machinery or apparatus for preparing, slubbing, and roving cotton, wool, and other fibrous materials."—June 22.

William Topling Nesham, of the London Docks, engineer, for "certain Improvements in the apparatus and mode of applying power for raising and lowering weights or heavy bodies."—June 22.

Ambrose Lord, of Allerton, Cheshire, toll-collector, for "certain Improvements in furnaces and the flues of steam-boilers, for the purposes of consuming the smoke and economising the fuel."—June 24.

CORRESPONDENTS.

J. M.—The abstracts of the proceedings of the Institution of Civil Engineers which appear in the weekly periodicals are generally of too popular a character to be of much value to the professional engineer. By the courtesy of the Institution we have been hitherto supplied with an official account of the proceedings, but owing to some unexplained delay, the publication of the papers of the present Session has not yet been commenced and consequently we are deprived of our usual source of information. It is really of no use in a work making any pretensions to philosophical accuracy to give any but *authentic* reports. For example, a long paper has recently been read at the Institution, by Mr. W. Harding, on resistances to Railway Trains. The only part of his conclusions which *is at all new*, is what he calls "resistance from concussion;" we therefore naturally wished to confine our attention to this part of his paper, but on turning to the reports in the weekly publications, we can find neither an explanation of what is meant by the phrase "resistance from concussion," nor any account of the reasons for adopting the expression "$\frac{1}{2}$ V" as the measure of this resistance.

A Working Mechanic, and J. B. will be answered next month.

THE FUTURE DEVELOPMENT OF MEDIÆVAL ARCHITECTURE.

Modern ecclesiology is the revived study of a neglected branch of human knowledge; and like all similar revivals compensates for previous neglect by present enthusiasm. It is by no means an uncommon occurrence in the history of literature and art that a zeal for reproduction and servile imitation should suddenly spring up which threatens, at first, to destroy not only all hope, but even all desire of originality.

These indications, so prejudicial to the true interests of art are however transitory—at least they have always hitherto proved so, as far as we are acquainted with intellectual history, and we may safely hope that they will be so with respect to the modern study of Mediæval architecture. While the first impulse and freshness of the novel pursuit lasts, all attempt to gain a characteristic individuality is sacrificed to an unthinking and undiscriminating admiration of the ancient models; but after a while the votaries of the new science become weary (and perhaps a little ashamed) of being mere copyists, they find for the first time that all the features of their idol are not admirable alike, that some parts are far more worthy of study than others, and then finally, if they themselves possess creative power, adopt those parts, not as patterns, but as so many hints—way-marks, as it were—of the direction in which their own genius may most successfully pursue its course. Just in the same way—the greatest orators, writers, sculptors, and painters have been content to be for a time disciples of ancient masters, in order that they might form their own style on the classical models, of which their creative genius forbad them from copying the actual ideas or modes of expression.

In accordance with these considerations it becomes a matter of great practical importance to ascertain exactly the degree and nature of the admiration with which we should regard Mediæval art, to discriminate between its merits and defects, and above all to determine which of its numerous varieties or styles are most worthy of being studied with a view to further development. We by no means claim the merit of originating this investigation, it has already been pursued to a considerable extent by others, although the conclusions at which they have arrived are extremely various.

One class of writers, who represent a considerable portion of the English students of Mediæval architecture, recommend the exclusive adoption of the second great style of Pointed Architecture, commonly known as the Decorated, which, to use their own peculiar mode of expression, "is the style of Pointed Architecture which we consider to have the most nearly approached perfection, or, as we should more truly say, the furthest departed from imperfection. It was but an approach, and but for an instant, it just unveiled to men a distant glimpse of heavenly things and dazzled his [their] poor eyes with that imperfect vision." Another class of writers describe Perpendicular as the most perfect style of Pointed Architecture, but recommend Romanesque for exclusive adoption in building new churches, as being the most suitable for modern purposes.

These contending opinions represent, we believe, with tolerable accuracy the respective views of two bodies who have rendered themselves celebrated by the zeal with which they pursue the study of church architecture—the Oxford Architectural Society, and the Cambridge Camden or Ecclesiological Society; and seeing, as it is impossible not to see, that these two bodies have promulgated, among much which is inconsistent, and much which is controvertible, a large mass of sound and valuable information respecting Pointed architecture, it is useless to treat their opinions with indifference.

We are very anxious to contribute to the attainment of a sound conclusion as to which of the styles of Mediæval architecture should be preferred, but in stating the views and arguments of the two Academical bodies mentioned, we are met by this difficulty, that the discussion has been made to assume a theological character, which renders it in a great measure unsuitable for these pages. The advocates of one or other of the various styles of Mediæval architecture do not rest the claims of either merely on its intrinsic beauty or constructive value, but chiefly on its typical reference, or supposed reference to religious doctrines. For the completeness of our argument it will be necessary to allude in general terms to the latter class of arguments, and show that even if we allow to them the weight given by their authors, they are still so nearly balanced as to leave the main question unaffected.

It is indisputable that during the middle ages there was a tendency to establish resemblances between material forms and abstract ideas. This tendency may probably have arisen from the prevalence of monastic institutions; for in the vacuity of thought unavoidable in a state of monotonous seclusion, the mind must either be occupied by some fanciful unreal employments, or become enfeebled by pure inaction. (And it may be remarked in passing that this consideration is a reasonable explanation of the fact that symbolic speculations are in our times most rife among academical and cathedral bodies, wherein the manner of life most nearly resembles ancient monachism.) These speculations were anciently applied to all the sciences—chemistry was neglected for alchemy, astronomy for astrology. The study of botany became a mere collection of comparisons between flowers and church festivals—the snow-drop and Candlemas, the daffodil and the Annunciation, the ranunculus and the Invention of the Cross, the white lily and the Visitation of our Lady, &c., the passion flower being however the favourite subject of this species of mental indulgence. To the same source must be attributed the cabalastic interpretation of mysterious numbers, and lines on the human hand, the black art and the whole cycle of occult sciences. The whole material and intellectual world were arranged in a universal system of type and antitype; and all things visible were supposed capable of a recondite symbolic interpretation. The Germans in modern times have somewhat refined on this method of double-signification by their system of exoteric and esoteric ideas, that is, in simple English—the system of saying one thing and meaning another.

It is easy to suppose that in the Mediæval times the love of symbolism would be frequently exhibited in architecture, and as a matter of fact there is no doubt that it frequently was so exhibited. For to what other cause can we assign the cruciformity of churches, the position of the font near the entrance, and orientation or the position of the chancel at the eastern end? Occasionally the symbolism seems to have been carried into minute particulars, and affords a curious reflex of the mind of the architect, for it is generally observable that where these indications of trivial resemblances exist, the architecture is of a feeble character, and does not exhibit that boldness and vigour of conception which belong to a vigorous masculine intellect.

But that symbolism of every kind, whether minute or general, depended on the individual caprice of the architect, and not upon any accepted law of church architecture, is evident from the partial manner in which it is exhibited. Taking all Christendom through, the number of churches with cross transepts is far exceeded by those of which the plan is rectangular or irregular. In the same way the orientation has been as frequently disregarded as observed; in continental churches especially, the disregard of orientation was so great that in one church the chancel is sometimes nearly opposite in direction to the chancel in a neighbouring church. Of the position of fonts it is not so easy to speak, because, being moved with tolerable facility, they have been frequently displaced from their original situation. Another architectural form, which has been supposed to bear an obvious symbolic meaning, the eastern triplet window, is by no means of universal occurrence: in every successive style of church architecture there are numerous examples of other kinds of windows at the east end of the church. And it is important to observe also that the Mediæval architects were by no means jealous of restricting to ecclesiastical uses the forms which are capable of a symbolic interpretation, for the triplet window is commonly found in edifices constructed for secular purposes.

That the general affectation of analogies and fanciful conceits which prevailed in the middle ages should be occasionally displayed in architecture was naturally to be expected—that it should be universally displayed was practically impossible. And this reason, if no other existed, would have sufficed to prevent symbolism becoming a positive law of church building. If for instance it had been determined that one essential requisite in the construction of a church was that the plan of the building should typify the doctrine of the Cross, if this kind of teaching were considered a religious necessity, then it is evident that a church without transepts must exhibit some other kind of teaching, that it must inculcate a heresy, and that the worshippers in it must be heretics. It would however be frequently necessary to build churches where it was physically impossible that the plan should be cruciform. This necessity alone would prevent symbolism from assuming the sanction of universal custom; for it is to be observed, greatly to the credit of the Mediæval architects, that they never sacrificed real palpable advantages for the gratification of their speculative prejudices—that their minds constantly exhibited a practical tendency entirely unknown to or unappreciated by those who now ape their idiosyncrasies.

We trust that the reader will perceive in the sequel that our argument on the point before us has not been unnecessarily minute, for the whole question of the future development of Mediæval architecture depends upon it. If those who assume the office of pronouncing publicly on the merits of modern church architects ground their criticisms on speculative doctrines, such as those here alluded to, it becomes the direct interest of architects to ascertain how far those doctrines are correct.

What seems a fatal objection to doctrinal instruction by the aid of material forms is, that the system never did and never can become general, and moreover that if it could, it would never be free from ambiguity. This kind of teaching must belong to one or the other of two classes—suggestive or conventional: that is to say, the forms in which it is embodied must be either suggestive of their intention, or if they bear no outward resemblance to the thing typified, their signification must be purely arbitrary. To the first of these classes belong cruciformity and orientation which as we have shown are liable to the objection of want of generality, because occasionally they would from local circumstances become practically impossibilities. In the same class of suggestive symbols must be ranked the eastern triplet: a species of symbolism which makes out a case stronger even than that derived from the two former species. In the case of the eastern triplet the deviation from the general rule (if such rule existed) was perfectly gratuitous and unwarranted by necessity: for it is impossible to suppose that the architect was ever practically compelled by local requirements to build a window of five or seven lights in preference to a triple window. What then shall we say of a conventual church like that of Jesus College, Cambridge, for example? Were the worshippers polytheists? They must have been so if they derived a symbolical teaching from the eastern window.

The argument respecting ambiguity applies with equal force. If the eastern triplet consisted of three separate and distinct windows, then it taught a heresy, and if the centre window were larger and more important than the rest, it taught another heresy. The nature of these heresies need not be here specified, they are both denounced in the *Quicunque vult*, in the expression "una est divinitas, œqualis gloria."

But the ambiguity would become absolutely inextricable confusion when forms possessing similar peculiarities were made to represent different doctrines. For instance, if anything like system and distinctness were to be maintained, it would be obviously necessary that all forms of which the most distinguishing mark was their triplicity, should suggest one and the same doctrine. The fleur-de-lys, for instance, three component parts united by a band, ought to teach the same thing as the eastern triplet embraced by one hood moulding. The fleur-de-lys however teaches something altogether different. It has, says the *Ecclesiologist*, "from the twelfth century at least, probably for ages long anterior, been the recognized emblem of the Virgin Mother as such." We must beg the reader to take notice of the words "recognized emblem," because we will show by another quotation from the same place how far the emblem actually was recognized. The reason of its being "appropriated as an ornament to the seats of the Laity in particular," was that it suggested what was peculiarly "the peoples' doctrine." Now then how far did the people understand the suggestion? We are told that the popular name of this ornament (*popie*) was derived from its supposed resemblance to a bundle of hemp. The old church-designers had however "something more significant in view than the mere giving of an ornamental finish to an otherwise plain seat-end. Nor had they any intention of imitating 'bundles' of hemp or of any other substance: *that was a mere fancy of the workmen.*" It appears therefore that whatever may have been the *intention* of the designers, it failed of its effect. The workmen misunderstood the meaning intended, and the people generally committed the same error, for the name "popie" seems to have been a popular one, and the result of a vulgar error similar to that by which "Pan and his Bacchanals" was corrupted into "the devil and his bag o' nails," which was a common sign of old inns.

So much for the efficacy of symbolic teaching, where the form of the symbol was suggestive: with purely conventional symbols the matter must have been still worse; for here even the *memoria technica*, which afforded some little help in the former case was wanting. To understand at all the meaning of the types, constant reference must be had to a written code, like that now used in the navy for interpreting signals made by flags or rockets. Such a code has been compiled by Durandus, though never authoritatively recognized. We confess, without much shame, that we know as little of this work as we do of the "Aurea Legenda," or Butler's marvellous "Lives of the Saints," and that little is obtained from merely meeting with a few occasional extracts. Still, we apprehend, the great body of the people, in the most flourishing times of the unreformed church, were in the same state of lamentable ignorance. At least we are certain they are at present, and that there would be some slight difficulty in getting them to read Durandus now,—if they did not, really we cannot see what the use of the symbols would be. It would become the case of the rockets without the signal book.

But suppose the difficulty removed. Suppose the people *were* at last got to study Durandus (which by-the-by seems as likely as that the inhabitants of St. Giles's should take it into their heads to commit the Nautical Almanack to memory), would not the labour of teaching be twice as great as that required by a more direct method? First the forms are to be learned, then the code of interpretation has to be "got up," then the application of the interpretations. But why go by such a circuitous route? We are convinced the thing would never answer. Among so many scholars with very different degrees of desire and aptitude for learning, so many mistakes would occur that we should soon have to revert to the more direct process. Complicated machinery is seldom successful in practice.

But there remains another argument for symbolism, one derived from mere architectural considerations, and not connected with theological doctrines. It is this, that symbolism is a source of the beautiful—that truth and beauty are so nearly allied, that material representations of truth must exhibit beautiful forms. This is one of those showy sentiments which entrap unwary readers, especially if they have a taste for magniloquence. But what is the fact? The beauty of the symbol depends, not on the nature of the truth symbolized, but on the method of representation adopted by the artist. If the artist have taste and genius the symbol may be beautiful, if not, the symbol will most likely be absurd and ugly. The restriction put upon the designer that the forms adopted by him shall typify abstract ideas, will add so much to the difficulty of his task, as to have in all probability the very reverse of a beneficial tendency. The design instead of being improved (as it is argued) by symbolism, will most likely be greatly injured: unless we suppose that the desire of symbolizing religious truth will necessarily be accompanied by the faculty for doing it in a graceful manner—which is much the same thing as supposing that every religious person is *ipso facto* imbued with good taste. We will not cite examples to the contrary,* but we may at least mention one or two instances which disprove the converse proposition, namely, that men imbued with good taste are *ipso facto* religious. Material beauty is far better represented in the paintings of Salvator Rosa, and Raphael, than moral beauty in their lives and conversation.

There seem therefore no reasons (except those which fanatacism would suggest) why ecclesiastical symbolism should be more beautiful than any other. The Chinese characters are a kind of symbolism, for they originated in the representation of natural objects by conventional forms, so did Egyptian hieroglyphics, so did our own heraldic devices. Is there any thing of beauty or propriety in these forms? We fail of discerning the gracefulness of a rampant spare-waisted unicorn, or a double-headed dragon covered though they be with Mediæval rust, and honestly confess that we prefer the Elgin marbles.

We have alluded in another place to the significant symbolism of skulls, cross-bones, and chains, which decorate the front of Newgate gaol, as a proof that symbolic architecture is not always beautiful, but we have not spoken yet of the profanity and indecency occasionally exhibited by Mediæval symbols and grotesque carvings. The sculpture of the Hotel-de-Ville of Louvain, for example, representing the mortal sins and their punishment, displays forms revolting to any but the foulest imagination. Again, the constant collocation of serious and ridiculous subjects sanctioned by Mediæval architects would be deemed intolerable now. We have seen in an old continent churches an absurd representation of a monk with his toe in his mouth, &c. These and similar extravagances might be permitted in

* Yet we may be allowed under this head to remind the Ecclesiologist of the fact mentioned by our cotemporary, that Archbishop Laud (the theme and admiration of all ritualists) caused Inigo Jones to disfigure one of the noblest of our Cathedrals, old St. Paul's, with a detestable Corinthian portico.

the time of the ancient "moralities" or "mysteries," religious dramas in which the Divine names were freely introduced among the *dramatis personæ*, but no amount of precedent would suffice for their revival now. If there be one instance more striking than another of the necessity of distinguishing between the valuable and the valueless parts of Mediæval art, it is this of grotesque or monstrous devices. Nothing which is unnatural can be beautiful, for nature is the source of all ideas of beautiful forms—the heraldic monsters of the new Palace at Westminster, the hideous encaustic tiles recently laid in the Temple Church, and if we remember rightly, similar modern absurdities in the Round Church at Cambridge, are no better than simious displays of the faculty of imitation.

Symbols such as these will never probably be ranked in serious argument among the valuable parts of Mediæval architecture. But there remains yet another class to be alluded to which may be termed historic symbols, symbols employed in church architecture to represent not doctrines which are true through all ages, but current facts of ecclesiastical history. We are not certain that this distinction was really made by ancient architects, but notice it because it is laid down by Durandus, and adopted by modern ecclesiologists. To take an instance—

"It is well known that all Mediæval cathedrals either do now or did formerly contain stalls in their choirs: we know also that in the primitive basilcs there were no stalls in the choirs, but that the Divine offices were sung standing. We know from history that stalls were not introduced without a struggle. They however became a "fact," (to use a much abused word), and what does Durandus say of them? 'The stalls in the church signify the contemplative.' . . . . . Truly the contemplative life in a healthy state of churchmanship is a most fit vocation for the canons of a cathedral-church, and it is certainly not very hard in this case to discern the analogy between type and antitype. But suppose a vast increase of Bishops to be made in England under an improved state of churchmanship and cathedrals to be built in our poor and teeming trading and manufacturing town—Liverpool for instance and Sheffield—charity and common sense would dictate that the canons of these cathedrals would have a very different vocation from their brethren at Lichfield or Ely; that they would have in the strictest sense of the word to do the work of Evangelists; that they have to go forth as *preachers of the very first rudiments of religion to a virtually heathen population*. Contemplation therefore to them must be a recreation not an occupation, and the symbolism that should point them out as contemplatives *would not be borne out by facts* . . The canon of the symbolism of choirs would then be embodied in the following form:—In some churches are found stalls. These stalls signify contemplation, &c. (as in Durandus). In other churches built in large towns to serve as missionary stations, there are no stalls, but there the Divine office is performed standing.* These choirs signify wretchedness as it is said in the Prophet, 'How beautiful upon the mountains are the feet of him that bringeth glad tidings.'

"We have, we trust, sufficiently vindicated the truthfulness of that minute system of symbolism which is found in the writings of Durandus and other authors of the middle ages"!!—*Ecclesiologist*, p. 226.

After the reader has carefully perused this extract and noticed the passages which we have marked in italics, let him reflect on the result likely to follow from the system here impliedly recommended. How much gratified the good people of Liverpool and Sheffield would feel to have cathedrals on the terms suggested! To be reminded continually by visible signs that they, in contradistinction to the people of Ely, are heathen idolaters! The proposition forcibly reminds us of Sydney Smith's celebrated selections from the Evangelical Magazine—"Christianity introduced into the parish of Lanston, near Bicester in 1807." "Chapels opened—Hambleton Bucks—eighteen months ago this parish was destitute of the Gospel: the people now have one of the Rev. G. Collison's students," &c.

But the principal consideration in an architectural point of view is this—we are told in the extract before us, that the kind of symbolism which would be appropriate to a particular church at one time, at another "would not be borne out by facts." How then shall the species of symbolism be appropriate to each locality be decided upon? Who will undertake the delicate task? And for localities halfway between the heathenism of Sheffield and the godliness of Ely, what intermediate system of symbolism shall be adopted? Who will invent a finely gratuated scale of symbolism which will exactly suit all the variations of that spiritual thermometer of which Ely and Sheffield are boiling point, and zero respectively? And when Sheffield has begun to improve—when the influence of the standing canons has begun to tell upon the people—when the original symbolism is no longer "borne out by facts," who is to make the alteration, and how is to be ascertained the exact moment for making it?

We are told that the main object of symbolism is not so much to teach religion, as to honour it. We will not stop to prove that the system here advocated would lead to the grossest materialism and dishonour religion by making it appear ridiculous; it is enough for us to show that the scheme is impracticable. It would be beyond the collective wisdom of the Cambridge Camden Society, it would be beyond the compass of all human sagacity and invention to overcome the practical difficulties here mentioned. If the system were a mutable one—true at one time and not true at another, then it, or at least the mutable portion of it, even though we wave all dispute as to its actual merits, must yield to the fatal objection of its impracticability.

A large proportion of the whole number of church symbols, namely, the historic class is thus disposed of. Respecting the remainder, those symbols which refer to immutable truths, we may be certain that the greatest part, like the "popies" aforesaid, would be the subjects of vulgar perversions, which would render them useless if no worse. The representation of abstract truths by material forms is difficult enough even when those forms are the 26 letters of the alphabet combined into words and sentences. If the greatest of philosophers and divines have found all the resources of written language scarcely sufficient for the perpicuous explanation of their thoughts, if the church herself have been unable to express her articles and rubrics with a distinctness which would place them beyond insidious misrepresentations and additions, what shall we say of the difficulty of expressing the same abstruse doctrines by the unyielding form of architecture? To every unprejudiced mind it must be obvious that bricks and stones, however contorted, could never answer the purpose effectually, that the architecture must become a congeries of hideous and absurd devices, and above all, that where honour and reverence were intended vulgar ridicule and desecration must infallibly ensue. This consideration disposes of the second sort of symbols; and so the whole delusion melts into air—thin air.

To some of our readers we may perhaps appear to have been unnecessarily minute in the arguments by which we arrive at this conclusion. There are some who would have us treat church symbolism as an obvious absurdity, not worth arguing about: and the whole doctrine is doubtless one which might easily be made the subject of sarcasm and ridicule, but we have been careful to view every part of the question seriously and patiently, because upon the due settlement of it greatly depends the future development of Mediæval architecture. The principal arguments brought forward by those who advocate the exclusive adoption of the Decorated style are founded on symbolic considerations; those who would adopt Romanesque exclusively rest their case *entirely* on the supposed doctrinal interpretation of the prevailing forms of that style. Having then explained to the best of our power the grounds on which we would exclude from the question of the future development all symbolic considerations, we shall have less difficulty in discussing the remaining part of the question, namely, the purely architectural considerations.

To begin with the consideration of the architectural value of Romanesque or Norman architecture, our own opinion is decidedly against any very general re-adoption of that style. It is essentially imperfect in its general character and individual details. It is a transition style—not a transition from one of two congruous modes to the other—but a transition from the Classic mode to another in every way antagonistic to it, the Pointed. Romanesque constantly exhibits traces of the effort frequently made in Roman, namely, that of reconciling two directly opposite and irreconcileable modes of construction, TRABEATION or construction by straight beams, and ARCUATION or construction by arches. Every transitional or mixed style must of necessity be incomplete: and for this reason a great objection will always exist against the revival of Romanesque. It does not however follow that because it is an incomplete style that it is absolutely valueless. It is an important rule of criticism that a work of art may have beauty and yet not be perfectly beautiful. Now this we apprehend is precisely the case with Romanesque architecture; the very effort to combine two incongruous modes was the source of beauties which belong exclusively to this faulty but effective style. The enormous massive pillars and walls are evidences

* We have already noticed the circumstance that the writers here quoted do not consider it always imperative to observe the ordinary rules of English composition. In the expression "the Divine office is performed standing," the participle "standing" should by the principles of Syntax refer to the preceding noun "office;" the meaning is however, not that the Divine office stands—which is nonsense—but (we presume) that the canons stand when the Divine office is performed.

of imperfect knowledge of construction. Had the Normans possessed the constructional skill of later architects, had their knowledge of mechanics enabled them to construct a spire with the magical appearance of lightness which belongs to the Strasburg spire, they would certainly have availed themselves of that knowledge. Modern ecclesiologists tell us that the Normans built massively and imperfectly, because their mode of contruction typified the state of the church in their own times. The reason which we should assign is far too simple and unsophisticated to find much favour in the Universities, but we are disposed to think that if the Normans did not build with the symmetry and graceful proportions which distinguish later architects, it was simply because they could not.

Romanesque, like all mixed architecture (cinque cento for instance) abounds in surface decorations. For the reason of this circumstance we need not look far. A style which combines incongruous modes of construction must afford means for masking the inconsistency: and accordingly we find in Italian and Romanesque, and every other impure kind of architecture, that the construction is never clearly exhibited, the decorations do not arise naturally from the constructive arrangements, and that the architect is compelled to resort to surface ornaments as alternative expedients for producing variety. The arches of decoration which characterise Romanesque towers, &c. are examples of these inconstructive ornaments.

A practical objection to the general adoption of Romanesque—an objection which perhaps will weigh more with the professional than the amateur architect—is that it is a very expensive style. The modern kickshaw Romanesque structures with thin walls and slender pillars are not very costly; but we speak here of real Romanesque—not of a mongrel architecture which mimics the details of that style without possessing the least portion of its spirit. The characteristic solidity and massiveness of Romanesque masonry can seldom be reproduced in modern times. Besides, it is poor affectation to copy defects—to return to imperfect modes of construction when we possess more perfect modes.

The advocates of Decorated architecture are not quite so exclusive as the advocates of Romanesque. It is true that the former usually condemn new churches built in any style but their favourite one; they admit however the merits of other styles. "Will it be maintained," say they, "that though Middle Pointed be as a whole more perfect than First Pointed, yet that there are not parts and details in the latter more perfect than in the former, and that it is *primâ facie* clear that there can be no absolute impossibility in engrafting them upon Middle Pointed? Therefore any style which shall combine them with the mass of Middle Pointed must be a more perfect form of architecture than has yet been produced. We admire the smooth flowing delicate sweep of a Middle Pointed moulding, still we cannot but desiderate the wonderful boldness, the solemn depth of light and shade in a mass of First Pointed mouldings. . . . . Again, we will be bold to say, why should not back surfaces and splays display that prodigal variety of surface ornament which is the distinguishing embellishment of Romanesque?"

This question appears to us capable of a satisfactory answer. The attempt to combine two different styles has always failed—always will fail—because it destroys the individuality of both. This necessity of characteristic physiognomy is quite independent of intrinsic beauty, and is much overlooked in modern art. The artist who endeavours to give a water-colour painting the effect of oil colours—the musician who would impart to the violin the peculiar ictus of the piano or intonation of the organ—the sculptor who by piercing the eyes of his statues borrows the effects of colour, entertains, we hold, defective notions of the true purposes of art. Each of these combinations is made at the sacrifice, so to speak, of identity. The mixed result instead of preserving the merits of both its archetypes usually injures both.

To view the subject historically—had not the architects of the Decorated Period fully as many opportunities of combining with their own architecture, the characteristics of the previous period as we have? The very fact that they did not avail themselves of these opportunities is a strong presumptive argument against the expediency of making the attempt now. We see, as the second great style of Mediæval architecture approached perfection, the characteristics of the first style, one after another, voluntarily relinquished. The deep undercut mouldings of Early English, the exquisite lancet windows with detached shafts, &c., fell into disuse. Can we imagine that men who showed such a thorough appreciation of the beautiful as did the architects of the Decorated period, would have given up forms of so much beauty wantonly, and without they had entertained a fixed purpose for which those forms were incompatible? If we examine an Early English church or a Decorated church separately, we shall find that the details of each are exactly consistent with the general character of the building. And this observation applies not only to the actual forms but the modes in which those forms are applied. In Early English some parts are elaborately ornamented, which in Decorated were left plain. It is difficult to explain these characteristics by verbal description, but we feel convinced that the architectural reader who has become familiar with them, by actual observation, will bear us out in the assertion that the character of each style so thoroughly prevades every portion of it, and is so strongly marked in its minutest details, that the attempt to transfer parts of one style to another must produce confusion.

This unsatisfactory result may be partially traced in the transition styles of each period. It cannot be denied that the monuments of transition architecture are usually very interesting, and that their prodigal display of rich embellishments elicits the highest admiration. But these buildings seldom have a distinct character of their own. They are, as it were, borderers on the confines of two countries, and exhibit some of the good and bad qualities of both, without possessing the nationality of either.

The remainder of our space must be devoted to the defence of Perpendicular architecture from the obloquy to which it has been subjected. The principal objection urged against this style is that it is not symbolic. We do not consider it necessary to resume the discussion; we shall merely make one observation with respect to the absence of the Triforium. The symbolists protest against the disuse of a feature which, with the clerestory above and the arcade below it, constitutes the triplicity which they love to trace in every part of a sacred edifice. To ourselves, however, a sufficient argument against the re-adoption of Triforia is that they are useless. In the unreformed Church they appear to have served as galleries from which were hung draperies on high festivals. It is clear that they could never be applied to such purposes in modern English churches, and it must or ought to follow thence, that all who advocate faithfulness in architecture must object to the introduction of members which are not merely useless but fictitious also, from assuming an appearance of utility which does not really belong to them.

The objection that the mullions of Perpendicular windows are inconstructive has but little weight, for it applies to all mullions whatever, whether they meet the soffit of the arch vertically or obliquely. Any one who is acquainted with the mechanical properties of an arch knows that it ought to be supported on its abutments only—that it does not require support from intermediate props. If, then, such props be applied either by the vertical mullions of Perpendicular windows or by the curved tracery of Decorated windows, these additional members are *alike* inconstructive; and *quoad hoc* the Lancet style is more constructive than either of the other two. But it would be impossible to fetter art by these minute restrictions. If a comparison be established between two styles to ascertain which is the most constructional, it is not the *ornamental* details, but those larger parts to which the building owes its stability, which should be compared.

Viewed in this manner, we have no hesitation in saying that Perpendicular is the most constructional of all the styles of Pointed architecture. Its very name implies as much. It might be pronounced *a priori* that a style distinguished by continuous vertical lines would afford the most convenient bearings for sustaining superincumbent weights, and would therefore be the most useful for lofty buildings. Accordingly, we find vertical shafts, such as those which run up between the windows of King's College Chapel, from the ground to the vaulting, support the roof more directly, and therefore more efficiently, than do the clerestory walls of a Decorated church. At all events, it cannot be disputed that the construction is more apparent in the former case.

Vaulted roofs appear more consistent with Pointed architecture than wooden roofs, because the construction of the latter is usually of the kind which we have termed trabeate. The principle of arcuation has never been so thoroughly and magnificently developed as in the fan-vaulting peculiar to Perpendicular architecture.

It has been objected to the panel-work of this style that it produces "an easy but gaudy system of surface decoration." The objectors seem to forget that each style is capable of being treated skilfully and unskilfully, and that, after all, its excellence depends principally on the competency of each individual architect. It cannot be denied that throughout the Perpendicular period the facility of producing embellishment by panel-work was frequently abused—just as in the Decorated period flowing tracery frequently became entangled and confused. The Mediæval architects with all their skill were not infallible (*bonus dormitat Homerus*). What then?—because the use of panelling was sometimes excessive was it always so? Was the whole character of Perpendicular an easy but gaudy system of surface decoration? Look at the external architecture of King's College Chapel. Not much surface decoration there! Plain almost to severity—bold almost to ruggedness, this glorious pile exhibits more *massiveness* than any other Mediæval monument whatever. In the colossal disposition of its parts, it outvies even Norman architecture; as for Decorated buildings, there is not one of them that exhibits the same play of light and shadow. It seems almost incredible that those who have constant opportunities of seeing this Chapel should speak of Perpendicular architecture as characterised by superficial decorations.

If art is to progress, its resources must be increased—not diminished. Yet, how much must we relinquish if we decide on abandoning Perpendicular architecture? Fan-groining, the most magnificent of all methods of roofing; the four-centred arch which, not to speak of its constructive value, exhibits in its outline when correctly worked a peculiar grace which no other arch possesses; the curves of contrary flexure in Perpendicular canopies; the square headed Tudor arches with their exquisite spandrels; these are part only of the wealth which we lose by the rejection of Perpendicular architecture. In no other style were the windows entirely incorporated with the rest of the building. In Early English they were frequently nothing but mere perforations; in Decorated they appear more connected with the rest of the architecture, but it was not until the Perpendicular period that the problem of identifying them with it was truly solved. There are many Decorated churches in which some of the windows might be blocked up without any perceptible alteration in the character of the architecture; but it would be absurd to make the same experiment in a Perpendicular edifice. Unity and harmony are essential elements of beauty, and the most perfect architecture is surely that in which each member is an integral and essential portion of the whole system.

The most effective way of advancing Pointed architecture seems to be the liberal adoption of all three styles, and the careful preservation of the distinctive characters of each. They who object to this course would have us give up all the peculiar beauties of the third style, and would recommend Decorated architecture, or rather a transition between it and Early English, as the model for invariable adoption. A new church of the pure Lancet architecture, or Romanesque, or Perpendicular, *ipso facto*, meets with their condemnation. They affect a zeal for the future progress of Pointed architecture, and yet would confine it within the narrowest compass. They would fill the land with buildings of which the variety and originality should be a minimum;

Facies non omnibus una,
Nec diversa tamen.

Such edifices would bear the same relation to the glorious works of our ancestors which prize poems do to poetry. They would bear all the academical polish and insipidity of the former, without a particle of the genius and spirit of the latter.

It remains with architects to judge for themselves which path they will choose—whether they will limit themselves to one style, or adopt the catholic feeling which we have here advocated. We have, however, one parting word of advice to those who presume to build in styles proscribed by either of the Universities. These architects are almost certain to be condemned by one or the other class of academical critics, and if the criticisms be founded merely upon the distinctive prejudices of either body, may safely congratulate themselves that no more serious objections have been alleged against them.

We are sorry to have to inculcate a certain amount of indifference to criticism, but it is necessary for the purpose of our present paper—a more liberal and extended view of Pointed architecture—that we should do so. At the same time, the architect must be warned that if his efforts be condemned on purely architectural grounds, the condemnation usually proceeds from those who are qualified to pronounce it. We have no reluctance in saying that we have learned much from the pages of the *Ecclesiologist* and the Reports of the Oxford Architecture Society. With respect to our contemporary especially, we have seen with great satisfaction the tendency recently exhibited to advocate progress in architecture: instead of being told that antiquity and perfection are synonomous, we are now bidden to look forward to a perfection of English architecture, compared with which the glories of Cologne shall be as nothing. There are many other points of sympathy between us—the war against unfaithful architecture, which, however, we do not limit to the Mediæval styles—the condemnation of superficial "save-trouble" expedients—the admiration of such men as Didron, Willis, and—let us add—the author of the Manual of Gothic Mouldings. We recognise the general soundness af the architectonic criticisms of the *Ecclesiologist*, and if ever we dissent from them it is with regret; but we have uniformly found the most liberal and general views of art to be the most valuable, and are unwilling to sacrifice its interests to an exclusive spirit which, we believe, will be found on examination to result from the prejudices of academical education.

Our paper has already reached considerable length, and this must be the excuse for not fully examining the proposed alterations in the nomenclature of Pointed architecture. Brevity on this subject is the less to be regretted, because names are less important than things. A good nomenclature is that which is definite, generally received, and not liable to be changed. For this reason we are unwilling to disturb the well known appellations invented by Rickman for the three great divisions of Pointed architecture—Early English—Decorated—Perpendicular. These names have certainly the fault of want of homogeneity: the first refers to a date, the second to the amount of ornament, the third to the character of the ornament. The dissimilarity between the second and third is however avoided by remembering that Rickman spoke of Decorated in contradistinction to Florid, one of his names for the third style. These names however are well understood, and being suggestive are easily remembered. The titles First, Second, and Third Pointed, are not so suggestive, and besides are unnecessary innovations. They are also deficient in homogeneity. For the term Pointed should be balanced against the term Round, as the Ecclesiologist tacitly confesses, in the same way as the French term Ogival is balanced against Plein Ceintre. Yet the advocates of the new names inconsistently call the style anterior to Pointed—"Romanesque," from the name of the People from whom this style was mediately derived. The term Third Pointed has also the grand defect of confounding Perpendicular with a style altogether different—Flamboyant. The old nomenclature is not theoretically perfect, still it is more so than the new one, and besides is sufficient for all practical purposes.

We agree with the *Ecclesiologist* in condemning the term Gothic. Historically speaking, it involves an anachronism, and, moreover, it was invented as a term of reproach by those who knew nothing about it. For the latter reason we also object to calling Classic architecture Pagan—we would as soon speak of classic literature as Pagan. The term confounds a style which the *Ecclesiologist* confesses to be "faithful," "beautiful," and to have been produced by a "beauty-loving people," with the architecture of the Hindoos and Mexicans. There can be no objection, however, to the application of the term to the mongrel architecture of "Classic" cathedrals, and to all attempts at combining the horizontal construction of the Grecian with the vertical construction of the Mediæval architects.*

ARCHITECTURAL RECOLLECTIONS OF ITALY.

By Frederick Lush.

(*Continued from page* 169).

In considering any ornaments in connection with the architecture of Italy, or the numerous bronze and marble works which adorn her piazzas, we see how much the grander and more imposing character of buildings is set off by these smaller embellishments. In Tuscany, and elsewhere, in the time of Lorenzo Ghiberti and Donatello, the churches and cathedrals were decorated with apostles and scriptural subjects, and heroes occupied her colonnades; in the same way as formerly fables were represented by Phidias on the temples, and statues of gods and sages stood under the porticoes of Greece. And the similar works were attended with corresponding happy results. In each epoch and country, the artist "felt himself a public benefactor;"† and he was one. Now, in Italy, the respect paid by the lowest and most uneducated classes to artists, whether native or foreign, is greater, perhaps, than it is in any other country; and we think this is chiefly owing to the exhibition of works of art in all her public places. However easy of access they may be, museums and picture-galleries will do little towards enlightening the people and interesting them in the cause of the fine arts, compared with the good derived from the works of acknowledged artists, in spots which men habitually frequent. Nothing has had such a tendency in the south to engage the feelings and

* We must guard ourselves against appearing to condemn the use of heraldic devices where occasion renders them necessary. The condemnation in the text refers to the gratuitous employment of monstrous and unnatural forms as purely architectural ornaments.

† Hazlitt.

induce the mind to reflect and grow refined, or instil into it patriotic ideas, as the presence of such productions in the squares and in the streets. The public taste is thereby constantly exercised. Indeed, so many are the portions of ground appropriated exclusively to works of genius, that it may be said the taste of the people could not degenerate, even were the treasures of the Vatican or Uffizii unknown to them. The effects, also, of viewing these works in the open air are more healthful, and, on account of the freedom and independence of the spectator, yield a pleasure superior to that afforded by works of the same description within a palace; the glorious sun that heightens these beautiful objects rendering the Italians at the same time susceptible of every emotion which it is in the power of art to inspire. Every traveller must have heard the exclamations of praise that are uttered by mule-drivers, beggars, porters, and boatmen, when looking on the colossal figures which adorn some fountain, or a noble group of statuary in one of their favorite squares. And all admire these places abroad, from prince to peasant. It was gratifying to me, when in Venice, to see the blind Holmein feeling and passing his hands over the beautiful bronze and marble works in that city, and to witness the lively pleasure he experienced from such monuments. The impressions thus produced only make us regret that art does not develope itself to the same extent in England, and that such things are not carried out on that magnificent and liberal scale we see in the Italian cities. An opportunity which was lately offered for making one of the most splendid piazzas in the world, in front of the National Gallery, was thrown away; and, with the exception of the equestrian statue to King Charles, the whole is now a disgrace to the nation, and one mass of rubbish. This is the more to be regretted, because the artists of our time take precedence of the moderns in Italy; and were there less *false* and more *real* patronage, some of our first sculptors would have graced the spot with subjects rivalling the best productions of ancient Greece.

To those men who contributed so much to the restoration of art in Italy, we owe the most beautiful works in her great squares; and we cannot forget that the sculptors of those grand works in the Piazza del Granduca, at Florence, of the bronze gates to the Baptistery in the same city, of the fountains in Rome, Perugia, and Bologna, whilst they attained excellence in that high style of art which they exhibit, were at the same time, or had been, jewellers, *mosaicisti*, and medallists; and that the practice of putting together the minute fragments of stone or glass, or cutting the shell or cornelian into admired cameos, did not prevent them from executing some of the grandest works ever known in sculpture; works, of which the reputation is sealed by the enconiums of Michael Angelo and of our own Flaxman.

II.

"Few of these palaces are of good architecture—some of very bad; others are whimsical, but present among their strange forms many happy ideas."—Wood's "Letters of an Architect," &c.

The details of the Venetian palaces are valuable, because they lead the mind, like all eccentric but beautiful things, to think and invent for itself. Their peculiarities and caprices of style are positive faults if tested by the standard of the Classic examples, or by Palladio; yet, for all this, we see in the composition of the windows, balconies, and other parts of the palaces of Venice, principles of real beauty. An early and too exclusive admiration of the Roman edifices is apt to prejudice the mind against them; but we think they must be studied by all who would not separate the painter from the architect.

The architecture of Venice is what the city itself is in its history and associations—strange and romantic; and her Doge's palace, fairy-like and Eastern in its appearance, reverses the principles of all other architecture. As Forsyth* says,—"Here the solid rests on the open, a wall of enormous mass rests on a slender fretwork of shafts, arches, and intersected circles. The very corners are cut to admit a thin spiral column, a barbarism which I saw imitated in several old palaces. A front thus bisected into thick and thin, such contrast of flat and fretted, can please only in perspective. It is not enough that the structure be really durable, it should also appear so." The writer had, however, formed his notions of architectural beauty and propriety on the precepts of Vitruvius and Palladio, and anything contrary to these was immediately ridiculed and censured by him. Now, the sketch of the Doge's palace (fig. 1) shows, with all its defects, what a pleasing beauty it has about it; an effect which it owes solely to its departure from those prescribed rules. On the other hand, we see edifices which the judgment might pronounce faultless, most correct in the proportions usually given to them, most perfect in the features suitable to their particular class, and, indeed, without any of those vagaries which are here displayed—before which the mind remains cold and unexcited. A total incapacity of raising pleasurable emotion must beget apathy, if not

Fig. 1.

disgust, towards an object. A building, like a book or a picture, may be without a single absurdity, yet be very far from beautiful. Now, in the works of those men who thought for themselves, and were more ambitious to be artists than imitators, we often find that, in departing from conventional rules, the defects (if such they were) were redeemed by the invention of some striking beauties which pleased the imagination, exercised, whilst it fascinated the eye, and at least possessed the merit of originality and that charm which all works of great invention have—of which dull copies are always destitute. Instances of these abound in Venice, and in many of the Italian cities, exhibiting an approximation to the Gothic in feeling, although that result was attained in quite a different way; in the Loggia of Sansovino, for example, and that of Lanzi, and in the cornices and other parts of these celebrated designs, on which has been bestowed great attention; in San Michele, Florence, also, remarkable for the beauty of its crowning member and the tracery of its windows: and in the Palazzo Publico at Placenza and Como.* It should only be remembered that whilst on one side, by too strictly following precedent, we often substitute elegance for sentiment; on the other, a too open defiance of it, might lead to a corruption of true taste.

It is observable in the Ducal palace, as in many other Venetian buildings, how well the contrast between the flat mass of wall and its windows is effected; how admirably one part serves to relieve the other; also how the coloured diamond patterns on those masses reduce the heaviness which might otherwise appear too great for the light, ornamental corridor below.

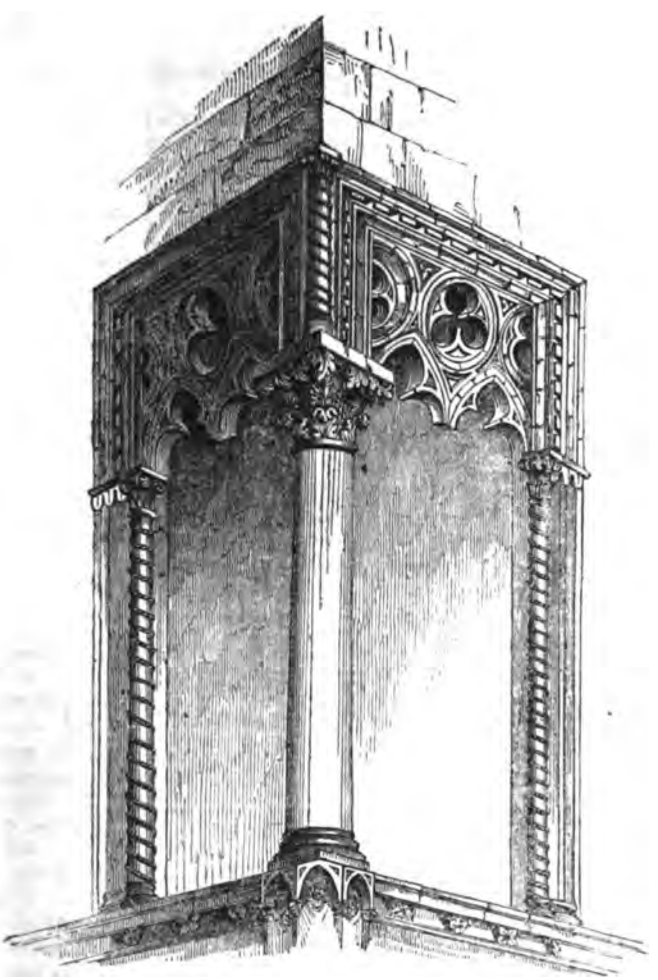
The angular balcony and recess (fig. 2) from another palace is a "barbarism" perhaps not likely to be committed by many English architects. Nevertheless it is very beautiful. It was ingeniously contrived for commanding, from one point, different views on the canals; but for this and a thousand other similar picturesque features in her buildings, with the memories they awaken of her former pageantries, Venice would lose more than half its enchantment. Such things fully express their meaning in this wonderful city, and impress the mind with all that poetry and romance that is infused over it. They must be applied, however, with great caution to other places and circumstances, for, bearing, as they do, more the stamp of power and the force of original thought, than the evidence of good taste, they should serve rather as stimuli to invention than as examples for imitation. The danger of sacrificing correct drawing and just representation to a love of splendour, of which Reynolds, Fuseli, and others, warned the student in the fascinating colours and wild compositions of the great Venetian painters, might equally be incurred in an immoderate fondness for the florid palaces of Venice and the fanciful creations of the Moor.

* "Antiquities, Arts, and Letters in Italy."

* See "Illustrations to Hope's Historical Essay on Architecture," and Cicognara—Fabbriche piu cospicue di Venezia.

It is easy to recognise a correspondence in the principles and effects both in the painting and architecture of Venice.

Fig. 2.



That variety of tints, of forms, of colours, and of the manner of breaking and blending them into one another, which is seen, with one or two exceptions, in the Venetian painters, was in itself extremely attractive; but its merit of beauty and picturesqueness was fatal to all grandeur and dignity. So in the architecture, there were such a richness, such an intricacy, so many curves of contrary flexure (archi proteiformi), and, as it would sometimes seem, such a positive avoidance of anything like uniformity or a long continuation of lines, that, picturesque though it be, and interesting for reasons already given, it was yet far removed from simplicity and grandeur of effect. All these highly ornamental qualities were rejected by the Roman and Florentine schools, which excelled in the grand and imposing style; and those palaces of Rome and Florence, which have the national features most strongly marked on them, as the Farnese, Strozzi, and Pitti, contrasted with those in Venice most remarkable for *their* peculiarities, present the opposite characteristics of grandeur and mere picturesque beauty as much as objects totally differing from each other possibly can do.

III.

Although the marked characteristics of these styles arose out of peculiar times and circumstances; yet it must be allowed that the details of these edifices are attributable partly to the amount of the labour bestowed on them and, in a great measure, to the degree of artistic skill and knowledge of pictorial effect possessed by the Italians. At a period happy for art they united the painter with the architect. Dominichino, Raphael, Michael Angelo, were the better able (as were also our Christopher Wren and Vanbrugh) to impress some originality and power on their works, from possessing this combination of talent. Ornaments, showing great attention to *chiar' oscuro*, and a knowledge of the artificies of contrasting light with shade and producing relief, and executed with reference to the distance at which they would be viewed, are well displayed in some of the details of buildings in Italy, as well Roman as Italian-Gothic; although is a different, rather than, perhaps, to a less extent than that seen in the elaborate enrichments of Gothic architecture.

Thus in many of the Italian cornices,* as in the brick and terra-cotta ones in Padua and Ferrara, but especially (as being likewise of superior material) in that to the Strozzi palace, there is such a union of boldness and richness—and sometimes these qualities stand out so conspicuously singly, that they make all the impression on the spectator which it is possible for such things to do; deriving their effects from bold projection, breadth of shade, and judicious arrangement of surfaces; and not these members only, but the chimneys, which make such sorry figures on our roofs, are remarkable for their beauty and the outline they offer against the sky; and the deep effective border ornaments and decoration to doors and windows often receive all the character and importance of which they are susceptible.

Let any one compare this Strozzi cornice with any cornices in England, designed on buildings of an equal size with that palazzo, and he will see and lament the difference. The former has been accused of "projecting beyond all authority"—by so doing it becomes a bold and spirited production. In England, too often this feature, even in large public buildings, where it is capable of being made imposing, and ought to be so, dwindles into insignificance and meanness; for their parts are seldom large and definite enough; but often too small and too confused; no account is taken of the point of view whence they are beheld; and little attention is given to increase as much as possible the effect of light and shade, by making some parts prominent and deepening the recesses of others, as, for instance, in the dentiles, and egg and tongue moulding. From neglecting this, those portions of the cornice are often entirely lost in the open air to the eye, and require, in order to be seen at all, to be brought within the bounds of the architect's own room, or else to be viewed through a telescope.

* "When they came to the cornices—the massive unbroken cornices of their palaces—the littleness of the other parts is so completely lost, that it is evident they were actuated by the same feelings of unity and breadth that lent so much value to the best works of the ancients. . ... I cannot refrain from calling the attention of the student to the cornices employed by the Florentine school, inasmuch as there is no member of a building from which it receives so great an assistance and effect as from the cornice. In the best and most celebrated examples, such as the Strozzi and Pandolfini palaces, and the Picolomini palace at Sienna, whose court and staircase are of extraordinary beauty, the cornice is proportioned to the whole height of the building, as the height of an order, notwithstanding the horizontal subdivisions and small cornices that occur between the ground and the crowning members. Not less celebrated than those just mentioned, is that of the Farnese palace at Rome, which has always been considered one of the most powerful architectural efforts of Michael Angelo."—Gwilt's "Elements of Architectural Criticism."

A NEW THEORY OF THE STRENGTH AND STRESS OF MATERIALS.

By Oliver Byrne, Professor of Mathematics.

(*Continued from page 167.*)

The work done in elongating a bar to its elastic limit, whose sectional area is one square inch, and length one foot, equal to $\frac{1}{2} M_e \left(\frac{l}{L}\right)^2$, supposing the limit to be expressed by the fraction $\frac{l}{L}$; in this case $A L = 1$

The units of work done in elongating any other bar of the same material as the last, whose length equal L, and sectional area equal A, to its elastic limit, $= \frac{1}{2} M_e \left(\frac{l}{L}\right)^2 A L$. It is evident that $\frac{l}{L}$ is the same value as in the last case, hence, $\frac{1}{2} M_e \left(\frac{l}{L}\right)^2$ is the same in all cases with bars of the elongated to their elastic limit. $\frac{1}{2} M_e \left(\frac{l}{L}\right)^2$ is called the modulus of Resistance, and may be written M_r, and is sometimes called the modulus of longitudinal Resilience. If the work of elongating goes on till fracture is produced M_f, the work necessary to cause fracture in a bar a foot long and an inch square, is styled the modulus of fragility, so that $M_f L A$, will express the units of work that will cause fracture, in the same manner that $M_r L A$ expresses the units of work to extend a bar to its elastic limit. By-and-by we shall explain what is understood by the term Modulus of Rupture in Transverse Strains. The modulus of fragility, M_f, must not be mistaken for the unit of tenacity, which is the number of pounds that would tear asunder a bar one square inch in section. Length is not taken into account in the unit of tenacity, but as the strain is supposed to be on the highest section of the bar, it is therefore at this section the rupture will take place, hence the length must be taken into account in determining the weight that produces fracture.

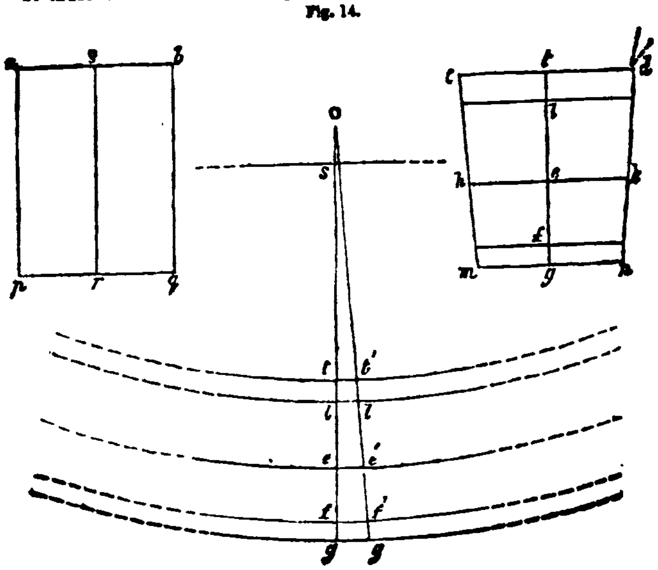
Condition of rupture in a rectangular beam under a transverse strain.

Let us next consider the nature of the forces exerted by the filaments of the cross section, near g, when the beam is in the state bordering upon rupture.

Let g' be any point of the curve $g\,g'$, very near g; and let the normals $t\,e\,g$ and $t'\,e'\,g'$ meet in the point o. Let ρ = the radius of curvature of the mean filament, $e\,e'$, at the point e, that is, the filament which is in a middle state between $t\,t'$ and $g\,g'$; it is represented by $h\,k$ in the cross section through $t\,g$; $h\,k$ is in such a position that it is equal in length to $a\,b$ or $p\,q$, the breadth of the beam before the weight W was applied.

It must be observed that fig. 14 is part of fig. 13 enlarged, the same

Fig. 14.



letters represent the same parts, and that $e\,e'$ is not considered neutral. Let $\sigma = e\,e'$; x = the distance of any filament whatever as ff', from the mean filament, and σ' the length of ff'

$of' = \rho + x$ = radius of curvature of ff', at the point f, then,

$$\sigma : \sigma' :: \rho : \rho + x$$

$$\therefore \sigma' \rho = \sigma \rho + x \sigma, \quad \sigma' = \sigma + \frac{x\sigma}{\rho}.$$

On account of the forces applied, the longitudinal filaments undergo small dilations, which will destroy the equality that existed between σ and σ' before the forces were applied. Let a = the primitive magnitude, then, supposing δ and δ' very small fractional parts of a, so that

$$\sigma = a(1+\delta) \text{ and } \sigma' = a(1+\delta')$$

$$\therefore a(1+\delta') = a(1+\delta) + x\,\frac{a(1+\delta)}{\rho}$$

$$\therefore \delta' = \delta + \frac{x(1+\delta)}{\rho} = \delta + \frac{x}{\rho} + \frac{x\delta}{\rho}.$$

Let $t\,t' = a(1-\epsilon')$; $g\,g' = a(1+\epsilon)$; $l\,l' = a(1-\delta'')$; and let the height of the fibre at $g = i$, and breadth $a\,b$ or $p\,q = \beta$, that is, the breadth before the force is applied. $e\,f = x$; $e\,l = y$; $e\,g = a_1$; and $e\,t = a_2$. When the element or fibre at g, becomes expanded till its length a becomes $a(1+\epsilon)$, then its breadth will be $\frac{\beta}{(1+\epsilon)^{\frac{1}{2}}}$, and height $\frac{i}{(1+\epsilon)^{\frac{1}{2}}}$, the height i is so small, this supposes the cross section of the extreme fibre, before the expansion takes place, to be similar to it after being expanded,*—mind we say similar, not equal, for $\frac{\beta}{(1+\epsilon)^{\frac{1}{2}}}$ is less than β; so the breadth is diminished. It will be perceived that we are here speaking of the lower filaments at g.

* The assumption seems inconsistent with the assumed flattening of the beam. For it is clear that if the proportion between the depth and width of the constituent elements remains unaltered, the proportion between the depth and width of the whole beam must be unaltered. If the upper surface of the beam bulged out, the depth of the upper filaments would be diminished and the width increased—if we assume the density to remain constant. But this assumption also is contrary to our knowledge of elastic bodies and to Hooke's Law.—Ed.

$$a_1 : (a_1 - x) :: \beta - \frac{\beta}{(1+\epsilon)^{\frac{1}{2}}} : \frac{a_1 - x}{a_1}\left(\beta - \frac{\beta}{(1+\epsilon)^{\frac{1}{2}}}\right)$$

$\therefore$ the breadth of the fibres at $ff' = \frac{\beta}{(1+\epsilon)^{\frac{1}{2}}} + \frac{a_1 - x}{a_1}\left(\beta - \frac{\beta}{(1+\epsilon)^{\frac{1}{2}}}\right)$ $= \frac{\beta}{a_1}\left\{a_1 - \left(1 - \frac{1}{(1+\epsilon)^{\frac{1}{2}}}\right)x\right\}$. The force arising from the action of ff' is proportional to δ', and may be represented by $m\,\delta'$, m being a constant depending upon the nature of the material of which the bar consists; therefore, the normal force which corresponds to the point f, normal to $t\,g$, is represented by $\frac{\beta}{a_1}\left\{a_1 - \left(1 - \frac{1}{(1+\epsilon)^{\frac{1}{2}}}\right)x\right\} m\,\delta'\,dx$, and the moment of all the forces normal to $e\,g$ with respect to the axis $h\,k$ = M =

$$\frac{m\beta}{a_1}\int_0^{a_1}\left\{a_1 - \left(1 - \frac{1}{(1+\epsilon)^{\frac{1}{2}}}\right)x\right\}\delta'\,x\,dx$$

but $\delta' = \delta + \frac{(1+\delta)x}{\rho}$; hence, by substitution,

$$\mathrm{M} = \frac{m\beta}{a_1}\int_0^{a_1}\left\{a_1 - \left(1 - \frac{1}{(1+\epsilon)^{\frac{1}{2}}}\right)x\right\}x\left(\delta + \frac{(1+\delta)x}{\rho}\right)dx$$

Therefore M equal

$$\frac{m\beta}{12\rho}\left\{\left[6 - 4\left(1 - \frac{1}{(1+\epsilon)^{\frac{1}{2}}}\right)\right]\delta\rho a_1^2 + \left[4 - 3\left(1 - \frac{1}{(1+\epsilon)^{\frac{1}{2}}}\right)\right](1+\delta)a^3\right.$$
$$\left.(1+\delta)a_1^3\right\}; \text{ but } \rho : \rho + a_1 :: a(1+\delta) : a(1+\epsilon);$$

$$\therefore 1 + \delta = \frac{\rho(1+\epsilon)}{\rho + a_1} \text{ and } \delta = \frac{\rho\epsilon - a_1}{\rho + a_1}$$

$$\therefore \mathrm{M} = \frac{m\beta a_1^2 \rho}{12(\rho + a_1)(1+\epsilon)^{\frac{1}{2}}} \times$$

$$\left\{\left(2(1+\epsilon)^{\frac{1}{2}} + 4\right)(\rho\epsilon a_1) + \left((1+\epsilon)^{\frac{1}{2}} + 3\right)(1+\epsilon)a_1\right\}$$

This being established, we shall next determine the nature of the forces between e and t, or on the area $h\,k\,d\,c$. The breadth of the extreme fibres at $t\,t' = \frac{\beta}{(1-\epsilon)^{\frac{1}{2}}}$; $o\,t = \rho - a_2$; $o\,l = \rho - y$.

$$a_2 : y :: \frac{\beta}{(1-\epsilon_1)^{\frac{1}{2}}} - \beta : \frac{y}{a_2}\left(\frac{1}{(1-\epsilon_1)^{\frac{1}{2}}} - 1\right)\beta$$

$\therefore \frac{y}{a_2}\left(\frac{1}{(1-\epsilon_1)^{\frac{1}{2}}} - 1\right)\beta + \beta = \frac{\beta}{a_2}\left\{a_2 + \left(\frac{1}{(1-\epsilon_1)^{\frac{1}{2}}} - 1\right)y\right\}$ = the breadth of the fibres at $l\,l'$. The elastic forces of compression between e and t, as well as those of extension between e and g, tend to turn the surface of rupture in the same direction about the axis of rupture. The moment of all the forces normal to $e\,t$, with respect to the axis $h\,k$, which we shall call M_1, is equal

$$\frac{m_1\beta}{a_2}\int_{-a_2}^{0}\left\{a_2 + \left(\frac{1}{(1-\epsilon_1)^{\frac{1}{2}}} - 1\right)y\right\}\delta''\,y\,dy;$$

$$\text{but } \delta'' = \frac{\epsilon_1\rho - a_2 + (1-\epsilon_1)y}{\rho - a_2},$$

$$\text{for } \rho - a_2 : \rho - y :: a(1-\epsilon_1) : a(1-\delta'').$$

$$\therefore \mathrm{M}_1 = \frac{a_2(\rho - a_2)}{m_1\beta} \times$$

$$\int_{-a_2}^{0}\left\{a_2 + \left(\frac{1}{(1-\epsilon_1)^{\frac{1}{2}}} - 1\right)y\right\}\left\{(\epsilon_1\rho - a_2) + (1-\epsilon_1)y\right\}y\,dy.$$

$$\therefore \mathrm{M}_1 = \frac{m_1\beta a_2^3}{12(\rho - a_2)(1-\epsilon_1)^{\frac{1}{2}}} \times$$

$$\left\{\left(-10(1-\epsilon_1)^{\frac{1}{2}} + 4\right)(\epsilon_1\rho - a_2) + \left(-3 + 7(1-\epsilon_1)^{\frac{1}{2}}\right)(1-\epsilon_1)a_2\right\}$$

Now the elastic forces M and M_1, when the beam is on the point of breaking, together with the pressure applied at B or A (fig. 7), which is equal to half the weight W and half the weight of the beam.

Representing, therefore, by w the weight of the beam,

$$\mathrm{M} + \mathrm{M}_1 = \tfrac{1}{2}(\mathrm{W} + w) \times r\,\mathrm{B}$$

Let $r\,\mathrm{B} = p$ = half the distance between the supports = the perpendicular let fall from the axis round which the section of rupture turns upon the direction of the pressure at A or B. In the next number will be pointed out the erroneous principle upon which Hooke's law is founded.

(To be continued.)

CANDIDUS'S NOTE-BOOK.
FASCICULUS LXIX.

"I must have liberty
Withal, as large a charter as the winds,
To blow on whom I please."

I. Even should Burton's arch prove able to bear Wyatt's Wellington comfortably, it is more than in all present likelihood good taste will be able to do. If those who are mainly concerned and interested in hoisting up the statue to that "bad eminence" and unenviable point of exaltation for it, have felt all along so assured of a satisfactory result, how happens it that they have not imparted some degree of that same comfortable assurance to the public, if only to stop the mouth of criticism? Some half dozen years ago, indeed, a mere flat pasteboard sort of scheme of the figure was stuck up on the top of the arch for a day or two,—and a strange figure it cut, which may have been one reason for taking it down again as expeditiously as possible, instead of allowing time for its being generally seen. In the interim, which has been a tolerably long one, nothing farther has been done in the way of precautionary trial, or if it has been done, the public have not been informed of it. Yet most assuredly it would not have been amiss, had a good-sized model of the structure with the equestrian figure upon it, been prepared, and exhibited at the Royal Academy; besides which there should have been perspective views also taken from different points, in order the better to determine what would be the effect of such contemplated "improvement" of the arch, upon the other buildings and objects in its immediate vicinity. Hardly could the expense attending such model and drawings have been made any objection or difficulty, where so goodly and serious a sum as Thirty-thousand pounds or thereabouts was to be expended, and that upon a single work of art. It is well should the managers not prove to have been penny-wise and pound-foolish in the matter, and should the work so liberally subscribed for, not verify the proverb of buying a pig in a poke. The thirty thousand pounds for the bran-new statue by our modern Phidias, is not much less than what the priceless Elgin Marbles cost the country; or than what would have secured to us the entire Houghton collection, and prevented its going out of the country. Alas! for those days! Among the whole monied aristocracy, among all our wealthy collectors, nay among our city millionaires, there was not one who cared to glorify his own name by inseparably uniting it with that of the Houghton Collection. Many could easily have snatched the prize from the grasp of the Russian Catherine, by merely taking up a pen, and giving a cheque for the sum demanded—a sum that has frequently been staked at the gaming table without compunction or hesitation.

II. By way of apology for, or in order the better to reconcile us to the Wyatt Wellington—which might adorn some other situation, being put where it will prove a Wellington "out of place," we are told that the idea has been sanctioned by the consent of the late and present Sovereign. Now as to William IV. it is notorious that he neither had nor pretended to have any taste at all for art—and that last was some merit; he neither knew nor cared about it; and as to the consent of her present Majesty, it may fairly be suspected that it is merely a negative one. Like Dickens' Mrs. Davis—if such very uncourtly comparison be allowable—she does not care to be "worritted" about the matter,—though of course there is no such word as "*worrit*" in the vocabulary of royalty,—so leaves the managers and subscribers to please themselves in the affair.—Granting that the Arch may be able to bear the enormous weight that will be put upon, secure enough for some time to come, yet the time will come, sooner perhaps than is thought of, when the structure will require repair, and when it be so loaded, will not that be an operation attended with some hazard, as well as very great difficulty? It will not be matter for much surprize should it eventually be found necessary to fortify the work by converting the hollow parts within the structure into solid masses of earth, concrete, and brickwork. At all events should the scheme be persisted in, we shall have a huge Wellington mounted on guard before little Apsley House, which for an *Arch*-duke's mansion is as lilliputian in taste as it is in dimensions. Instead of giving us a mere "sentinel" statue, might not the artist have properly thrown a little allegory into his work,—have represented the hero of Waterloo not exactly fast asleep, but merely taking a nap, while perfectly wide awake?—or rather, putting that said Nap to flight.

III. Speaking of the decoration of rooms and of his conversations with the late Stuttgart architect, Thouret (who died January 17, 1845) on the subject, Goethe says that the *imitation* of granite, porphyry, and all sorts of marbles, &c., is matter of great importance (*sehr wichtig*). Consequently he for one—and his opinion may be allowed to stand for something, even should it not entirely remove the scruples of the ultra-conscientious,—did not look upon such imitation as mere "sham," unworthy the dignity of genuine architecture. The deception is surely of perfectly legitimate as well as innocent kind, for we all know that in the most sumptuous palaces or other buildings the internal walls never are or can be of solid marble, at the utmost are only incrusted with such material. So long as the construction of a building be sound, and calculated for durability, what matters it though the beauty which array it, and captivates the eye, be only skin-deep? Fresco paintings themselves are only superficial; the external surface once gone, no redressing or repolishing can revive it. It is no argument against the imitation of costly and perhaps somewhat inapplicable materials also, that it is apt to be very paltry. It certainly is not necessarily so, for it may, on the contrary, be very excellent; and as the processes by which it is produced partake more of mere manipulation than art, excellence—positive merit can safely be ensured for it beforehand, which is assuredly no small advantage. Those who affect to despise all deception of the kind, may be left to reconcile to themselves as well as they can, that of gilding, by means of which the most valuable of all metals is counterfeited for purposes to which that or any other metal would be perfectly inapplicable,—picture frames, for instance, which though apparently of gold are, and are known to be, only of ordinary wood gilded over.

IV. Barry is now not only eclipsing Soane, but absolutely extinguishing him bit by bit, at least in the purlieus of Westminster. Poor Soane! not only has the exterior of his "Board of Trade" been so completely refashioned, as to be metamorphosed into a different piece of architecture, but his Scala Regia and Gallery, and his Law Courts—on which last he prided himself so especially, are doomed to pass away, without leaving a wreck behind, or other memorial of them than the wretchedly vile engravings of them in his "Public and Private Buildings," a work remarkable for nothing so much as the extraordinary penuriousness with which it was got up, more particularly the old architect's character for "munificence" considered. Poor Soane! pity that he had not the heart to be a little more liberal towards himself,—somewhat less positively stingy. Poor Soane! too, it will be doubly, if Britton should now pass by him without mention, when recording the other distinguished patrons and persons of talent whom it has been his good fortune to attract to himself during his long and industrious career. Will he now cut "his esteemed friend Sir John Soane," or will he recant,—at least qualify his former admiration by giving a dark *à la* Rembrandt portrait of him?—*Nous verrons.*

V. Welby Pugin has obtained a distinction very rarely conferred in any shape, upon members of the architectural profession, however eminent they may be, namely, that of having an engraved portrait of him published. To say the truth, architects are treated as a sort of *Impersonals* by the public,—creatures without bodies, therefore it is to be presumed, all intellect, all mind. At any rate, it seems to be taken for granted that no one cares to behold what manner of men they are in outward shape and physiognomy. You shall look over catalogues and lists of portraits, and among thousands will scarcely find one of a single architect. It fares very little better with foreign architects than with English ones: portraits of recent or living ones are rare phenomena. Things of the kind may be painted, but they are not transferred to copper or stone, *pro bono publico.* There is a published portrait of Cagnola, one—nay two, if not more, of Schinkel; beyond which number the list can hardly be extended. It may be questioned if there be one even of Zwirner, although a likeness of him ought to be in request with the multitude, he being the architect employed upon the works at Cologne Cathedral. What Nagler will say of Zwirner is not likely to be known—at the rate his work progresses—till some twenty years hence. When he does reach him, it is to be hoped that he will not blunder so egregiously, as he did about Pugin—or rather the two Pugins, father and son, of whom he completely made mincemeat, by chopping them both up together, and stuffing the compound into one article.

VI. The second series of Allom's "France Illustrated," is decidedly inferior to the first, as regards interest of subjects. In that respect it exhibits a deplorable falling-off; and hardly less than deplorable it is to find him, after giving us such delicious interiors of the Madelaine, the Pantheon, and several of the apartments at Fontainebleau—that excepted, called the Salon d'Abdication, a very commonplace room, remarkable for nothing more than a very big-headed Napoleon in an arm-chair,—he should dish up for the second course, such watergruel things as monotonous landscapes—chiefly all mountains and skies, that we seem to have met with before, again and again, there being nothing in scenery of the kind to individualize and extinguish one particular spot from another, wherefore one or two specimens are as good as a score or two,—nay, very much better, because there is then more room for better subjects. And pray, has Mr. Allom taken leave of Paris?—does he not intend to let us have from his truant pencil—views (interior and exterior) of Notre Dame de Lorette, and St. Vincent de Paule, of the Ecole des Beauh Arts, the Hotel du Quai Orsay, the Hotel of the Banker Hope, and many other edifices which would show his forte? Let him labour in his own proper vocation and he will be almost unrivalled in that department of architectural illustration in which he has evidenced such captivating talent in his "Constantinople," and his "France." As much cannot be said for the putter-together of the letter-press in the latter work, for of architecture he seems to know actually nothing,—is altogether unable to speak of buildings, except by sometimes blundering most *deliciously*, as when he talks of the Theatre at Bordeaux been adorned with "interesting"! Corinthian pilasters, which is nearly all that he says of it!

VII. Schlegel was not very wide of the mark in saying "Art has become a slop-shop for pedantic antiquities." Those who pretend most to busy themselves and to take interest in it, give their attention chiefly, and sometimes exclusively, to what is not of the slightest æsthetic or artistic importance. In what are called Celtic monuments, for instance, there is no architectural articulation, they consisting of no more than so many *brute* stones,—unshapen, shapeless, or misshapen. Such things are wholly destitute of organization; hardly can they be called the work of man's hand, being merely rude blocks of stone in their natural form, testifying that those who set them up, had no architectural skill or science, and were unable to reduce them to even the simplest artificial regular form, as the Egyptians did the monoliths which they erected as obelisks. Yet though they possess neither pictorial nor architectural interest, several plates are devoted—literally sacrificed to the subject of Celtic monuments, in both the first and second series of Gailhabaud's Ancient and Modern Architecture. Surely a single plate of specimens of them would have sufficed, would have been quite as much as was their due share; whereas modern architecture has as yet come off very poorly, and must do so at last, unless the work is intended to be carried on indefinitely. A really new and fresh subject has not yet been given in it at all: they are all old acquaintances derived from other publications,—new only to those who are themselves new in architectural study. Yet if unedited subjects—such as have not yet been made known in this country at least, there is abundance,—even perplexity of choice. Out of the number of recently erected structures at Paris, there are some infinitely more worthy of notice than those which have been selected from that capital. There is for one the new church of St. Vincent de Paule, also that of Notre Dame de Lorette; and a section of the Madeleine, which seems to have never yet been so shown, would be very acceptable. The new Theatre at Dresden by Semper, the new Palace at Brunswick, by Ottmer, would be novelties worth setting before us; whereas the modern specimens selected are stale and mouldy,—are of what, in speaking of ladies, is termed a "certain age," being neither old nor young, neither lovely, nor venerable.

VIII. Architectural description is generally very dry stuff; few bring that rich poetical imagination to it, or scatter such flowers of "gay rhetoric" over it, as does the accomplished George Robins. As an example take the following effusion from his pen, which appeared the other day in the Times, relative to a place distinguished by the not particularly inviting name of Thistle Grove, but he has such a Midas touch that he makes every subject he handles glitter like pure gold.—"The house," he tells us, "is a solid piece of architecture *based* on the Corinthian order, adorned by a conservatory in capital taste, with painted glass; and within this little Elysium comfort is conspicuous in every department." An uncomfortable Elysinm, however, would be something more marvellous. "The tact that prevails is of peculiar cast; it disdains the prevailing order"! This is somewhat transcendental in meaning; and requires some cogitation to make it out. The prevailing order, by which it may be presumed the above-mentioned Corinthian order is to be understood, is it seems after all, prevailed over—even disdained by the still more prevailing tact. The tact and the order contend for pre-eminence, and poor order comes off with the worst of it, wherefore there is likely to be some disorder in the matter.—"The doors of the drawing-room are *distinguished* by plate-glass:" what an ingenious and delicate way of giving us to understand that there is no plate glass in any other part of the house! Passing by the rest of the description, it will be sufficient to give the conclusion—a climax not to be surpassed: "These apartments are so perfect that really Elysium is brought to recollection"!! As George Robins is the only mortal upon earth who *recollects* Elysium, he cannot possibly do better than enlighten the world by an accurate topographical *description* of it from his own poetico-graphic pen.

RUSTIC MASONRY.

The value of what is termed rustic masonry has been alluded to incidentally in the paper on the employment of pediments and columns in the decoration of windows; we now propose to consider the æsthetic propriety of "rustication," a little more generally.

Of this kind of masonry there are two principal species. In the one exterior surfaces of the stones are indented to resemble imperfect tooling; in the other the walls are streaked with prism-shaped channels in imitation of defective jointing. Both kinds of rustication are studied counterfeits of deformity—not merely deceptive imitations, but imitations of defects.

Were not our eyes familiar with every absurdity important into classic architecture, during what is termed the Revival of the Arts, it would not be necessary to defend by argument the condemnation of studied defects. As it is, however, it will be necessary to show in what manner the defects under consideration violate the fundamental principles of classic architecture.

The origin of rustic masonry was necessity. At a very early period of Grecian architecture, while the mechanical arts were rude and immature, the irregularities in the masonry were unavoidable evils, and the edges of the stones were chamfered to palliate in some degree the defects in the jointing. In proportion however as art advanced, the surface of the stone was more smoothly wrought, and the arris better squared, till at last the Greek masons were able to build that which is or ought to be a pleasing object to every architect—perfectly finished masonry. In this manner and no other were built the glorious temples of the age of Pericles. Many centuries however after these monuments of perfect art had been forgotten, and when also the decay of mediæval architecture evidenced how rapidly the principles of pure taste were being abandoned, an Italian architect, Brunelleschi (the same who built the cupola of Sta. Maria del Fiore at Florence, a structure in which the essential feeling of classic architecture is systematically misinterpreted throughout) re-adopted rustic masonry along with a multitude of similar solecisms, for which he has received, facetiously we suppose, the title of Restorer of Architecture.

A writer who has attempted to defend the propriety of rustic decoration, observes that though it be the imitation of defects, it exhibits a studied intention, which is a sufficient excuse for its adoption; and yet the same writer, by a singular inconsistency, condemns the use of rustic dies on columns in which, beyond controversy, studied intention is more distinctly exhibited than in rustic or tatooed masonry.* But we wish to found our condemnation of the practice not on the inconsistencies of a single writer, but on general principles.

It has been shown in a previous paper, and will therefore be taken for granted in this, that the distinctive characteristics of Pointed and Classic Architecture are multiplicity in the one, and simplicity in the other. The former style (when correctly developed) consists in the picturesque combination of a multitude of dissimilar parts; the latter exhibits but a very few forms, and those of the simplest kind. Now directly chamfered masonry is adopted, this essential character of simplicity is lost at once; each stone assumes a separate individuality and appears as if set in a frame; instead of showing but few lines the structure exhibits an infinite number everywhere intersecting each other and forming a rectangular net-work. Where columns are employed, as in porticoes, the horizontal lines of this reticulation appearing behind the columns, appear to cut them athwart, and destroy that idea of verticality which is their essential attribute.

A remarkable instance of the injury produced by horizontal lines crossing or appearing to cross the columns of a classic edifice, is seen in the church La Madeleine at Paris, certainly as far as regards the exterior, one of the most successful of modern attempts to revive pure classic architecture. The channels scored on the masonry of the cella have a most injurious effect on the character of the columns, and this injury is further increased by the imperfect (French) workmanship of the columns themselves. The shafts are composed of stones so imperfectly united that they appear encircled with a series of hoops or rings which, except the observer be at a considerable distance, cause the columns to appear discontinuous and *vertebrated*.

* We presume that there are few people who think at all on the subject who would advocate the employment of rustic dies in columns. The French apply the word "Bossage," the derivative of which signifies a tumour or hump, to projecting stones left rough in building, to be carved and finished subsequently; just as we now see in new churches, &c., corbel stones or crockets merely boasted out in the first instance and sculptured afterwards when built into their places. There is no doubt that rustic dies originated in a stupid blunder by which mere Bossages were mistaken for finished work. What should we think of the taste which would leave the irregular lumps of stone now to be seen in some of the arch-mouldings of the Palace of Westminster in their present unfinished state?

It is obviously impossible that mere streaks and crevices on a wall can be dignified by the appelation of mouldings, for they never could be made to have the same value and importance; but even if for the sake of argument, we set aside this unavoidable inferiority, is it not palpably absurd to decorate a building *all over* with mouldings? These decorations owe their effect to their rarity and their contrast with the simpler portions of the structure; and the value of them if applied every where indiscriminately is entirely lost. There is nothing in which the Greeks showed themselves more eminent than in introducing mouldings just where they were required and *no where else*. It cannot be expressed too emphatically that the whole effect of mouldings, the whole of the relief which they afford, arises from their being used sparingly and marking distinctly the outlines of separate portions of the building. If they be used otherwise confusion—not enrichment—is the result. The dressings of a doorway are not new accessories, but answer a distinctive purpose: the listel or horizontal fillet, which in a Doric order separates the triglyphs and metopes from the architrave is essentially a constinctive decoration for it exhibits the method by which the joists of the roof are supported by the columns. And in the same way we might explain the purpose of every moulding used in pure classic architecture; but mere channels cut in the surface of the walls canhot answer any purpose either real or imaginary: they do not serve to mark distinct parts of the building, for they merely separate one portion of the wall from another exactly similar portion; they do not, like mouldings properly so called, divide the building into large well-defined masses, but cut it up into a confused multitude of little parts.

If the composition of a building be properly managed it will present no large continuous surfaces which unless so scored all over appear blank and naked. If we examine actual examples of rustication we shall find it to be a mere make-shift expedient, the palliative of an evil which if the architectural grouping had been duly attended to, would never have heen called into existence. It may be safely asserted that no buildings whatever, be the style adopted, can be architecturally effective unless some portions of the building throw shadows on the remainder. This consideration is much overlooked in the present age. The great defect of modern architecture is that it seldom displays sufficient depth of shadow; it is usually to shallow and flat; it is not made up of large strongly defined masses, and the variety which ought to be obtained by depth is imperfectly compensated for by surface-decorations and minute details. Rustic work is essentially a surface-decoration, and for that reason alone, if no other existed will find little fevour among those who would restore architecture to that place among the fine arts which it once possessed.

If the architect had to deal, not with solids, but surfaces, he might take lessons of a line-engraver and the River façade of the Palace of Westminster would be perfect. A mere façade however no more constitutes a palace, than a modern church-front constitutes a church. Much more than this is necessary—especially in classic architecture of which the constituent forms are so few and simple that unless the effective disposition of light and shadow be observed, meretricious ornaments *must* be resorted to prevent the monotony and nakedness becoming absolutely intolerable. There is scarcely any thing which has more debasing and fatal influence upon art than a system of *save trouble* expedients: among them must be reckoned all superfluous surface-decorations, and especially rustication. We know but one class of buildings for which this kind of masonry is appropriate—namely, prisons, which it seems agreed should be as ugly as possible, consistently with security. In them at least rustic masonry is in sufficiently good taste and accompanied by the ornaments of skull and cross-bones, and iron chains will constitute a species of perfectly symbolic architecture which may be safely recommended to the admiration of the Cambridge Camden Society.

The subordinate decorations of a building ought, it is clear, to correspond in character to style of architecture to which they are adopted. A most important consideration under this head is that while Mediœval Architecture delights in free forms, in Classic architecture, perfect finish and accuracy are essential. An ancient church-tower of rough rubble work is a picturesque object, however simple and unpretending the architecture may be, but if the cella of Greek temple were built in a similar manner, can it be denied the coarseness of the workmanship would be totally out of character with the rest of the building. The delicacy and accuracy of outline which distinguish Greek architecture are characteristics which would be naturally looked for in a southern climate; the bold and almost rugged lines of northern architecture seem exactly to correspond to the energetic character of the people, among whom they were produced. Now these considerations, simple as they appear, are of the utmost value in determining a question like that before us. Rustic masonry displays ruggedness and coarseness of execution which, if what has just been said respecting the distinctive character of Classic and Pointed Architecture be correct, show it to be inappropriate to the former style.

This brings us to our last argument. These who defend the propriety of rustic work seem totally to overlook this consideration—that they ought to be prepared to adapt it to Pointed architecture as well as Classic, or else to point out some characteristic differences between the two styles which render rustication suitable for the one and not for the other. This however has never yet been done; on the contrary, any argument drawn from the comparison suggested would lead to the conclusion that if there be any style for which this mode of decoration is suitable, it must be Pointed architecture. The attempt to so apply it would, we apprehend, meet with universal ridicule; should not this feeling be a sufficient argument for abandoning rustic masonry altogether?

To what heresies have we not given utterance! We have condemned the use of columns which support nothing, of show sides used as masks, of pigmy columns used as window mouldings; we have declared the attempt to combine Classic and Mediæval architecture absurd; and now we include rustic masonry in our list of barbarisms. But what an amount of precedent and written testimony is against us! Does not *every one* of the things which we have condemned exist in St. Paul's Cathedral, the pride of the metropolis, and one of the wonders of the world? And yet we maintain our position, simply because we have in no case substituted assertion for argument. If we have in any case failed to prove our point we shall be very glad to be set right. That in promulgating these opinions we must contend against an enormous amount of educational prejudices is unavoidable; but it is better to do this than to let *pure* Classic architecture be forgotten in the detestation of *debased* Classic architecture which the modern improved taste for the Mediæval styles has justly inspired.

RESTORATION OF ST. BOTOLPH'S CHURCH,

Boston, Lincolnshire.

Among the Church Restorations, which the revival of Christian architecture in the present century has instigated, few deserve more the public attention than that of the Church of St. Botolph, Boston, Lincolnshire, both from the celebrity of the edifice itself, and from the extent and excellence of the work of which we make this brief notice.

The church is a Decorated structure of the 13th century, originally consisting of a nave and chancel with side aisles as at present; to this a magnificent tower in the Perpendicular style, was added in the beginning of the 14th century.

The dimensions are—	Ft.	In.
Exterior length, including buttresses	305	8
„ breadth, including porch	138	0
Interior breadth of nave	98	6
Interior height of inner roof of nave	62	8
Span of arches	18	8
Height of ditto	40	1½
Columns { Base 3 ft. 9 in.; Shaft 22 ft. 10½ in.; Cap 1 ft. 0½ in. }	27	8
Tower—		
From the ground to coping stone of lower battlement	149	11
From do. do. of upper battlement	55	4
From base of lantern to top of stone-work of ditto ..	59	2
From base of lantern to top of vanes	5	0
Whole height of tower	269	5
Tower base interior .. .. 22 ft. 5 in. ×	26	5
Glazed part of windows in tower (length)	52	0
Thickness of walls { Below windows in nave ..	4	6
Thickness of walls { Above ditto ..	4	0

Being the largest church in the United Kingdom without cross aisles.

The tower is a feature of such beauty and architectural celebrity as to need no descripition here. The octagonal lantern by which it is surmounted furnished the model from which that at St. Dunstans, in West Fleet-street, was designed.

The building is constructed of an oolite of great durability, procured, it is supposed, from the quarries at Ketton, near Stamford, Northamptonshire. The inclemencies of the weather during the winters of 5 centuries (for there are no traces or records of substantial repairs since the original erection) have but slightly impaired the general effect of the structure, though the corroding influences of damp and exposure had long been seen in the lighter and ornamental parts, and here and there on the surface of the stone work in the walls and buttresses. The circumstance, not unknown to architects in the present day, deserves a notice here, that the stones placed in a horizontal position, corresponding to that which they occupied in the quarry, have entirely escaped corrosion, while those in other positions are invariably injured). To vindicate the integrity of this chief ornament of the province of Gothic architects, the first efforts of the Restorer were directed to the mullions and arch-mouldings of the windows, and these have been replaced almost throughout with fresh stone, the glass-work of the windows being at the same time re-arranged in diamond squares, for which the oblong arrangement had been substituted at a comparatively recent date. The whole of the pannelled parapet of the nave and parts of that of the aisles and chancel were next rebuilt, the use of iron braces to compact the stone work, having caused considerable distortion, especially of the south side where the variations of temperature are more felt. The stonework on this side was so much injured as to require in a great measure to be replaced by new work, in which either copper or stone has been used. At the same time the decayed stone in the walls of the church were entirely removed and fresh stones substituted.

The restoration of the woodwork in the roof was one of the heaviest of the expenses to be incurred in necessary repairs: the ends of the larger beams being decayed to some distance from the walls, which imperfectly supported their vast bulks, sound timbers were dovetailed with that part of the larger beams which still remained sound, and along their whole length on either side strengthened by cast iron bars, which have secured the stability of this part of the structure probably for centuries to come.

The restoration necessary for the safe continuance of the structure thus provided for, the ornamental parts were next proceeded with. Four large pinnacles of 16 feet in height, and of elaborate workmanship, standing at the east and western corners of the north and south aisles were entirely rebuilt for the most part with fresh stone, and the ornamental heads of buttresses, crocketed finials, &c., throughout the structure restored or replaced.

The work of reparation was conducted by Messrs. Scott and Moffat, who have, as usual, evinced their appreciation of the spirit of mediæval architecture. The following are some extracts from the report presented by the former gentleman to the Restoration Committee. The remarks respecting the restoration of the ceilings are worthy of attention. We need scarcely say how fully we agree with the condemnation of the painted imitations of stone and oak.

The church appears, from the style of its architecture, to have been built during the reign of King Edward the Third, a period during which a great movement in the way of church building seems to have taken place throughout this district, as nearly every church in the neighbourhood seems to have been, either wholly or in part, rebuilt at the same time. It originally consisted of a nave with aisles (perhaps the largest to any parish church in the kingdom); a chancel of *three bays* only in length; a south porch of *one* story only; and a chapel at the south-western angle. It appears to have been begun and completed in the first instance without any tower—the original west wall being built perfect and distinct from the present tower, and the arch now leading into the tower having evidently been the western window, which was converted into a tower arch, by removing its tracery and mullions, and lowering the cill to the floor. At a subsequent period, probably about fifty years from its first completion, the present most wonderful and magnificent tower was added: and at about the same time the additional bays were added to the chancel, bringing the church to its present splendid proportions. The porch has since been increased in height by the addition of the chamber now used as a library, and some other minor additions have been made, and again removed, but in the main the church retains the same appearance which it must have presented on the first completion of the tower, at the commencement of the fifteenth century; and considering its age, and the neglect which it has suffered, it is in a remarkably fine state of preservation.

Nave Roof.

The nave, or central portion of the church, is the most important as being of the greatest span, and is unfortunately in the worst condition of any part of the roof, so far as can at present be ascertained. It was at first very securely and substantially constructed. The walls were tied together by fourteen beams of most ponderous dimensions, which were secured to wall plates sunk in grooves in the stone cornice, which runs in one width of stone through the whole thickness of the wall. These beams have in parts become much decayed—the ends of many having in fact completely perished, so much so, that had it not been for some rather clumsily contrived precautions, which have from time to time been taken for their support, they could not have retained their position, but must have fallen in.

The precautions alluded to, may possibly be sufficient to provide for the *immediate* security of the roof (though even of this I cannot speak with certainty), but there can be no doubt that it is anything but a satisfactory state for so essential a part of the fabric to be allowed to remain in; and that if the decay of the beams should increase, very serious consequences might be apprehended. In addition to this, I find, on a closer inspection, that the wall plates (of which there are two on each side) are (so far as I have been able to get at them) entirely perished, by which the connection of the timbers with the walls has in a great measure been destroyed. An attempt has been made (probably at a very early period) to remedy this, by the introduction of the huge iron hooks which so much disfigure the exterior of the clerestory wall; these, however, obviate the evil in a very partial manner, being ill-constructed for their purpose. There are some further defects in others of the timbers, particularly in the feet of some of the upright wall-pieces and braces, which have been partially decayed through the water having been allowed to get down into the pockets or springing points of the groined ceiling, and to saturate the masses of dust and decayed wood which have there accumulated. The extent to which this defect exists it is almost impossible at present correctly to ascertain, the parts affected being completely concealed by the mouldings of the groining; but I am inclined to think that it has not proceeded to a very serious extent.

The effect of these different defects has been to cause an undue thrust upon the southern wall, the timbers being most decayed on that side, which has occasioned a considerable curvature in the length of the wall. The wall having been, by the joint pressure of the rafters above, and the braces below, thrust outward, and partially drawn off from the ends of the tie-beams; and the enormous weight of these (each beam of itself weighing nearly three tons) being thrown in great measure upon the braces, has tended still further to increase the evil, which must even now be constantly becoming greater; and must, if not remedied, greatly endanger this part of the building. The north side of the roof not being so much decayed as the south,—and the latter having been the first to give way,—the effect upon the north wall has been of a contrary nature to that on the south; and, as might have been expected, this wall has been drawn inwards, though to a much less extent than the outward tendency of the other.

It would probably be hopeless to attempt to restore these walls to their proper position, and the utmost we can do is to prevnt their getting worse, and to do this we must endeavour—1st, to restore that longitudinal stiffness to the walls, which has been lost through the decay of the wall plates.—2nd, to complete the connection between the opposite walls, which has been cut off, partly by the same cause, and partly by the decay of the ends of the beams: and 3rdly, to support the tie-beams themselves in such a manner that by their own weight they may not be causing the failures which they were intended to prevent. The first object cannot, I fear, be effected without the introduction of new wall plates of oak, where the old ones are decayed; this appears particularly necessary on the south side. The second and third objects I should recommend to be provided for, by cutting off all the decayed ends of the beams, and replacing them with new oak, well scarfed, and with strong iron plates above and below the scarfe; and by introducing to each beam a chain truss of wrought iron, on such a construction that it would at once form a perfect tie to the roof, and would in great measure support the weight of the beam. Such other timbers as are decayed should also be replaced with new. The above repairs could be effected without materially disturbing the covering of the roof, with the exception of the gutters and some other parts of the lead work, which must be taken up and relaid.

External Stone Work.

The stone work generally is just in that state which renders it most difficult to determine the extent to which it requires reparation: it is in many parts much decayed and injured, but still not to that extent to warrant the renewal of all the decayed parts; indeed, it is generally the smaller portions of the ornamental work which are most affected; the more solid features generally remaining tolerably sound. The great object appears to prevent it from getting worse, by refixing or renewing all such parts as are in a shaken and dilapidated condition, or which are so decayed as to endanger their stability, and to replace all those detached ornamental features, such as pinnacles, finials, &c., which have been displaced or shaken, and such other injured parts as can be repaired without interfering too much with the more substantial parts of the building. There are some decayed portions of such a nature as to render it doubtful to what extent it might be prudent to attempt to replace them, such as the base-mouldings of the tower and church, and other parts which are intimately connected with the strength of the buildings, and the decay of which has not gone further than partially to efface the mouldings on their surface. No general rule can be laid down for these, but they must be viewed separately on their own merits, and according to the extent of their dilapidation, and the comparative difficulty and importance of replacing them.

I will now attempt to enumerate, in order, the several parts requiring reparation.

Clerestory.

South Side.—The upper part of the stair turret is in a very shattered state. This stair belongs to the nave rather than the tower, having in fact existed before the tower was built. It appears to be quite distinct from the tower till within a few feet of the top, where it has been connected with it by turning the stairs into those of the tower. It is this connection which has caused its dilapidation; the settlement occasioned by the weight of the tower having completely crushed it and disjointed the stone work, which has from time to time been further injured by the iron ties which have been introduced. I am of opinion that it will be necessary to rebuild it from the gutter upwards, a height of about 8 or 10 feet.

The Parapet on this side has been much injured by the undue pressure of the roof, and by the improper use of iron cramps. It is twisted into every variety of curve, and in some part overhangs considerably. Many of the stones have been split by the iron wedges imprudently used by the plumbers, and the whole is in very bad condition; so much so, that I think it necessary that it should be taken off and re-set, using new stone for such parts as are injured.

The Buttresses to the sides of the clerestory have lost their finials, and the heads are a good deal broken. The niche-heads on the same side are much decayed and broken, and all the figures but one are gone.

The Windows require considerable repairs. The mullions are many of them very much out of the perpendicular, and the tracery is displaced and broken, both by the settlement of the whole, and from the effects of the iron-work. The ashlar-work also requires to be generally repaired, that which is decayed being replaced, and the whole pointed where necessary.

North Side.—The stair turret is as bad, or worse, than that already described.

The Parapet is not so bad, but some parts at least must be rebuilt. The eastern pinnacle is not quite so bad as that on the other side.

The Side Buttresses, with their heads and finials, are not quite so much injured as those on the south side, but the finials are all gone, the niche heads are much decayed, and only four figures remain. The windows and ashlar require similar repairs, though to a less extent.

South Aisle.

The Parapet is in some parts shaken and crooked, and the ornamental tracery decayed. The part of the west end, and some few other portions, must be taken down and refixed, and the decayed parts generally repaired with new stone.

The Buttress heads have generally lost their finials, and are in other respects defective; these must be effectually repaired, and new finials provided.

The two large angle pinnacles are very much shattered, and will require very considerable repairs. That at the western angle is particularly dilapidated, almost every part of it being more or less shaken or defaced—this must in a great measure be worked anew: that at the eastern angle is not so bad, but still requires considerable work to make it perfect. The figures from the niches are all gone, and should be replaced with new ones. The greatest care should be taken in the restoration of these beautiful features, as if repaired by men who are ignorant of the style and character of the ornamental work of the period, their beauty would be entirely destroyed, which would be far worse than leaving them in their present dilapidated state.

The buttresses, string courses, and ashlar on this side are in parts decayed and defaced, and will require general restoration where injured.

The South-West Chapel.

(Now used as the Vestry and Engine-house.)

The exterior of this chapel is more dilapidated than any other part of the building; it is needless to enter into particulars, as nearly all the stone-work is more or less decayed. It is a very beautiful feature, and merits a perfect restoration.

North Aisle.

The parapet is generally substantial, and requires but little repair; excepting the exquisitely pierced parapet at the eastern gable, which requires some restoration, being in parts decayed. The buttress heads require some general repairs, and new finials throughout. The large angle pinnacle at the western end is sadly shattered, and requires the same extent of repair with that on the south aisle. That at the eastern angle has been partially repaired, but without much regard to correctness of detail; it requires still a good deal of work, and the figures should be made perfect. These, like those on the other side, require a very careful study of the details, to render them correct.

Interior.

Stonework.—I should recommend that the entire surface of the freestone work, such as doorways, windows, pillars, arches, &c., should be carefully cleaned from the yellow-wash and paint by which they are at present disfigured, and that they should, where broken or injured, be repaired and brought to a clean and perfect surface. The parts which have always been rough, should be carefully pointed, and those which have always been plastered, should be re-coloured and repaired. This would improve the general aspect of the interior more than anything, and would remove that *plastery*, disagreeable character which now so much injures the effect of the building. The great surface of the building causes this to be a rather more expensive operation, than might at first be expected, but the cost would be amply repaid by the improved aspect of the building.

The Ceilings would require painting, but on this a question might arise as to the colour which should be used. There are three ways in which it might be done. First, to paint it in imitation of stone, which I think objectionable, as being an imitation of a totally different material from that of which they are actually constructed, and one of which, in their present form, it would be hardly possible that they could have been made. This system of imitation of one material in another, is so contrary to the principles of the ancient church builders, that I think it very desirable to avoid it; particularly in restoring an old building. The centre ceiling is ancient, though not so old as the church; it was originally all of oak, though much of the boarding has since been replaced in deal. Strictly speaking, it should not be made to appear like anything but oak. The second kind of painting would be graining it in imitation of oak; this would be coming nearer to the truth than the former method, but is to a certain extent open to the same objections, as being a mere imitation. Perhaps, therefore, the most correct way would be that which was frequently used in old churches, for the decoration of wood ceilings, viz.:—merely ornamental painting, not imitating any particular material. Some of the ancient ceilings were most richly decorated in this way, and it produces a very beautiful effect. It might perhaps be practicable to take off the present painting altogether, and to restore the original surface of the wood; which would, if it could be done perfectly, be preferable to any kind of paint: in this case the oak boarding must be restored throughout. The experiment might be tried on a portion of the ceiling. This would not, however, apply to the ceilings of the aisles, which are of deal.

The Stone Floor

Is in many parts very much broken, and is throughout very damp. I should think it desirable to relay it on a good bed of concrete or shingle. I would, however, strongly recommend that the ancient monumental slabs should be retained, and that wherever they are found to be over the graves, they should be relaid in their proper places. They add much to the interest of an old church, even when worn and defaced, and should not be removed merely to gratify a love of neatness and novelty.

The Glass.

The glazing throughout is in a very imperfect state, and needs extensive repairs. It has been much weakened by the removal of the upright iron stancheons, with which every light was formerly strengthened. Its strength has also been much diminished by the use of squares instead of diamonds, which are much less capable of withstanding the effects of the wind.

These repairs may be varied greatly in their cost, according to their greater or less completeness. Should the funds be sufficient, I should recommend the whole to be re-glazed in diamonds, with new iron-work, which would vastly improve the appearance of the church, both externally and internally, which is much disfigured by the bad character of the present glazing.

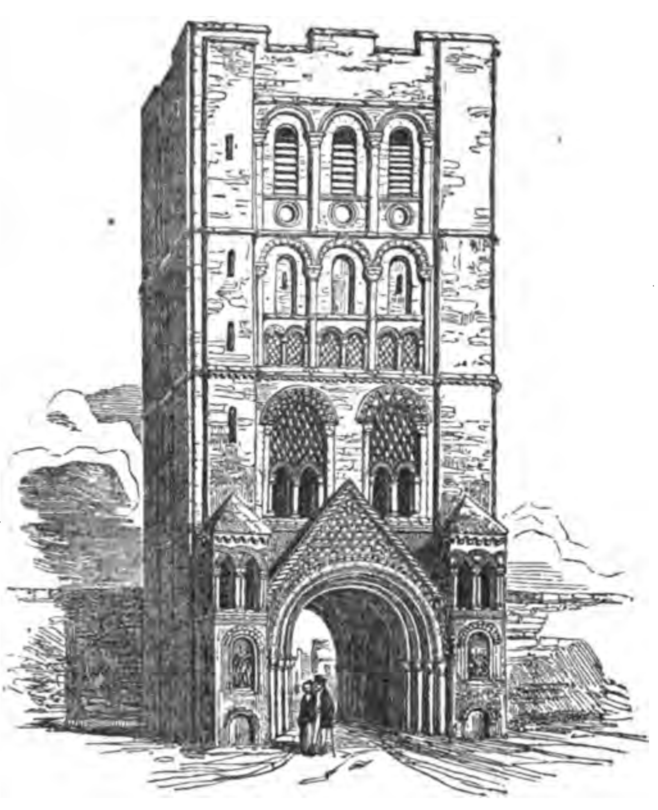
To the above suggestions I will add a few more, which though not immediately necessary are still requisite, to render the state of the church worthy of the original magnificence of the design. The first is the expediency of raising a separate fund for refitting the interior in oak in a manner worthy of such a building, the present fittings being so mean in their appearance, and absurd in their arrangement, as to destroy the whole effect and propriety of the internal character of the building. Should this be done, a more suitable situation might probably be found for the organ, which is a great obstruction to the chancel. The second suggestion is, that the external and internal restoration should be extended to the chancel, and that its beautiful stalls should be cleaned from the thick coatings of paint with which they are disfigured. I would thirdly suggest that the portion of the south-western chapel, now used as the engine-house, should be united to the remaining portion which is used as the vestry, and that the arches between the latter and the church should be thrown open, enclosing the lower part only with an oak screen. And also that the beautiful roof and other internal features of this chapel should be restored.

It would also be a most noble restoration if the present ringing floor could be removed, and the magnificent story above, with its groined vaulting and its beautiful windows, restored to its original intention. This would then be one of the finest things in existence, of this description. I was, on the first examination of this part of the building, at a loss to imagine how the bells were originally rung, but on a closer inspection, I find that they were formerly rung from the little stone galleries, which run round the second story on the level of the window cills, the ropes passing through the heads of the windows, thence for a considerable height through the interior of the wall, and over blocks or pullies set in openings in the walls of the belfry. The holes through which they passed, may yet be seen in each window-head, and also in the belfry above.

I will now conclude by strongly urging the necessity of a faithful adherence to the ancient details, which can only be done by a most careful study of their existing remains, and a comparison between them, and those of other churches of a corresponding age: without this, the beauty of the building will be destroyed, and the present work become a subject more to be lamented than rejoiced in.

I would beg to add, as a practical suggestion, that in restoring the stonework, the use of iron should be as much as possible avoided; its place being substituted by stone plugs and copper cramps, or dowells.

ST. EDMUND'S-BURY GATE-TOWER.



WEST VIEW.

Much interest has recently been excited among the reading portion of the public respecting the antiquities of the Great Abbey Church of St. Edmund, at Bury, by the Camden Society's publication of the *Chronica Jocelini de Brackelonda.* This work contains the earlier annals of the Monastery, written by a monk of the house, named Jocelyn; the reader who is curious in such matters may obtain a most vivid and graphic picture of the monastic life in the times of Kings Henry II and Richard I, by referring to the republished "Chronicles," or to the interesting and most original analysis of them in Carlyle's "Past and Present."

Of the Abbey Church little is now preserved. The magnificence which from the existing remains and the testimony of historians, we must suppose to have characterised its architecture, did not preserve it from the effect of Vandalism which accompanied the general Dissolution of Monasteries. The Norman gate tower, the Abbey Gateway and parts of the enclosure walls are now the only *vestigia* of glories which caused the historian Leland to exclaim enthusiastically, "The sun has not shone upon a monastery more illustrious, whether we consider its wealth, its extent, or its incomparable magnificence. You might indeed say that the monastery itself is a town; so many gates are there, some of them of brass; so many towers, and a church than which none can be more magnificent, and subservient to which are three others also splendidly adorned with admirable workmanship and standing in one and the same churchyard."

The growing zeal for architectural restoration has never shown itself more worthily than in the efforts now making to preserve to posterity so much of the inestimable monumental legacies bequeathed to us by our ancestors, as yet remains at Bury St. Edmunds; and accordingly we view with great satisfaction the works in progress for repairing and reinstating the Norman gate or campanile. By the terms repairing and reinstating, must not be understood merely the removal of rubbish and plaster, and the obliteration of churchwarden "beautifyings," but those substantial works also which are requisite to preserve the building from actual destruction. For it appears from a well written pamphlet now before us, in which are described the present state of the tower and the steps taken for its restoration, that it has suffered so much from violence and injudicious repairs as to threaten imminent danger by its fall. The masonry, six feet in thickness, displays numerous fissures in every part; several stones of the principal arch have fallen out; and the walls have swerved considerably from the vertical. This dangerous condition of the tower has during the last few years been the subject of serious apprehension, and attempts have been made to repair the evil, or at least prevent it from increasing. In 1811, the parish being threatened with an indictment, some injudicious patchings were commenced, and an elegant "pepper-box" was erected on the top of the tower. The fissures however increased; in 1818 two of them extended from the very summit to the lower or ground arch.

The cause of this last disaster appears to have been the vibration produced by the ringing a large peal of bells in the tower. All that was done was however to replace some of the stones which had fallen out, and to *fill up the fissures with cement!* They did "but skin and film the ulcerous place."

At length however the work of restoration was commenced in earnest. A minute report of the state of the building having been drawn up by Mr. Cottingham, a committee has been formed for the purpose of superintending the works recommended in that document, and raising funds for defraying the expenses. In the pr ogress of the survey there have been removed nearly 100 tons of rubbish and bricks, the weight of which added to the insecurity of the building. The adjacent ground has been cleared of the mean tenements with which it was encumbered, and the general work of restoration is now proceeding in a very satisfactory manner. The Restoration Committee have published "a [n] historical and architectural notice of the Gate-tower;" the profits arising from the sale of this notice are to be presented to the restoration fund. This tract, which contains a view of the tower, is exceedingly interesting, and displays great research. We should have liked however to have seen a more minute account of the nature of the reparations proposed, and of the advance which has been made in them. The following extracts from the architectural description will show how worthy the building is of the efforts made for its preservation, and may perhaps awaken the interest of some of our readers and render them anxious to aid the undertaking.

"The Tower is in height, from the plinth to the parapet, 86 feet, and in area 36 feet square. The walls, nearly six feet in thickness, are built with rubble and boulder, and faced with an ashlaring or Barnack stone. The ashlar stones, as usual in the most finished buildings of the Norman era are hewn of the size which a labourer could carry on his back, without much inconvenience, to the top of the building; and which the Norman architects, from their knowledge of the principles of equilibrium, knew so well how to apply.

"The four stories of the tower are marked on the exterior by horizontal fascias, or string-courses, of varied mouldings, which go uniformly round the four sides. The first string-course is ornamented with the chevron or zig-zag moulding, the most common and distinctive characteristic of Norman architecture. Here it is triplicate, with pendant drops somewhat resembling the guttæ of a Doric entablature. The second string-course exhibits the plain nebule corbel table; and the third is a simple tile moulding.

"In the lower story is a large archway, lofty and wide, for carriages, and in the centre of the South wall is the postern entrance, being a Norman transom doorway, the lintel of which has been cut out of solid stone. This doorway has been blocked up and hitherto unobserved, from being principally in that part of the wall which is below the present road. The principal entrance of the archway is to the West, under an elaborate deeply receding arch, with an angular pediment projecting from the face of the tower about five feet. This noble arch springs from three single pillars and a triplicate column on each side; and its mouldings are plain, with the exception of the outer one, which exhibits the double roll billet. The bases of these pillars are bold and plain, but being below the level of the road have been long hidden; the capitals are cushion-shaped and plain, with the exception of those to the triple-columns, which are sculptured—that on the South side with a representation, in bold basso relievo, of a lion destroying a serpent, which is subdued and under his feet; the other with a human figure between two winged dragons, who are biting their tails. A print of St. James's Church and Tower, engraved by Godfrey in 1779, represents the great arch as filled up, above the capitals, with masonry and sculpture, similar to that of the Abbey Gateway.

"The pediment is formed by two angular lines exhibiting the cable moulding; and the tympanum is decorated by a kind of diaper work of small segments of circles in lines, somewhat resembling scale-armour.

"The main entrance arch is flanked on either side by a square turret of three stories, terminated by a pyramidical apex. The lower story has a semicircular niche with the nail-head moulding. The second story has a similar niche with the double roll billet moulding on each jamb, and around the curve of the niche. In this niche, in the south turret, was a marble sculpture, which has been removed by Mr. Cottingham as it evidently formed no part of the original edifice. It appears designed to represent the casting of the apostate angels out of heaven.

"The corresponding niche in the north turret had also a piece of stone sculpture, till removed by Mr. Cottingham, which, though of more ancient date, was evidently an interpolation into the original building, the south jamb of the arch having been cut away to admit of its insertion. It must have been sculptured for the corner of some building, having two sides finished in high relief. It was probably found at some distant period among the Abbey ruins placed here for preservation, of which it is still worthy. The third story of each turret is ornamented with an arcade of interlaced arches springing from duplicate columns, and above is a corbel table cornice, with the corbels carved into heads, some of which are in good preservation. The whole is finished by a pyramidical apex.

"The second story of the Tower is pierced by two blank arches, each enclosing a small duplicate arch, which served as lights to a small gallery, constructed within the thickness of the wall, to permit of the warder's observing what might be going on in the town. These lights, with the exception of a small loophole in each, were blocked up till Mr. Cottingham's survey, when they were opened, and now add much to the beauty of the façade. Within the tower on this story, and near to the western piers, are small doorways on the north and south sides, which communicated by a few steps, still remaining, with the parapet of the embattled wall that surrounded the entire grounds of the Abbey. Their position is indicated on the north and south faces of the tower, by simicircular apertures in small flat buttresses. There must have been an unbroken communication along the whole line of the Abbatial walls, and these doorways show where the warders entered from the north, and passed to the south battlements. They also render it certain that there must originally have been a floor, in a line with the string-course, over the archway; and the contrivance by which it was thrown across was developed during a recent survey, by Mr. Cottingham. Equilateral spaces were left in the ashlaring on one side, for the insertion of the floor-beams, and on the other side were oblong spaces, between two and three feet high, into which the beams were dropped to their level. This plan of flooring furnished the old builders with great facilities for the repair of the floor; and avoided the necessity for those unsightly trusses introduced in modern carpentry. The architraves of the two front arches in this story exhibit some unusual and very beautiful mouldings, with a kind of arabesque and chain work, of a rare and singularly rich character. The masonry above the duplicate arches is ornamented by rows of small cones, resembling sugar loaves.

"The third story exhibits an arcade of three arches, divided into two stories by a plain transom running through the whole. The lower story is decorated by a duplicate blank arcade ornamented by a net-work. The bases of the two central pillars have groups of carved heads on their faces, and those of the lateral pillars exhibit a single head.

"The fourth story has an arcade of three lights with a circular panel in each base. The architrave is plain. Immediately above this arcade is the tile string-course marking the line of the embattlements, which are presumed to be the original finishing.

"The ascent to the embattlements is by a circular stone staircase in the north-west pier; entered through a narrow doorway in the north wall, which was originally approached by an external flight of steps."

In speaking of the manner of flooring the second story, the writer tells us in a note that in one of the caissons for the ends of the floor-beams, the workmen found the perfect mummy of a cat, who had probably taken refuge there when the building was in the course of erection, and had been immured by "the ignorance or wantonness of a Norman mason." By the licence of an abominable figure of speech, the caisson in which puss was found is termed a *cat*acomb. Mention being made of a *vesica piscis*, supposed to have formerly adorned the great arch, the following account of the term is given in a note, page 4.

"The "Oxford Glossary" describes the *vesica piscis* "as a mystical figure, of a pointed oval or egg-shaped form, originating in the figure of a fish, one of the most ancient Christian symbols, emblematically significant of the word ιχθυς, which contained the initial letters of the name and titles of our Saviour. The symbolic representation of a fish we find sculptured on some of the sarcophagi of the early Christians, [who, Tertullian says, called themselves *Pisciculi*, considering that the Christian life commenced in the waters of baptism] discovered in the catacombs at Rome; but the actual figure of the fish afterwards gave place to an oval-shaped compartment, pointed at both extremities, bearing the same mystic signification as the fish itself, and formed by two circles intersecting each other in the centre. This was the most common symbol used in the middle ages." In this country it is found in a variety of positions, and of various dimensions, both in stone and on painted glass. It is to be seen over many Norman doorways enclosing the figure of Christ; in the form of certain windows, as in the beautiful chancel window at Mildenhall parish Church; in the shape of the seals of religious houses; and to it some writers have attributed the origin of the pointed style of Architecture. French antiquaries see nothing in this oval but "a glory;" and M. Didron says the term "*vecisa piscis*," which was invented, and is abused, by English antiquaries, ought to be repudiated for its grossness. The term, however, is spoken of by Albert Dürer, at the commencement of the 16th century as one well understood at that time. An interesting paper on this subject, from the pen of Mr. George Godwin, Jun., F.R.S., illustrated by various examples of its use, will be found in the *Civil Engineer and Architect's Journal*, for April 1842."

The attempt to derive the forms of arches and plans of churches from the form of the bladder of a fish was made by Mr. Kerrich, of Cambridge, in the Archæologia. The able pamphlet from which the preceding extracts are made is, we believe, written by Mr. Tymms, the secretary to the Restoration Committee, to whom we are indebted for the wood-cut at the head of this paper.

RAILWAY SYSTEM.

The following extract is taken from the Evidence of Mr. Cubitt before the Select Committee of the House of Lords. Instead of recommending for general adoption the gauge of those railways in which he himself is particularly interested, Mr. Cubitt appears to view the question on its general merits.

I think an uniform gauge might be made throughout the kingdom, which will be better than either of the present gauges, and at a very moderate cost; at a cost which would be scarcely felt by the railway companies.

Can you make any sort of estimate of what the expense of the alteration would be?—Not a decided estimate what it would cost to alter the gauges; but I could state a minimum and a maximum. I would say it would cost from £500 to £1,000 per mile to alter the gauges. That is not a large sum.

Will you state how you would propose to alter the gauges?—It is a thing very easy to do practically; but there is a little to be cleared away first. Almost all persons think, or are taught by a certain class of persons to think, that if we were to alter the narrow gauge to a wider gauge it would be necessary to alter the existing bridges and tunnels, and so on, through which the carriages pass. Now that is not at all necessary; the carriages on the Birmingham line, and the generality of carriages almost, are sufficiently large for any gauge whatever; their post-office carriages, and their large horse boxes, and the very largest trucks, are sufficiently wide for any gauge that could be a fair workable gauge. They are big enough for the wide gauge, for I believe their post-office carriages are as large as the Great Western passenger carriages. That being premised, it will be evident that if we take for example the large carriages of the London and Birmingham Railway, which now pass upon that line through the bridges and tunnels, and pass within a certain distance of each other, and pass safely, you have only to suppose the carriages to remain unmoved sideways, and simply to imagine that the wheels are slipped right and left, brought out a little, about six or eight inches. A six feet gauge would work with the wheels set within the breadth of those large carriages, and the carriages would run exactly in the track as they did before. Consequently if you do that there is no necessity for any alteration of the tunnels, &c., about which so much objection is made. If we want to make the gauge wider, we have only to bring the rails out about eight inches on each side, and there is still plenty of room.

You only alter the under carriage?—Yes.

You put the wheels at a greater distance?—Yes; and the wheels will still be within the width of the carriages. Therefore, as the carriages pass each other now at a certain distance, they will still continue to pass each other at the same distance. The gauge will be a better gauge, and it will enable us to bring the centre of gravity of the engine lower down, as well as to widen the gauge.

Do you consider that the bringing the centre of gravity of the engine lower is a very important point for safety?—Yes; but that has never been done yet.

And practically the carriages now in use upon the narrow gauge are of such a width as to allow of that operation?—Yes. Since this thing has been rather more upon my mind I have given particular attention to it. I have now the prospect of having some control over nearly 1,000 miles of railway between the north and south, in large and direct lines, and I should be most happy if I could see my way open to improve the gauge which might be adopted in the first instance.

You have stated that there is no difficulty as to bridges and tunnels; is there any as to embankments?—There is no difficulty as to embankments; no carriage overhangs the embankments.

It ought not to do so?—I believe it never does. The means of widening that I should employ would be very simple. The rails are almost all laid upon cross sleepers or upon stone blocks; now with respect to those which are laid upon cross sleepers, it has been stated that it would cost a great deal to alter the railway because of the cost of taking it up and relaying it altogether. Now I will undertake to widen the gauge, if the road is in good order, in a very little time and at very little cost, and without disturbing a single rail on its chair, or a single chair in its sleeper. I should simply cut with a saw through the sleeper in the middle of the line, and just put each out eight inches, and then nail a short piece of wood in to connect the two parts of the sleeper. The thing would cost very little to do.

Would that leave you with a trustworthy sleeper?—Yes. And we will take the case of stone blocks. A great many miles of some of our greatest lines are laid with stone blocks; simply a small block upon the ballast. They will only want removing six or eight inches out.

The alteration, at all events, of the permanent way could be made without stopping the traffic?—Certainly. I am now going to relay a line entirely; a new set of rails and fixtures altogether, and I shall not stop the traffic; yet there are 80 trains a day on that line, or 40 each way.

Where is that? From London to Croydon.

Do you consider that there is room for great improvement in the permanent way?—The permanent way is the most defective part of the railway system.

Are not many of the rails that have been laid down upon the lines at present at work too light?—The rails are, many of them, too light; but we can always meet light rails by a different mode of laying them. But the great defect is the want of proper attention to the fastenings of the rails and the chairs. I attribute almost all the accidents that have happened from engines and wagons and carriages getting off lines of railway to the imperfect state of the road; and yet no sooner has an accident happened, than the engineers go to examine the engines, and examine the carriages, to find out what is the matter. The fact is, the cause is done away with; because it generally happens in most of those cases from the ends of the rails getting out of the joint-chairs, or the end getting loose, that it must inevitably throw off the engine, and throwing off the engine it tears up the line at the place, and we never can see it, because it is done away with. I have seen 100 yards of line torn up entirely from an engine running off the rails.

There was an accident not long ago upon the Brandling Junction, where the engineering officer sent down to report upon it stated that he could discover no cause for it. Do you think that it probably was from some defect of this kind?—No doubt of it. I have witnessed an accident upon that very line. The engine and carriages tumbled over one another, and the line was torn up for 100 yards; but I knew from what had taken place just before upon the line that that was from the defective state of the road.

And you think that in the case referred to in the preceding question, when it was clearly proved that there was no fault in the arrangement of the points, or in the engine, in all probability there must have been some fault in the permanent way?—Yes. When the permanent way is a little defective the shock becomes very sharp, and the rails, resting in an imperfect chair, are apt to work out. I am now having chairs made with a very long socket, to prevent the ends of the rails getting out, for when one of those ends gets loose it jumps up or gets sideways, and it must throw the engine off, and in doing that it must break the chair to pieces.

One of the witnesses has stated, when the Gauge Commissioners were down near York, the engine they had went off the line, and was upset; and that that was occasioned very much by the great length of the engine; and that they found on the rails the marks showing where it had struck, by the great sway backwards and forwards; till it found a defective rail, and then it went off?—I have seen rails and sleepers moved out of their place from the oscillations of an improper engine upon a badly laid road. I mean an engine not well balanced, and having too much play.

Do you think that if it were possible to get the weight lower down, by a greater width of gauge, it would in a great measure obviate that?—The difficulty would be obviated altogether by a wider gauge, a better road, and an improved engine. We might then go 100 miles an hour with as great safety as we no now do 30; there is nothing to limit the speed.

Is not it from the increased rate of speed that engines so frequently burst?—No; it is a small tube that bursts; a tube about two inches diameter. There are about 90 to 120 of them in each boiler. After they have been used some time they wear thin, with the draught and the fine particles of coke; one tube may be a little defective in its making; and when a great pressure of steam and the action of the wear upon them cut them thin, sometimes they will burst, and the water will flow into this tube, and the steam will flow out, and stop the engine going.

Does that ever happen with any but fast trains?—Yes; but you do not hear of it. Indeed it would be rather less likely to occur with an increased rate of speed, because when the engine is driven very fast there is less pressure upon those tubes.*

When the directors of a railway are desirous of remedying the want of power, what is the expedient to which they have recourse?—To build larger and more powerful engines. They require to be made either longer or larger to make them more powerful. Some of the engines on some of the lines, I believe, are worked up to more than 100-horse power. That is an enormous thing in that space.

If for the purpose of increasing the power the expedient adopted is that of lengthening the engine, does not that increase the danger upon the narrow gauge?—No; not the lengthening it, but the raising it higher makes it more dangerous. They have to make them higher when they make them larger and more powerful.

A witness stated the other day, that projecting the engine very much over the wheels, if they could not extend on account of the turn tables, caused oscillation from the weight being fore and aft?—So it does. That was the great defect of the engines on the Eastern Counties Railway, and caused the late accident on that railway. In making them longer it brings the wheels too far apart, and there was an overhanging weight.

Would not also the great length of the engine be inconvenient in a curve? The longer engines are between the wheels the more they are likely to impinge upon the rails in going round very sharp curves; but that is obviated in America upon another plan, and I recommend the plan very much to the Gauge Commissioners. I told them that all those things may be overcome with proper arrangements. On narrow gauge railways they cannot go so fast as on broad, because they cannot get as large driving wheels with safety, without carrying the centre of gravity too high. I could make an engine of any length which should be better adapted for going round curves than any engines now are. For instance, an engine 20 feet long might be made perfectly safe and steady with very large driving wheels upon a narrow gauge, even with wheels as large as the Great Western wheels, simply by having what the Americans call a "Bogy" carriage—a small carriage with four low wheels moving upon a centre horizontally. Imagine a small truck with four wheels upon the line; then imagine another small truck behind it with four wheels. Now those wheels and axles would be stronger than the present ones, and lighter. Then, if we support a very long boiler indeed upon those trucks, the trucks with four wheels can each turn independently at each end. Then anywhere between those we may have large driving wheels without flanges, there being eight other wheels to take the weight at both ends. We might have the driving wheels of any height; then they would turn round curves very rapidly indeed. I explain this to show that there are no insurmountable difficulties mechanically, for the wheel might be improved in every respect.

Still you would recommend, as the best security for safety, an alteration of the narrow gauge to a wider gauge?—Yes; to a reasonable gauge. The lower the centre of gravity the greater the safety.

Will you state what width of gauge you would consider the best?—A six feet gauge I take to be about the best that could be adopted, or it might be five feet eleven or six feet one; a few inches more or less is of no consequence, but six feet is about the best gauge; it is an integral measure, it is an even measure, it is an easy measure, and it is of easy reference, and well understood.

Is that the gauge which was recommended by the commissioners upon the Irish railways?—They recommended six feet two inches; but I do not know why the two inches were put on.

Have you ever made any estimate of the cost of altering the carriages or wagons?—The first, second, and third class carriages will cost about the same sum almost to alter. The average passenger carriages may be altered from a four feet eight inches and a half to a six feet gauge at an average cost of £30 each, and I think for less.

By multiplying the number of carriages constituting the stock of the different companies at present at work you could ascertain the total cost of altering the carriages?—Yes; and it would cost £350 to £400 to alter an engine and tender, leaving the working parts exactly as they are now.

So that it would be perfectly possible to ascertain the total cost of the alteration?—Yes.

Have you ever turned your attention to the means of providing the necessary sum to defray the expense of the alteration?—I think it should be paid for partly by time gone by and partly by futurity; that is to say, money might be taken up at a certain rate of interest for doing this work, either from Government or by transferable bonds, payable off by lot; any thing of that sort. Then the works should be paid for as they were done. Whatever they cost should be apportioned, as nearly as it could be, over about 40 years; that is, 20 by-gone years, and 20 future years of railway extension; and all newly-made railways should pay their quota of the alteration as the past had paid; so that in 40 years, or 45 or 50 years, the thing should be paid off, and the work all done. The work should be all done at once, for the sake of the public. It would be paid for in a long time, for the sake of the parties. It would not tax any company harshly to make the alteration, and therefore they could not complain of it in point of expense. All the new railways would have to pay a quota for the same thing, although they would make their gauges right in the first instance. I think that is but fair.

You have no doubt that it would be of considerable advantage to the country in many points of view that there should be but one uniform gauge?—There can be no doubt about that.

Both for traffic and for the military defences of the country?—Yes; in every respect; I will not make one exception, because I do not think one can be made. But I should be sorry to see other narrow gauge lines granted if there is likely to be an alteration, because there will be many miles of new railway; many more than are made; I think twice as many.

You think this is a good opportunity for making the alteration?—I think if the thing is ever to be done there should not be a season lost, certainly. I think the thing may be easily done, and economically done, and done without loss to the public and without loss to the companies, and in a very short time, and at a very moderate expense.

You think it very important that if anything of the kind is contemplated it should be settled with the least possible delay, in consequence of the numerous railways now in progress?—I think so. It is a very serious subject, but almost all parties who speak upon the subject are in some way or other interested in this, that, or the other gauge.

You think it is very important that it should be practicable to go at high speeds on railways for persons who have to go great distances?—I think that is evidenced every day, for if we put on express trains every day, and advertise to go at 60 miles an hour, people will risk their necks as long as you will carry them, and therefore it is highly necessary for the safety of the public (for people will not take care of themselves) to have all the machinery of the best kind, and if the permanent way is perfect, and the gauge a proper gauge, there is nothing to limit the speed but the resistance of the atmosphere. That I am sure of, as far as safety is concerned there is no danger.

No greater danger in going 60 than in going 30 miles an hour?—On a perfect railway there is no more danger in going 60 miles an hour than in going 30.

But the mere alteration of the gauge to the improved width which you propose to make it would not at once attain the increased speed which you hope to attain?—It would be the greatest step to it.

---

* It is asked with great deference whether the opinion be quite consistent with known mechanical principles. The pressure on the tubes will generally increase with an increase of velocity!—Ed

GASES AND EXPLOSIONS IN COLLIERIES.

The following interesting document is the report of a commission addressed by Lord Lincoln to Sir H. De La Beche and Dr. Lyon Playfair, for the purpose of obtaining information as to the best means of preventing, or mitigating, the fatal effects which are so frequently the result of the generation of noxious gases in coal mines:—

My Lord,—Having, in conformity with the instructions contained in the Earl of Lincoln's letter of the 27th of August, 1845, directed our attention to the composition of the gases evolved from coal beds, to the mode of ventilating collieries, and to the subject of explosions in them generally, we have the honour to submit the following statement for consideration.

With respect to the gases evolved from beds of coal, they may be viewed as the result of the continued decomposition of the vegetable matter from which coal is derived, a decomposition which may be regarded as still in progress under favourable conditions. Omitting the mineral substances, which, when burnt, are known as ashes, coal is essentially composed of carbon, oxygen, hydrogen, and nitrogen; and the quality of the coal depends upon the relative proportion of these ingredients. When the proportion of the carbon to the oxygen and hydrogen does not exceed about 75 per cent. the coal, in common terms, is called "bituminous;" when the carbon amounts to about 85 or 90 per cent. it is termed "anthracite," or stone coal: or, in other words, the most advanced state of decomposition of the original vegetable matter bears the latter name.

During the decomposition a portion of the carbon is removed by its union with oxygen, forming carbonic acid, and another portion by combining with hydrogen, as carburetted hydrogen. Thus by continued decomposition the carbon gradually becomes a more important constituent in the remaining part of the original vegetable mass. The change from bituminous coal to anthracite can be produced artificially, and in a manner to illustrate the subject, considered geologically.*

Though carbonic acid is, no doubt, found in many of our collieries in such a manner as to show it to be derived not only from the lights, horses, and workmen employed, but also to be partly the result of the progressive decomposition of the coal, it is with the carburetted hydrogen, or firedamp, as it is termed, that the collier has chiefly to contend. This comes upon him in various ways. Some coals more readily emit it than others, and hence they are locally termed fiery seams, beds, or veins. From some coals it would appear to escape more generally from the mass of the bed than from others, the gas gradually accumulating from the discharge over a wide surface. Other beds, again, are more fiery in the softer than the harder portions, and where joints or fissures are common. When two or more seams of coal, having different qualities, make up a workable bed, one will sometimes be more fiery than the other. Again, much depends, all other circumstances being equal, upon the kind of roof or covering rock of a coal-bed. If this be sufficiently porous, as many sandstones are, the conditions for the escape of the firedamp upwards through superincumbent rocks are more favourable than where the roof is composed of clay or argillaceous shell.

The dislocations of the strata termed "faults" or "troubles" act frequently also as channels for the passage of the firedamp into the works, as they conduct the gas from coal seams beneath, which may be highly charged with it, although the seam under work may be free.†

Although we may regard a large proportion of this gas as previously formed, and ready to escape when the necessary conditions, such as those of colliery workings, present themselves, we can scarcely suppose that carburetted hydrogen is not also formed during the time occupied by the progress of the same workings, much being evolved from the older portions of them. The manner in which splinters of coal are thrown off during the cutting of some beds has led to the hypothesis that the gas may be present in a liquid state, produced by condensation, so that when the needful pressure is removed during the progress of the work, the sudden expansion of the "fire-damp" from a liquid to a gaseous form throws off the fragments. The force also with which the gas bursts suddenly forth from clefts or joints in some beds of coal is so considerable as to prove much previous compression, particularly when those bursts or blowers last only for a short time. When they continue for protracted periods, we may infer a more constant supply from continued decomposition of the coal, though the first sudden burst would point to compression. It has been inferred that the small cavities in which the fluid gas is confined can be detected by the microscope in some coals. It is probable that soft places, the sides of joints and fissures, and the walls or faults, are more favourable to the decomposition of the coal than its more solid portions.

The escape of fire-damp is generally influenced by the barometrical state of the atmosphere, especially when much of the gas has become accumulated in the wastes or goafs. This is more or less experienced in all pits; but one striking case was pointed out to us by Mr. Jobling, of Jarrow Pit. In a pit of which he is the viewer the gas issues from cracks in the roof of the seam, and in low states of the barometer is evolved in considerable quantity. When the barometer is high, instead of this issue of gas, there is a sensible current of air which enters into the cracks. When this inward current takes place the pit is worked with naked candles, but when the evolution of fire-damp commences Davy's lamps are employed.

Assailed in this manner by a gas which, when mingled with atmospheric air in certain proportions, is highly explosive, a knowledge of its exact composition becomes a subject of great importance to the collier, since effective precautionary measures, more especially as regards the lights employed, must necessarily depend upon such knowledge.

Dr. Henry, Sir Humphry Davy, in this country, and Bischoff and others on the continent, have examined into the nature of the explosive gases of mines, but with results differing from each other; for while the English chemists found them to consist of carburetted hydrogen, with little or no admixture, the continental chemists have described them as very complex mixtures of olefiant gas, carburetted hydrogen, carbonic oxide, hydrogen, nitrogen, oxygen, and carbonic acid. On such a point ignorance would be culpable; and we were instructed to bring our knowledge up to the present advanced state of chemical analysis. Whilst we were engaged in this research, Professor Graham made a report to the Chemical Society on the same subject. The previous investigations of this chemist had rendered him well fitted for the task, and the results of his inquiries (according, as they do, with our own) amply guarantee that the subject, as far as relates to this country, may now be considered as decided, and show that the importance of an exact determination had simultaneously engaged the attention of the public.

It is unnecessary to describe in detail the methods which we pursued in the analysis; it may be sufficient to state that we adopted the methods mentioned in a report to the British Association on the analysis of gases by Professor Bunsen, and one of us. We may, therefore, at once tabulate our results, merely stating that we have devoted much attention to this investigation, so as to remove doubt upon a subject so important to the interests of the public. The gases were collected in various ways, some from blowers, others from the freshly exposed surfaces of the coal while the gas issued out with a singing noise, others from the explosive atmosphere of pits.

Gases.	Wallsend, from Pipe on Surface.	Wallsend, Bensham Seam.	Jarrow, Bensham Seam.	Hebburn, Bensham Seam. 161 fathoms deep	Jarrow, Low Main.	Jarrow, 5.4 Seam.	Gateshead, Oakwell Gate, 5 4 Seam.	Coal 24 ft. below Bensham Seam, Hebburn Colliery
Carburetted Hydrogen	92·8	77·5	83·1	86·0	79 7	93·4	98·2	92·7
Nitrogen ..	6·9	26·1	14·2	12·3	14·3	4·9	1·3	6·4
Oxygen ..	0·0	0·0	0·6	0·0	3·0	0·0	0·0	0·0
Carbonic Acid	0·3	1·3	2·1	1·7	2·0	1·7	0·5	0·9
Hydrogen ..	0·0	0·0	0·0	0·0	3·0	0·0	0·0	0·0

The general result of this examination is, that the only inflammable constituent present in the explosive gas of collieries is carburetted hydrogen or fire-damp; there is not a trace of olefiant gas, and only in one out of the eight gases analyzed is there hydrogen. It follows from the previous analysis that the issue of fire-damp into the atmosphere of a mine must deteriorate the air, by adding an undue proportion of nitrogen gas; in one case this gas amounts to 21 per cent. During an explosion the oxygen necessary to the respiration of the workers is removed by uniting with the carbon of the fire-damp, and thus producing carbonic acid, a gas most fatal to animal life. This carbonic acid, mixed with the residual nitrogen of the atmosphere, and that present in the explosive gas itself, forms what is termed after-damp, which produces effects more fatal even than those arising from the explosion. It often happens, that after an explosion a sufficient quantity of oxygen remains to support the respiration of those who survive its effects, were it not for the presence of carbonic acid. This gas, when present in no greater proportion than one or two per cent., is capable of producing the most injurious effects. It has therefore been suggested, that cheap mixtures, made of substances capable of absorbing carbonic acid, such as glauber salts and lime, would prove useful to those who try to aid the sufferers after the explosion. Such a mixture placed in a coarse bag and applied to the mouth would effectually absorb the carbonic acid, and prevent it exercising an injurious effect on respiration. Certainly the want of some such precaution in the case of the Jarrow explosion caused the death of a very meritorious man Jacob Difty, the overman of the pit.

An explosion is, however, generally attended with much more complex results than those described as attending the combustion of carburetted hydrogen. The amount of fire damp which may be first ignited may be trivial, and yet produce the most disastrous effects. From its lightness it accumulates at the upper part of the passages, and diffuses with considerable difficulty, often acting as a train, and communicating the explosion to the pent-up reservoirs of gas in the goafs. It is thus that in almost all accounts of explosions two are generally described as taking place; the first local, and at the seat of the explosion; the second more general, and aided by any accumulation of foul gas in other parts of the pit. In the case of Jarrow, the heat attending the explosion was so intense as to have thoroughly coked to the depth of nearly one quarter of an inch the coal lining part of

* Specimens in illustration of this, made by coking coal in a very gradual manner, are deposited in the Museum of Economic Geology.

the walls of one of the passages; an effect which could scarcely be conceived without supposing that the flame played for some time upon it with the intensity of a blow-pipe flame. The surface of coal thus acted upon was so considerable that the amount of explosive gases evolved during this coking must have been far from insignificant, and may have aided the explosion itself. Add to this, that the first effect of the explosion is to blow up and ignite the immense quantity of coal dust lying about the pit, and not only produce from it an evolution of gas, but also occasion the production of much carbonic acid. And it cannot escape attention that the whole subject becomes involved in much complexity. It is known that a certain mixture of air with carburetted hydrogen prevents its ascendibility; and, in the case of pure carburetted hydrogen, the proportion has been ascertained to be not less than 15 times its own bulk. But the variation in composition of the fire-damp of different mines, the uncertain modes of its issue, and the absence of any ready means of ascertaining its quantity, prevent any general rule being given as to the amount of air which should be thrown into mines to prevent the atmosphere ever attaining the explosive state. All this must be determined by practice to suit the varying conditions of different mines. It is certain that improvements might be made on the rude methods now in use for effecting the necessary mixture. The fire damp being, from its lightness, at the top, is not quickly, influenced by the current of cold heavy air descending the downcast shaft, and circulating through the passages. It is therefore not unfrequent to see colliers flapping their jackets among this light gas, so as to dilute it with the sufficient quantity of air, and thus disturb the train of communicating gas which, in a foul state, may connect two dangerous parts of a pit. Mechanical contrivances, such as fanners, would more efficaciously produce the result than the inefficient extemporaneous means referred to; but, in general, such arrangements are only necessary when, from a defective ventilation, the current of air through the pit is not sufficiently strong.

Various artificial means had been proposed to facilitate the withdrawal of fire-damp from a pit. Suggestions have been made to take advantage of the lightness of the gas by favouring its ascent to the upper parts of the pits, and drawing it off by special air ways. Pipes let down into the wastes have been proposed for the same purpose, while other suggestions have been made of pipes to blow in air at the tops of the passages, so as to cause the dilution of the gas.

We do not stop to consider these plans, because, as we have already stated, the conditions under which coal is worked are so numerous, that a plan which might prove useful in one pit would be wholly inapplicable and sometimes positively injurious in another, and the legislative application of any one plan might prove highly prejudical to this great branch of national industry.

In 1835, a Select Committee of the House of Commons was appointed to inquire "into the nature, cause, and extent of those lamentable catastrophes from explosions which have occurred in the mines of Great Britain, with the view of ascertaining and suggesting the means of preventing the recurrence of similar accidents." Numerous witnesses were examined before this Committee, a body of important evidence collected, and a report published in the same year,—a report replete with valuable information, and to which we would wish to refer for ample details connected with the general mode of working collieries, especially in the north of England. The Committee observe, on the subject of colliery explosions, that while the loss of interrupted trade by these accidents is enormous, "it is nevertheless rather with reference to the cause and interest of humanity than in a pecuniary point of view that this inquiry has assumed its great importance." This Committee did not recommend any remedial measures.

The difficulty experienced of obtaining accurate information respecting the number of lives lost from colliery explosions within a limited period is nearly as great at the present time as it was in 1835. And it should be borne in mind that the number of lives lost by the great explosions, those which chiefly become known and arrest public attention, by no means affords a correct view of the collective loss of life sustained by colliery explosions generally, including the minor accidents not commonly heard of beyond limited districts; neither does it represent the injury sustained by these explosions, short of the loss of life, but from which many persons are more or less disabled.

The Committee were enabled to ascertain that during the 25 years preceding these inquiries 2,070 persons had perished from colliery explosions; and they considered this number much underrated. During the last 10 years the rate of loss of life from this cause has certainly not diminished. The experience of the past year has shown that considerably more than 100 persons have been known to have thus perished.

It has so unfortunately happened that, during the few months we have been engaged upon this inquiry two explosions, one at Jarrow in Durham, and the other at Risca, in Monmouthshire, have together deprived 76 persons of their lives, 41 having perished at the former and 35 at the latter.

By direction of Sir James Graham and the Earl of Lincoln, we were commissioned to ascertain the causes of both explosions. It so occurred that, being at that time in the south of Ireland, engaged on the duties of the geological survey, Sir Henry de la Beche could not reach Jarrow in time for the inquiry, and therefore the investigation into the cause of the explosion at that place devolved upon Dr. Playfair, who, under these circumstances, availed himself of the services of Mr. David Williams, at that time one of the geologists attached to the geological survey of Great Britain, and well skilled in coal mining, but now in the service of the East India Company, examining the coal resources of India. The results of this inquiry are given in the accompanying report by Dr. Playfair.

Immediately after the explosion at Risca on the 14th of January, 1846, instructions were again received to proceed without loss of time to that colliery. Dr. Playfair being, however, so engaged upon duties in London, that he could not readily proceed to Risca, the investigation was undertaken by Sir Henry de la Beche, aided by Mr. Warrington Smyth, mining geologist to the geological survey of the United Kingdom, who was in every respect qualified for such an inquiry. The accompanying report contains the results of this investigation.

During these inquiries it became very important carefully to consider the kinds of lights employed in collieries, and the usual regulations respecting them. The subject was not new to us, since for more than 25 years the mode of working collieries in different parts of the United Kingdom, as also on the continent of Europe, had engaged the attention of one of us. On the subject of safety lamps, of lighting generally, and of the regulations connected with it, the Committee of 1835 collected a large amount of evidence, more especially regarding our northern collieries. In the report of the South Shields Committee of 1843 there is also much information on this head. To these reports, therefore, we would wish to refer for sufficient information on the subject.

The Committee of 1835 pointed out that more persons had lost their lives from colliery explosions for the 18 years succeeding the introduction of the Davy safety lamp in 1816 than in the 18 years preceding the invention, and accounted for this fact by the working of numerous "fiery" seams of coal, which had, in consequence of the assumed security of that lamp, been undertaken, and by the abandonment of many precautions considered requisite when candles were commonly employed in collieries.

As much doubt has been thrown upon the real safety of the Davy lamp, it is but justice to the memory of Sir Humphrey Davy to state that he was perfectly aware that, if a proper mixture of fire-damp and common air were thrown against the lamp with sufficient force to project the flame upon the gauze cylinder, it might communicate with the flame, and cause explosion. Mr. Buddle, in his evidence (Report of Committee of 1835, Nos. 2,226 and 2,227), clearly shows this to have been the case. He mentions an experiment at Morton West Pit, were a very powerful blower from the shaft was tried with the lamp, when the flame passed and the blower was fired. Sir Humphrey Davy then, addressing Lord Durham, and many other persons who were present, said, "Now, gentlemen, you see the nature of the danger to which you are exposed in using the lamp, and I caution you to guard against it in the manner I have shown you. This is to show the only case in which the lamp will explode; and I caution and warn you not to use it in any such case when you can avoid it without using the shield." The shield recommended was one of tin, inside the cylinder, to prevent a current of fire-damp from acting on the flame. Mr. Buddle stated before the Committee that in the lamps used in the collieries under his management the shield passed from one-half to two-thirds round the inside of the cylinder, and, being bright, reflected the light to such an extent as to be more advantageous than a glass cylinder inside that of wire gauze, a contrivance often recommended to obviate the risk of currents of fire-damp.

Dr. Pereira, at the request of the Committee of 1835, experimented upon many lamps before them, and passed the flame through all those tested, except that of Messrs. Upton and Roberts. The experiments have been repeated at the Museum of Economic Geology, by Dr. Pereira and by ourselves, with the ordinary Davy lamp, and with the same results.

There can, therefore, be very little doubt that the flame can pass, and explode fire-damp adjacent, if the current be sufficiently strong, and no protection be afforded either by a metallic shield or by an internal glass cylinder. The question as to the amount of current required seems not so well ascertained. Mr. Buddle considered that the blowers would rarely be found strong enough. Mr. Stephenson supposed that many accidents may have happened by the falling of the roof producing a sudden rush of explosive fire-damp. It will be obvious that the same effect might be produced by the careless swinging of the lamp with the required velocity through an explosive mixture of fire-damp and air, or from the lamp being so jerked out of a collier's hand, by an unlucky fall, that the cylinder presented the necessary front to the same compound.

Without desiring, in the slightest degree, to cast unnecessary doubt on the safety of the Davy lamp, since we consider its cautious use an immense boon to coal mining, and believe that much additional security is obtained by the proper use of the original Davy, or of its improvements, it can scarcely be denied that far more care in the use of safety lamps is needed than is commonly employed. Although shields or glass cylinders are used in some localities they are never employed in others; and the bare single cylinder of wire gauze, not always properly manufactured, is the only form in which the Davy lamp is known. And it should be observed that, with a few local exceptions, the Davy lamp is that commonly employed. Numerous modifications, and in some cases improvements, of the safety lamp have been made, but, either from the expense, or want of simplicity in management, have never come generally into use.

The colliers, by their usual mode of carrying the common Davy lamp, certainly, under ordinary circumstances, guard against the passage of any current of fire-damp sufficiently strong to pass the flame, by placing the lamp within their jacket flaps, or carefully protected in some other manner. Abundant carelessness is often, however, apparent; and, when the collieries are viewed as a whole, unnecessary risk is too common, especially when it is recollected that the fool-hardiness or carelessness of one may destroy the lives of many.

To those who have, during many years, had occasion to visit collieries in different parts of Great Britain, the thoughtless daring of many of our colliers, and their frequent carelessness under danger, must be familiar. They will often, in an endeavour to execute more work in a given time, when paid by the ton or piece, remove the covers of their lamps, or employ a candle at a risk. Some even prefer a candle to ascertain the presence of fire-damp, since by it they more readily see the change in the flame. In many districts, though in some they are anxious to employ the safety lamp, it requires much trouble on the part of the managers to prevent the continual use of candles in suspected places before the danger becomes known to them. The less light afforded by lamps is considered a great drawback to their use when it can be avoided. Many most careful men, no doubt, anxiously watch over the common danger, and great precautions are taken by many coalowners and workers; but looking at the subject generally, and without reference to many exceptions, especially to be found in the north of England, the want of system in the management of lights, and in due precautions respecting the kinds employed, can scarcely escape the observation of those whose opportunities have been sufficiently extended.

When we consider that the safety lamps have now been in use for so many years, causing security in all cases where proper care is employed, although they may not be absolutely safe under unusual circumstances, their utility appears sufficiently sanctioned by experience to make them the subject of legislative enactment. The evils complained of in the modifications of the Davy lamp are, that, while they add to the security, they diminish so much the amount of light, as to render them practically useless. These are described in the report of the Select Committee referred to. A new modification of Dr. Clanny's lamp, invented since then, is not subject to this fault, and in principle is an elegant application of the safety lamp, and consists of a wire-gauze cylinder, having beneath a thick glass cover to the lamp, which only ascends till it meets with the gauze; the thickness of this glass is supposed to free it from accidents, and, whilst strong enough to bear a considerable blow, it is sufficiently well annealed to resist sudden changes of temperature. But whether, in a manufacture so uncertain as glass, these conditions can always be attained, is questionable, and at all events has not been sufficiently tested by experience to induce the coalowners to employ this lamp in their mines.

It has been at various times proposed, during the last eight years, to employ electricity as a means of lighting collieries. The electricity, streaming between two charcoal points from a Grove's or Bunsen's battery, affords a light of much beauty, and perfectly safe, if completely surrounded by glass, but capable of igniting an explosive mixture if exposed. Professor Grove has constructed a lamp on this principle, which he kindly prepared for us, and which we have examined in action. It consisted of a box, containing four galvanic cells, and the light was obtained by the passage of electricity between two coils of platinum wire. These were surrounded with glass vessels; the inner one for the purpose of isolation, the exterior one being filled with water, so as to destroy the light should the inner glass vessel be broken. The light given out was rather more than that of a miner's candle. This, certainly, is a safe lamp, but in its present state still unfitted for the purpose of the collier as at present arranged. The acids, sulphuric and nitric, render the lamp so inconveniently heavy, that both hands must be used in carrying it; besides, from not being covered, the spilling of these corrosive liquids on the persons of the miners could scarcely be avoided. The water in the exterior vessel soon becomes heated, and ultimately boils, and the light only lasts in proper strength for two or three hours. There must, therefore, be considerable modification in this lamp before it can be rendered available for ordinary mining purposes, which we may readily expect, from the acknowledged talent of its inventor.

The means of obtaining the needful lights in collieries, though most important, would still appear subordinate, as has, indeed, been before remarked, to such a system of ventilation as should not expose men in such large portions of a colliery as is now frequently the case to the risk of death from explosion (the greater proportion, and often all, perishing from the carelessness of one man), or to unforeseen accidents under the greatest precautions in the use of lights. The too common use of single shafts in collieries, in cases where others might have been sunk, the single shaft divided into two or three portions by wooden partitions named brattices, a down current of pure air descending through one division, and the foul air from the colliery workings rising up through another, has often been reprobated. The Committee of the House of Commons of 1835, and many important witnesses examined, animadvert upon this practice; and the bad effects of this system is pointed out by the South Shields Committee in their report of 1843.

In a single shaft, as has been often remarked, the ventilation may be cut off from the workings of a whole colliery in an instant by an explosion sufficient to destroy the doors or partitions directing the air-courses, the air merely going down one division in the shaft and rising through another, when the brattices may not be destroyed by the explosion, and a kind of draught kept up. Thus all not destroyed by the explosion perish in the mixture of nitrogen and carbonic acid, known as after-damp, to which no fresh air can reach. In the explosion at Jarrow Colliery there was only a single shaft communicating with the workings upon two beds of coal one above the other, and the lower part of the brattice in the shaft was so shattered by the late explosion in it, that Dr. Playfair and Mr. Williams, in their descent into the pit, then containing a large amount of fire-damp, had to be let down a considerable distance by a loop in a rope. In this explosion the upper portion of the brattice fortunately remained, and thus the lives of many of those engaged in the upper workings were saved, although several perished.

Even in a double shaft, or two shafts not far distant from each other, if the air be not made to course for a considerable distance amid the workings by a firm thick parting of coal, any needful perforation in the parting for the progress of the colliery being firmly built up, a whole mass of workings may, by an explosion, be suddenly cut off from ventilation, and numbers of persons, not killed by the explosion, perish by the after damp. This was the case at the late explosion at Risca. It should, however, in this instance, be observed, that the colliery was, as regards ventilation, in a transition state, a more perfect arrangement for ventilation being in progress.

Great improvements were introduced in the ventilation of collieries in many districts, when the course of air was quickened by means of a furnace established near the bottom of the upcast shaft, or that through which the foul air passes outwards, and more particularly when, in the north of England, instead of permitting the air introduced by the downcast shaft to pass slowly and imperfectly along a course of 20 or 30 miles of passages, it was split or divided into separate courses, from two to six miles in length. Those, however, who may possess an extended acquaintance with our collieries in different parts of the country cannot but be aware, that, as a whole, their general ventilation is very imperfect, good as it may be in some collieries, particularly in certain districts.

When it is considered that coals are worked in the United Kingdom under every variety of condition,—from levels driven into mountain sides to pits sunk to great depths through masses of superincumbent rocks,—in beds ranging from a vertical to a horizontal position, and even contorted and bent,—sometimes traversed by faults, at others free from them,—the beds near the surface in one place, and ranging beneath mountains in another,—in fact, under a great variety of geological conditions, it is not difficult to see that many plans which have been suggested for the working of collieres, good as they may be for some localities, would be inapplicable generally, and would indeed fail, except under the conditions fitted for them.

So various are the conditions under which collieries are or can be worked in the United Kingdom, that we would suggest for consideration, if legislative measures should be deemed advisable, and an extension of the principle which regulates the employment of women and children in our mines, and the labour in our factories, be thought good, that effective discretionary powers should be vested in properly qualified persons, appointed in convenient districts, so that the needful adjustments to conditions may be effected, and no single system be attempted inapplicable to our collieries as a whole.

Any general system of legislation for conditions so different could only be productive of failure or of injurious consequences, both to owners and workers; but a local examination and inquiry, with power to adjust to special conditions, would, we apprehend, remove the difficulties which the Legislature has felt in dealing with interests so important.

Jealous as the coalowners should properly be of any undue intermeddling with their collieries, it may nevertheless be true that a judicious system of superintendence in a district, by which the proper ventilation of collieries, efficient knowledge on the part of subordinate agents, and proper punishment for fool-hardiness or carelessness on the part of the colliers may be secured, would be a great advantage to them individually and collectively, and be the saving not only of lives but of much capital, securing them, in the case of accidents, from many an unjust accusation for neglect.

On the other hand, careful but not overmeddling supervision would afford confidence to the collier. Proper persons being appointed as superintendents (and, if improper, their deficiencies would soon become apparent, and their removal the consequence), he would feel that he has the advantage of the existing knowledge of the day brought to bear upon the particular conditions under which the colliery in which he labours is worked. In some districts the working collier is far better informed upon the general principles which should receive attention than may be commonly supposed, and he would feel far more secure from danger than he now does, if assured that the State was not neglectful of his safety.

Though several collieries in particular districts possess good plans and sections of their workings, and an inspection of such plans and sections affords a view of the system of ventilation and general mode of working adopted, this is far from being the case generally, and has been much regretted alike by the enlightened coalowners and by the public. The importance of correct plans and sections has been prominently pointed out, both by the Committee of the House of Commons of 1835, and in the report of the South Shields Committee of 1843; indeed, the necessity of them is sufficiently obvious.

Should the suggestion of a system of judicious inspection be considered worthy of consideration, the ready access to proper plans and sections of collieries, brought up to given times, would necessarily form a part of any general system of regulations. If correct (and power to ascertain that they were so would be essential), they would at once disclose the system of working and ventilation adopted, and, with information respecting the police regulations, and an account of the kind of lights employed, would at once afford a general view of the mode of conducting any particular colliery, and of the adjustment of the workings to conditions.

It being considered that safety lamps, properly used, do effect much security in the working of coal, and that in so many cases explosions do take place when they are not employed, it has often been suggested that the Legislature should compel the general use of safety lamps in coal mines. But, on the other hand, there are many collieries in which fire-damp never appears, and it would justly be considered a hardship in such cases to compel a precaution altogether unnecessary.

We would suggest that it could not be considered unjust for the Legislature to compel the use of safety lamps in all fiery collieries; and, in the present state of the law of property, it might even be prudent to assume that all collieries in districts where explosions have been frequent are fiery, putting the *onus probandi* that they are not upon the owners of such collieries. If proved to the satisfaction of the inspectors that no reasonable danger was to be apprehended in their collieries, license might be given for them to work with naked candles, this license ceasing at short periods, but being renewable on ascertaining that the conditions of the mine had not altered.

Careful investigations into the causes of explosions in collieries, only part of which arrest public attention by their magnitude, appear to have led to the very general conclusion that the condition of our collieries is most unequal. While in some localities there is so little to improve that it becomes subject of regret that such examples should not more generally be followed, in others it becomes a matter of surprise how the works can be permitted to remain in so defective a state, seeing that the owners themselves suffer much loss thereby. Under such a state of things, and considering the number of valuable lives annually lost by colliery explosions, the continued risk to which so many are daily exposed, the national injury sustained by the imprudent and careless mode of extracting coal in many localities—one often felt oppressively also by the parties engaged in colliery speculations—and that the workings for coal must be adjusted to local conditions, we are led to consider that these evils might be at least mitigated by the careful and judicious inspection of convenient districts by competent persons, the necessary funds to be raised from such districts by a very slight impost, not even exceeding one farthing on each ton of coal raised in it; and we believe that the cause of humanity and the interests of the coalowners would be alike benefited by a well-considered legislative measure of this kind.

We have, &c.,
H. T. De La Beche.
Lyon Playfair.

THE HOUSES OF PARLIAMENT.

The following are portions of Mr. Barry's evidence before the Committee appointed to inquire into the progress of the Houses of Parliament:—

"The committee had an impression, from evidence given by you on a former occasion, that you would be willing to undertake to warm and ventilate the new House of Lords upon a system of your own?—I believe I so stated.

If you were to adopt a system of your own, would it render it impossible hereafter to revert to such a system as Dr. Reid has in a general way recommended or suggested?—Is it meant that that question should apply to the House of Lords exclusively, or to that and any other portions of the building?

To the House of Lords exclusively?—As the subject is altogether new to me, I could not at the present moment answer satisfactorily; but if your lordships would give me four-and-twenty hours to consider that point, I will then be prepared to give you a definite answer to the question.

Do you think that you could prepare the apartment for the Peers by the commencement of the session of 1847, if it were ventilated and warmed according to your own system, and without any interference with your system from any other quarter?—Until I have determined what that system shall be, it would be rather difficult for me to answer that question. With respect to the fixing of the joiners' work, as unfortunately a very large portion of the year, and the portion best adapted for fixing work of that description, has been suffered to elapse, I should be sorry to pledge myself that I would completely finish the House of Lords by the time mentioned, viz. the commencement of the next session; but all I can say is, that I will do every thing in my power to accomplish the object, and I trust that I should at least be able to bring the House into such a state as, if not completely finished, it might be occupied by your lordships.

The "session" is rather an indefinite word; do you mean by the 1st of February?—I understand the commencement of the session to mean the 1st of February.

You think you could get the House ready by the 1st of February?—I should not wish to pledge myself to have the House completely finished in all respects by that time; but I think I could finish it so completely that it might be occupied by your lordships.

You mean that every convenience for the sitting of the House might be supplied, although the more ornamental parts might not be finished?—Exactly.

Has any further advance been made in the arrangements of Dr. Reid since you were last examined before this committee?—Not that I am aware of.

Have you the slightest hope, from what has already transpired, and from what you are able to collect, that the work would be at all advanced by this time next year, unless some new arrangements were made with regard to the ventilation?—I must say that I have no hope whatever.

All the fittings are prepared?—They are, with the exception of portions of the throne, and they would be prepared during the time that the rest of the fittings were being fixed.

In making any arrangement for the ventilation, you do not conceive it will be necessary to destroy any part of that which has already been prepared in connection with the arrangements suggested by Dr. Reid?—I do not think it would be necessary to destroy any part; it would be necessary, probably, to modify some of the arrangements, in order to make them available to my own system, if I may so call it.

In the arrangement that you would contemplate for warming, you would not have to alter the ceiling, or any thing that has been done there?—Not at all.

Is the putting up of the ceiling a very expensive work?—The putting up of the fittings is a very expensive and rather tedious work; the work is of an unusual description, and will require the greatest possible care in fixing.

Are you in such a state that you could proceed immediately towards the completion of the House if you received the necessary authority?—Yes; I am quite prepared to do so.

Will you describe the state of forwardness of the building adjoining the House, including the lobbies?—The Victoria Hall, which is the apartment immediately adjoining the throne end of the House, is covered in, and the ceiling is nearly fixed. I think it possible to make that room available as well as the House, although the fittings which are to be placed in it might not be completed. The public lobby is also roofed in, and the ceiling is completed, and if it were necessary, that portion of the building also might, I think, be got ready for use. The finishings of the corridors adjoining the House on each side are entirely prepared, and I think, if the time is sufficient for fixing the work, which is very minute and elaborate, there is no reason why the corridors should not also be made available for occupation with the House.

What is the state of the royal gallery?—The roof of the royal gallery is on, and a commencement is made with the fixing of the ceiling.

What is the state of the Queen's robing room?—The roof is over the Queen's robing room, and the brick arches forming the ceiling are turned, but none of the fittings are commenced.

In what state is the staircase from the royal entrance?—That is in a very forward state. All the stonework is completed, or nearly so, with the exception of the steps.

Have you sufficiently digested your plan for the ventilation to be able to state in what manner you propose to introduce the air into the House and the lobbies?—No, I have not, because my attention has not been directed to that part of the subject.

But you have stated that you would be prepared to undertake the ventilation and warming of the new Houses, and to complete the arrangements before the meeting of next session?—Yes.

Without tying you down to a day, you can have no objection to the committee reporting that you propose to ventilate and warm the apartments upon your own responsibility?—None whatever.

And that that is not the portion of the work from which you contemplate any delay in preparing the House for next session?—Not at all.

If Dr. Reid's plan was abandoned, as it respects the House of Lords, will the central tower still be necessary?—If Dr. Reid's system, or any part of it, is adhered to in other parts of the building, it will certainly be necessary, according to the arrangements made, to have the central tower.

But not otherwise?—Not absolutely necessary, except for Dr. Reid's purposes.

With respect to the central tower being abandoned for the purposes of ventilation, might not that tower be made available for other public purposes?—I think it might.

Do not you think that even in the event of abandoning Dr. Reid's scheme it would be a great loss to the design if the central tower were given up?—I think it would be very desirable to retain the central tower; but I do not mean by that to say that it would be desirable to retain the same height or form of tower as would be required by Dr. Reid for his ventilating purposes. I think the central tower would be a great ornament to the building; but I am not of opinion that it is necessary to carry it to the height that Dr. Reid requires in order to obtain the effect that I should desire.

The central tower, such as contemplated by Dr. Reid, would be of a lower height than the Victoria tower?—I am hardly prepared to answer that question, because I am not aware that Dr. Reid has yet made up his mind as to the height of it. When I have spoken to him on the subject, he has said, "I should like to have it as high as possible; the higher the better; higher than Saint Paul's," and so forth.

What is the proposed height of the Victoria tower?—About 342 feet.

The following are the answers of Mr. Philip Hardwicke, Mr. George Stephenson, and Professor Graham, to questions submitted to them by the Chief Commissioner of Woods in regard to the warming and ventilation of the New Houses of Parliament.

I. To call upon Dr. Reid to lay before them the details of the system of warming and ventilation, as intended to be applied to the New Houses of Parliament?—In consequence of the instruction numbered I., we called upon Dr. Reid to lay before us the details of his system of warming and ventilation, as intended to be applied to the New Houses of Parliament. He has laid before us his general principles on warming and ventilation, the details only to a limited extent, but sufficient to enable us to form an opinion on the subject.

II. To consider and to report how far it is practicable, and if practicable whether it would be advisable, that such system should be extended to the whole building, including the subordinate offices and private residences contained therein; or whether the application of the system should be restricted to such portion as comprises the two Houses of Parliament, their corridors, libraries, kitchens, and refreshment rooms, or to a still more limited portion?—Agreeably to the instruction numbered II. we have considered Dr. Reid's system as he has explained it to us. It consists of of one general scheme for the warming and ventilation of the whole of this extensive building, bringing in the atmospheric air from a considerable altitude at the Victoria and clock towers at the two extremities of the building, carrying off all vitiated and impure air by a set of channels, both conveyed to a central tower proposed to be of greater elevation than the towers already mentioned. Although the scheme may be practicable, we are of opinion that it is too much complicated in its details and ultimate management to render such a system advisable to be applied to the whole building, including all subordinate offices and private residences contained therein, and that the application of the system considerably modified should be restricted to such portions as comprise the New Houses of Parliament, their corridors, libraries, kitchens, and refreshment rooms.

III. To consider and to report whether there would be advantage in applying the system, as far as its application should be deemed advisable, to different divisions of the building separately and independently of each other?—In reference to the third instruction, we are of opinion that there would be advantage in applying the system modified to two divisions of the building—viz., to each House of Parliament, and the various rooms and corridors belonging to it, and separately and independently of each other. We are further of opinion that it would be unnecessary to apply the system to the committee rooms, as we consider they are capable of being warmed and ventilated in a more simple manner. That whatever warming and ventilation may be required to the Speaker's residence and the other private residences should be effected separately and independently of any other parts of the building, and from each other.

IV. To ascertain and to report how far Dr. Reid's system of warming and ventilation is compatible or can be made compatible with rendering the buildings or the portions thereof to which it is applied fire-proof?—We have not been able to consider the fourth question so much in detail as could be desired to enable us to express a decided opinion upon it; but we have a strong impression that the system of warming and ventilation, as proposed by Dr. Reid (if carried out in conformity with his plan) cannot be made compatible with rendering many portions of the building fire-proof.

V. And, according to the opinions which may be formed of the points above mentioned, to ascertain and to report how far such plans and information in regard to the building have been supplied to Dr. Reid as are sufficient to enable him to furnish to the architect corresponding plans and information, in regard to ventilation, or if further information should be considered requisite for either party, to what extent and in what manner it should be furnished?—With respect to the fifth point it appears to us that Dr. Reid has had access to or been furnished with a great many plans and sections of the building, and has received sufficient assistance to enable him to apply his plans for warming and ventilation to the building in progress.

Philip Hardwicke.
Geo. Stephenson.
Thomas Graham.

South Audley-street, 25th June.

LIVERPOOL TOWN-HALL DECORATIONS.

The *Liverpool Mail* praises the deceptions employed in the decoration of the staircase of the Liverpool Town Hall in the following terms:—By some process, the invention of Mr. Ingram, decorative artist, of Birmingham and London, who is now, with about twenty of his own workmen, carrying on this work, the walls, which are of the usual description, and pillars, are made to represent the finest polished marble, and are susceptible of receiving a polish of great brilliancy. The walls are enamelled in imitation of Sienna marble, and the columns are finished in Jasper marble. So perfect is the work, that the best judges acknowledge the imitation to be perfect, and, *to the untutored eye, the deception, we are sure, would be complete.* On the window cases and framing are painted the arabesques from the Vatican—the arabesque style being strictly observed, nothing which has life being introduced. The door cases will be finished in imitation of statuary marble, highly polished, and the Jasper pillars stand out in bold relief from the Sienna and statuary marble. The whole of the ornaments in the door cases and under the dome, the friezes, cornices, &c., are richly etched with gold. This enamelled style differs much from that of scagliola, inasmuch as that great transparency and sparry character, peculiar to marble, can be produced."

WORKING STOCK OF EXISTING RAILWAYS.

The following is an abstract of the Returns made to the Railway Department of the Board of Trade, in pursuance of an order of the House of Lords, of the "Working stock (engines, carriages, and wagons) belonging to Railway Companies at present in operation":—

AMERICAN PATENTS.

Granted in April, 1845, reported in the American Franklin Journal.

For "*an Improvement in carriage wheels.*" Ellphalet S. Scripture, New York City.

The object of this improvement is to arrange the spokes and hub in such manner as to afford a ready means of tightening the wheel when the spokes become loose by shrinking, which is effected by inclining the spokes either way from the plane of the wheel to form what is termed a double dished wheel, one half of the spokes being inserted in a permanent hub or cheek piece, and the other half in a movable hub, or cheek piece, which slides on the pipe box, so that by means of a nut the moveable hub can be forced with its spokes towards the other, and thus tighten the spokes.

For "*an Improvement in the connecting rods for connecting the crank pins of three or more driving wheels of locomotives.*" Holmes Hinckley, Boston, Mass.

The object of this improvement is to connect three, four, or more, driving wheels with a single connecting rod, and permit those between the two end ones to have a vertical and lateral play, which is effected by having the crank pins of the intermediate wheels work in boxes that slide vertically in the connecting rods, the said crank pins being made of sufficient length to give end play to the axles.

Claim—"I claim making the boxes to slide vertically in the connecting rod, in combination with extending or lengthening the crank pins of the wheels beyond the said boxes, so as to slide through them in the direction of their axes, as set forth; the whole being for the purpose of converting all of the several wheels of the engine into drivers, as described.

For "*Improvements in the auxiliary steam engine for supplying steam boilers with water.*" John Cochrane, Baltimore, Md.

The patentee says, "The intention of an auxiliary supply engine is not only to supply water to a boiler, but to preserve the same at a uniform height therein, without its being affected by any irregularity in the consumption or evaporation of that fluid; said auxiliary engine stopping and starting, and working quickly or slowly, as the demands of the boiler may require. Under the arrangement that I prefer, the admission of steam to the auxiliary engine is governed by a float and balanced valves, placed in a chamber outside the boiler, but communicating therewith by two branches, one above and the other below the water line; so that the water may have the same level both in the chamber and boiler. The float is furnished with a tubular stem at bottom, opening into it, for the purpose of carrying off any leakage; this stem passes out through a stuffing-box in the lower part of the chamber, the arrangement of this part being substantially the same with that represented and described in the specification and drawings accompanying letters patent of the United States, granted to me on the 13th day of July, 1844, for regulating the supply of water in steam boilers. The float, however, may be otherwise arranged and modified, the only requisite being that its action on the steam valve should be governed by the height of water in the boiler.

"It is not pretended that an auxiliary engine for the supplying of water to steam boilers is in itself new, such engines having been heretofore employed for that purpose; but I have, as I believe, succeeded in so constructing and arranging the parts of such an engine as to obviate the main difficulties heretofore encountered in the attempts to employ them."

Claim.—"Having thus fully described the nature of my improvements in the auxiliary supply engine, what I claim therein as new and desire to secure by letters patent, is, first, the manner herein described of completing the stroke, or traversing motion, of the valve, by the commencing return stroke of the piston operating on the spring arms, substantially in the manner and for the purpose herein set forth.

"I likewise claim the manner of regulating the stroke of the water pump, by adjusting the same by means of a valve, or cock, as set forth, so that a smaller and regulated quantity of steam shall be admitted to the lifting, than is admitted to the forcing, side of the piston, as described."

For "*an improved method of supplying water to steam boilers by means of an auxiliary steam engine.*" Isaac N. Coffin, Washington, D. C.

Claim.—"What I claim as new, and desire to secure by letters patent, is the combination of the float with the valve, steam engine, and supply pumps, substantially as herein described, so that the depression of the float, caused by a deficiency of water, shall open a valve, and that the steam which escapes through said opening shall drive an engine to operate the supply pumps."

For "*a hydrostatic power machine.*" John Gregg, Rochester, Monroe county, N. Y.

The patentee says,—"There are many situations in which the power of water can be obtained under a very considerable head which, from local causes, cannot be rendered available by means of water wheels without an expenditure of money greater than could be made with prudence; it is principally in such situations that it is intended to employ the machinery invented by me. To effect this object, I employ two cylindrical or other formed water receivers, into which receivers, water is alternately admitted under any desired head, and is made by its pressure to condense atmospheric air, which air, so condensed, is to be conveyed by tubes to a cylinder furnished with a piston, valves, and other appurtenances, similar to those usually employed in a steam cylinder; the air being, in fact, substituted for steam in such manner as that an ordinary steam cylinder* will not require any alteration to adapt it to use by means of condensed air."

For "*Improvements in the steam engine.*" Ralph Pomeroy, Belleville, Essex county, N. J.

Within the cylinder of this engine there are four pistons, the two end ones being connected together and operating one crank; and of the other two, each operates a separate crank; and the three cranks being on the same shaft and dividing the circle into three equal parts. All the piston rods, except the last, are hollow, and pass through each other, and the steam is to be admitted alternately to the different pistons, and so cut off, that whilst it is expanding in one division, another division is receiving the steam directly from the boiler, but the manner of operating and arranging the valves for this purpose is not described or represented.

Claim—"What I claim as my invention and desire to secure by letters patent, is combining four pistons, constructed and arranged substantially in the manner set forth, in one cylinder; said pistons being connected with three cranks placed at about an angle of 120° from each other, all as herein described."

* Why not admit the water at once into the cylinder?—Ed.

MOULDING IRON.

William Mushet and Robert Mushet, iron-founders, of Dalkeith, Scotland, for "*Improvements in moulding iron.*" Granted Dec. 10, 1845; Enrolled June 10, 1846.

This invention consists in the application of stampers and rollers or other suitable apparatus for pressing the sand into the boxes instead of performing such operation by hand as heretofore. In carrying out this invention, the patentees propose to employ a machine having one or more stampers, or rammers, worked by means of eccentric or other convenient means, or the same may be effected by a roller or rollers in the following manner: that is to say, the sand after being put into the lower box, is placed upon a carriage and passed under the machine, for the purpose of compressing it into the box, the mould being inserted and suitable sand employed to form the parting; the top box is then put upon the lower one and filled with sand in the usual manner, when it is again subjected to this improved mode of ramming, after which the mould is finished in the ordinary manner. The patentees state that the moulding of railway chairs and other similar articles, when a great number of the same sort are required, will be greatly facilitated by the process above described.

STEAM ENGINE IMPROVEMENTS.

William M'Naught, of Glasgow, Scotland, engineer, for "*certain improvements in steam engines.*"—Granted December 10, 1845; Enrolled June 10, 1846.

This invention, which relates to certain improvements in steam engines, consists in the application of what the inventor terms a non-condensing cylinder, in addition to the present cylinder in beam engines, which present cylinder may be supposed to be the condensing cylinder. In carrying out these improvements, the patentee proposes to have a second steam cylinder placed between the centre of the beam and the connecting rod, the piston rod of such cylinder being attached to the beam by means of links, and to that part thereof about midway between the connecting rod and beam gudgeons. This auxiliary cylinder is provided with a valve of the ordinary construction, and worked by a rod, one end of which is attached to a lever keyed upon the weigh shaft of the ordinary cylinder, the other end being attached to a lever on the weigh shaft of the auxiliary cylinder, so that the valves of both cylinders are worked by one eccentric. The action of the engine is as follows: that is to say, the steam from the boiler is first admitted into the auxiliary cylinder, and having acted upon the piston so as to force the same from the top of the cylinder to the bottom, it passes through the eduction pipe into the ordinary cylinder at the opposite end of the beam, and into such cylinder at the upper part thereof, so as to force the piston down after performing the stroke; the steam passes through the eduction pipe into the condenser, which is of the ordinary construction. So that the steam from this additional or auxiliary cylinder, after having performed a stroke—say the up stroke—passes from the underside of the piston of that cylinder to the underside of the piston of the ordinary cylinder, which latter, it will be observed, is at the bottom of its cylinder when the other is at the top, so that the inventor works with high pressure steam in one cylinder and low pressure in the other, from which latter the steam passes into the condenser.

The specification shows a mode of applying the invention to marine steam engines, in which case there is a cylinder placed at each end of the beam, one of which, that is, the high pressure cylinder, being somewhat smaller in diameter than the other; by this means the power is said to be more equally distributed than in engines having but one cylinder.

RAILWAY CARRIAGE WHEELS.

Joseph Romnald Bozek, of Cheapside, mechanic, for "*Improvements in the construction and application of railway carriage wheels.*"—Granted January 6; Enrolled June 24, 1846.

The improvements relate to the application of the flange of railway wheels on the outside instead of on the inside of the wheel.

GLASS TILES.

JOHN RUSSELL, of Edinburgh, accountant, for "*Manufacture of glass tiles.*"—Granted December 30, 1845; Enrolled June 30, 1846.

This invention relates to making tiles out of sheets or pieces of glass; the pieces have two of their opposite sides turned up perpendicularly, from half an inch to an inch, to form flanges, and made in such a manner that the plane or flat part of the glass shall be wider at the upper end of the tile than the lower end, so as to allow the lower end of one tile to lap and fit into the top of another between the two flanges. These tiles, the inventor states, may be formed of any shape, suitable for hips, valleys, domes, or arcades, and either of stained, coloured, or opaque glass. The tiles when used are laid on laths nailed on to the rafters, in the usual manner, and the apertures between the flanges are to be filled up with putty or any other suitable cement, and covered over with a hollow bead of metal or glass, or a thin slip of metal may be fastened to the rafters and passed up between each tile and then turned over the flanges on the top.

The patentee states that he does not claim the mode of shaping or manufacturing the glass, but only for the form or shape of the glass and for the purposes of roofing, as above described.

ATMOSPHERIC RAILWAYS.

JOHN ROBERT JOHNSON, of Alfred-place, Blackfriars, in the county of Surrey, chemist, for "*Improvements in the materials employed in constructing and working atmospheric railways.*"—Granted December 6, 1845; Enrolled June 6, 1846.

This invention relates, first, to a new composition for sealing the longitudinal valves of atmospheric railway tubes. It is made by adding to various mixtures of resinous, oily, and bituminous substances, dry clay, ochre, and chalk, in powder, as much as will make the composition of the proper consistency; the following mixture is preferred and found to succeed: 1 part palm oil, 2 parts brown resin, and 4 parts china clay, in fine powder. Insoluble soaps, prepared by a combination of fat and an oxide or earth with oily or resinous substances, may answer the same purpose.

The second improvement is a composition for lubricating the interior of the traction tubes, made by mixing with fat or oil, and resin or pitch, a quantity of earthy matter, as before described; the following proportions are recommended: 7 parts resin, 4 parts stearine, 4 parts tallow, and 12 parts clay.

The third improvement is for making fabrics impervious to air and moisture with elastic varnish, for the purpose of using them instead of leather for the longitudinal valves. The fabric may be made either of cotton, flax, hemp, or wool, in the form of a belt, of the breadth and thickness required. The varnish must be such that oils or fats will not act upon it when dry, and it must possess sufficient elasticity to bear the bending resulting from its use; linseed or nut-oil is preferred, particularly boiled linseed oil, which is made to penetrate the fabric by heating the oil to 250°, and immersing it therein until the air and vapour is expelled from the interstices of the fabric. The fabric is then passed between a pair of iron rollers, to squeeze out the superfluous oil, and dried in a warm room, and afterwards again passed through oil heated to 200°, and also between the rollers, and dried. The operations are repeated until the interstices are filled by the successive coats of varnish and the fibres cemented together into one mass. To remove the inequalities, if any, on the surface, pumice stone must be used, after which a finishing coat of varnish is to be applied.

The fourth and last improvement is for constructing the traction tubes of materials not before used for that purpose, such as calcareous cement, Keene's cement, Roman cement, and the like, which can be cast in the form desired, and do not require burning. The cement may be mixed with sand or fine gravel and rammed into moulds of the form required. The patentee prefers to form the pipes by the aid of an apparatus made with a cylindrical case and a hollow core for forming the inside of the pipe. When the tubes are dry and seasoned they are rendered impervious to air and moisture, by causing the cement to absorb coal-tar, which has had its more volatile portions separated by distillation.

STEAM ENGINES AND PROPELLERS.

JOHN PENN, of Greenwich, engineer and manufacturer of steam engines, WILLIAM HARTREE, the younger, and JOHN MATTHEW, of Greenwich, engineers, for "*the invention of certain improvements in steam engines and machinery for propelling vessels, which improvements are also applicable for other purposes.*"—Granted December 25, 1845; Enrolled June 25, 1846.—Reported in the *Patent Journal.* (*See Engraving, Plate* XIII.)

These improvements in steam engines relate to a certain mode heretofore invented, of making the piston rod of steam engines of enlarged size, and hollow, like a tube, to admit a long connecting rod to be received within the hollow of the piston rod, for transmitting the force and motion of the piston to the revolving crank on the axis, which is to be turned round by the force of the steam engine, like the direct acting steam engines, the said connecting rod being jointed to the piston at that end of the rod which is furthest within the said hollow of the piston rod (and which for distinction may be termed its inner end), and the other (which may be termed the outer end, because that end extends out from the said hollow beyond the hollow end of the piston rod) being jointed upon the crank pin of the revolving crank, so as to operate by direct action for turning the crank and axis thereof round. The said hollow within the piston rod is sufficiently wide for permitting the vibration of the connecting rod, without touching the inside of the hollow, so that the connecting rod being moved round with continuous onward motion in the circumference described by the crank pin, the joint at the inner end of the connecting rod will move with alternating motion in a line which is central with the line of the piston rod, the said joint being guided in the said line by the sliding motion of the hollow piston rod, through its stuffing box in the cylinder covers, as the motion of the crank pin in the circumference of its orbit will occasion a very considerable extent of vibration of the connecting rod within the hollow of the piston rod, which is of so large size externally, in order to have sufficient hollow to allow its vibration without touching. The large size of the hollow piston rod deducts materially from the surface of the piston against which the steam is to act for impelling the piston in that direction which will move the large hollow piston rod (through its stuffing boxes in the cylinder covers) into the interior of the cylinder; consequently the piston will be impelled with less force than if the rod were small, or of proper size to such piston. But, on the other hand, steam will operate against the whole area of the piston, without any such deduction therefrom, when steam operates for impelling the piston in a contrary direction to that already said, or in that direction which will move the large hollow piston rod (through its stuffing box), out of the interior of the cylinder. Hence, the piston of a direct-acting steam engine, with large hollow piston rod as aforesaid, will move by the steam with more velocity in one direction during one half of the stroke, than in a contrary direction during the other half of the stroke. And to avoid any unnecessary size of the hollow piston rod, the same (instead of being of cylindrical form and circumference in its transverse section), has been made oblong in its transverse section, having two flat sides and two semicircular ends, so that the lengthway or oblong should allow as much room within the hollow of the connecting rod as required for the performing of its vibrations, but in breadthway the oblong hollow being no wider between the two flat sides than necessary for admitting the connecting rod to move freely. The stuffing box in the cylinder-cover was adapted to the oblong form of the said hollow piston rod. In direct-acting steam engines, with such oblong flattened form of hollow piston rod, have been called trunk engines, and were subject of patent granted to Francis Humphreys, for England, 28th March, 1835.* Our improvement in steam engines of the aforesaid description, consists in extending the aforesaid hollow piston rod or trunk each way from the piston, instead of merely on one side as heretofore. And with that improvement, the surface against which steam will operate for impelling the piston, will be the same when impelled in one direction as the other. Also, the guidance of the piston in its alternating rectilinear motion within the cylinder, will be rendered more complete in consequence of the said prolonged hollow piston rod passing through the stuffing boxes at both ends of the cylinder. Also, the joint at the inner end of the long link or connecting rod, is rendered more accessible than heretofore. Fig. 1, is a horizontal section of an engine constructed according to this part of our improvements; *a a*, is the steam cylinder; *b b* the steam piston fitted into the cylinder, and moving up and down therein; *c c*, the hollow piston rod or trunk, fastened to the piston, and moving therewith; *d d*, the end of the cylinder; and E E, the cylinder cover, having the stuffing box, *e e*, at the centre part of it for hollow piston rod, *c c*, to pass through; *f* is the long link or connecting rod, jointed at its inner end upon a pin, A, at the centre of the piston, and jointed at its outer end upon the crank pin, B, of the revolving end of the crank, G, which is on the main revolving axis of the steam engine; *i i*, is the frame-work for sustaining the said axis. The hollow piston rod may be either of cylindrical or oblong form, as aforesaid, but must be truly prismatic. In the motion of the engine, the centre of the joint-pin, A, at the inner end of the connecting rod, will move along the cylinder with an alternating rectilinear motion, whilst the centre of the crank pin, B, at the outer end of the said rod, *f*, is moved onwards around, in the circle described by the crank pin with a continuous rotary motion, and during such motion the connecting rod *f* will require to vibrate from the direction of the central line of cylinder to the extent of the internal diameter of the piston rod, with alternate deviation on opposite sides. The hollow within the hollow piston rod *c c*, is sufficiently large to permit of such extent of vibration of connecting rod *f* on either side. Thus far this engine is the same as other trunk engines, or hollow piston rod engines; but fig. 1 show the hollow piston rod *c*, *c* to be prolonged at 1, 1, from opposite side of the piston *b*, *b* to that side thereof from which the aforesaid part *c*, *c* proceeds; the prolonged part 1, 1 passing through, and being fitted with a stuffing box 2, 2, at the centre part of end, *d*, *d*, of cylinder, and the part 1, 1 being a continuation of the part *c*, *c*, which, together with the said part 1, 1, forms a long hollow piston rod, *c*, *c*, having piston *b*, *b* fastened to it at or near the middle of such rod, and the said long hollow rod *c*, *c*, being guided by both stuffing boxes at *e*, *e* and 2, 2; the piston *b* is thereby securely retained in a proper position at the centre of the cylinder when moving with its alternating motion therein, without any undue rubbing with more force at one side than the other of the inside of the cylinder; and the said long hollow rod *c*, *c* being open at the end of the prolonged part 1, 1, the joint of the inner end of the connecting rod *f* upon

* See C. E. and A. Journal, vol. 3, 1840, page 142.

the pin A can be got at for screwing up or tightening brasses of such joint when the engine is stopped. Fig. 1 is supposed to be in every other respect exactly like other direct acting engines, which, being well known, need not be described. The air pump may be worked by means of another short crank or an eccentric upon the main revolving axis. Such an engine may have the fly wheel on its main axis, and may be applied for actuating any machinery requiring a continuous rotary motion; or may be applied in steam vessels, in which case the main axis would be prolonged each way across the vessel to serve as the axis for wheels on each side of midship line of vessel with the main axis of both engines in the same horizontal line across the vessel, the air pump or pumps being amidship in a space left for the purpose between the two engines, and the air pump or pumps may be worked by a short crank or cranks, or eccentric or eccentrics on the main axis, all which being the same as in direct acting engines need not further be described; and in consequence of the effectual guidance of the piston during its motion in the cylinder, which results from the long hollow piston rod passing through stuffing boxes in both ends of the cylinder as above described, such an engine is well qualified for working with the centre line of the cylinder in a horizontal position, as in fig. 1, because the weight of the piston and its hollow piston rod is effectually sustained by the fitting of long hollow piston rods into and through the stuffing boxes at both ends of the cylinder, and therefore that weight will not cause the circumference of the piston to rest with any more force at the lowest part of the internal surface of the cylinder than at the upper or other part of that internal surface. Engines of this description are well adapted for steam vessels having revolving propellers at the stern under water, or nearly so, operating in water by an oblique or spiral screw, or windmill-shaped propeller, that require their axis to be low down within the vessel, and to be turned round with a rapid motion.

Several different engines are given in the drawings attached to the specification,—some vertical, others with the connecting rod projecting from the lower part of the hollow piston rod, with the cylinder at right angles to each other, and attached to the same crank, or the end of the propeller shaft.

Another part of the said improvements in steam engines relates to the air pump, or rather to the valves of the air pump in cases where the air pump is placed in a central line in a horizontal position, and is double acting, so as to draw water and air from condensers, when the piston of the air pump is moved either backwards or forwards in its horizontal barrel; an air pump, disposed in a horizontal position, double acting, as aforesaid, must have four valves and a solid piston; such air pumps have been proposed, and are not new, but, according to this part of the improvements, those valves, and the seats to which they fit, are so disposed with respect to the barrel of the pump, as to be able to be removed with ease, and spare valves and seats substituted when required. Fig. 1 contains a longitudinal section of a condenser and air pump, or a pair of condensers and air pumps, suitable for a steam engine or pair of steam engines, as already described. *q, q* is a metallic vessel, serving for condenser and hot water cistern. It may be divided with a vertical partition to divide its internal capacity into separate condensers for the two engines, or else may be two separate vessels, disposed side by side. In either case, the air-pump barrel, *r, r*, extends in a horizontal direction through the inside of each compartment (or of each condenser), with an opening into an end of the barrel, whereof one opening may be closed by a door, *q*, and the other by an air-pump cover, R, R, which has, as usual, a shifting box at the centre of it, for the rod, *s*, of an air-pump, to pass through the piston, *t*, of the air-pump, which is fastened on the rod *s*, is solid. The space left within vessel *q, q* around the extent of each horizontal air-pump barrel is further divided by a horizontal partition not shown in drawing, but it is nearly at the level of the upper part of each barrel, *r, r*, and so much of the upper space as is beneath the level of the horizontal partition is the actual capacity of the condenser for reception of steam that is to be condensed, and of the injection of cold water by which the condensation is to be effected. The eduction pipe, R, from the cylinder of the engine, joins by a side branch to that lower part or condenser; the space above the level of such horizontal portion is for the hot water cistern or hot well, into which the air-pump is to discharge the hot water, and air is extracted by it from the condenser, and the surplus of which hot water will pass away as usual by the overflow pipe, *v*.

The air-pump, being double-acting, requires to be constructed with four valves, two at each end of barrel, *r*, one of these valves being a foot-valve, for admitting water and air to pass from the condenser into the barrel, *r*, when the air-pump piston, *t*, is moving away from that end of barrel, *r*, at which such foot-valve is situate, and the other of the said two valves being a discharge valve for allowing air and water to pass out from barrel, *r*, into hot well, *w*, when air-pump piston, *t*, is moving towards that end of barrel, *r*, at which such discharge-valve is situated. This part of the improvements consists in disposing the said two valves, which are at the same end of the barrel of air-pump with said discharge-valve, exactly over foot-valve, so that the same upright spindle or guide rod will serve for both valves, and will also serve to keep seats for both valves in their respective places in the metal work at the end of pump-barrel, into which places the said valve-seats are accurately fitted. But when the guide-rod is withdrawn, then the valves become loose, and can be taken out for examination or repair, and the valve seats can also be removed out of their said places, if necessary, and other spare valve seats put in, and valves thereon. 6, and 4, are the lower or foot-valves, and 5, upper or discharge at each end of air-pump barrel, *r*, 6 and 7 being their respective valve seats, accurately fitted into recesses in the metal at end of barrel, *r*, those recesses being bored correctly circular, and slightly conical, so as to be correctly concentric with upright guide rod or spindle, 8, which passes through central hole of upper valve seat, 7, and into central hole of lower valve seat, 6, and has suitable shoulders formed upon it, for confining both seats, 6 and 7, down in their respective places, when rod 8 is forced and held down end-ways, by a cover, *g*, screwed down over a hole in upper part of hot water cistern, *q*, and which cistern bears on the upper end of the rod, 8, so as to press and hold the same down, and consequently fasten down the two valve seats, 6 and 7. Valves 4 and 5 have central holes through which the rod 8 passes, so as to allow the valves to fall and rise on the rod which guides them when so rising and falling, and the rod has suitable slip shoulders formed or fastened upon it, to limit the height to which the valves shall be allowed to rise. Valves 4 and 5 may be fitted to their seats, 6 and 7, with flat surfaces, or with conical fittings, when the door, *q*, or air-pump cover, R, is also corresponding with the door, in same end of hot water cistern, W, or one door on the top thereof, and likewise the Co 9; then the upright rod, 8, being withdrawn upwards through hole 9, will leave valves 4 and 5 loose, and at liberty to be removed through doors or openings aforesaid; and the valve seats, 6 and 7, may be also lifted out of their respective recesses into which they are fitted, with a sufficient tapering to be tight, but without any other fastening than by means of rod 8, as aforesaid. And the upper valve seat, 7, may be made so much larger than the lower valve seat, 6, as well as the upper one, through the hot water cistern, *w*, and its doors, as aforesaid. The upright spindle, 8, of two valves, 5 and 6, which are at the same end of the barrel, *r*, as its cover, R, is so much on one side of the central line of the barrel as to avoid any interference with the air pump rod, *s*. But *s* can be disconnected, and, together with the air pump present, can be withdrawn from the barrel, *r*, through the door, *q* or R, and the packing of piston *t*, can be performed at those doors. The recesses into which the valve seats for the foot valves, 6, 6, are lodged, should be continued downwards, as at *s, s*, near toward the bottom of the condenser, in order that water may be effectually drawn up from the lowest part of the condenser by the action of the pump; and as to our said improvements for propelling and other purposes, the same are, for the most part, applicable to vessels, with revolving screw propellers for diminishing friction and wearing which takes place at that extremity of the horizontal axis of the revolving propeller within the vessel, and which extremity, at the same time it is turning rapidly round, must press endways against some suitable fixed end bearing in the vessel, so as to transmit to that bearing the whole endway force of the propeller, by which the vessel is to be urged on through the water. This part of the improvements relates to such fixed end bearing or extremity of revolving axis, or any other end bearing for quick revolving axis in mill work or machinery of any kind, and consists in applying a flat circular disc of hardened steel or other hard metal, in a vertical plane at the proper place for receiving the flat end of the revolving axis, which end is also to be hardened steel, the said disc being larger in diameter than the said flat end, and being lodged in a cell at the central part of a toothed wheel, which is mounted at the end of a short horizontal axis, sustained in some suitably fixed socket, so as to be somewhat eccentric to the central line of the axis of the propeller, and the said toothed wheel being turned round by means of other wheel work, carries the steel disc slowly round with it in the same direction as the end of the axis of the propeller is, at the same time, revolving with a rapid motion; and owing to the said slow revolving motion of the disc being eccentric to the quick revolving motion of the end of the axis, fresh parts of the said surface of steel disc are continually brought opposite to, and in contact with, the same end, in order to avoid any tendency to wearing the rubbing surfaces into rings, as usually takes place, and also to introduce oil or water more effectually between the rubbing surfaces.

Figs. 2, 3, 4, show some of the improvements by way of example, but the details of construction there represented may be greatly varied. Fig. 2 is a longitudinal vertical section; fig. 3 a plan view, and fig. 4 a horizontal section taken at the propeller shaft. The box A, A, is to be securely fastened in the vessel, so that a spindle, H, will correspond with the direction of centre line of the axis of the propeller, the said spindle, H, being inserted and fastened into the end of the axis; but there is another suitable bearing not shown, which sustains the axis laterally on its intended place as it revolves. The spindle, H, passes through a hole in one end of the box, A, A, which has partition across it at A, through which the spindle, H, also passes in a stuffing box, *b*, the smaller compartment of which box contains the circular steel disc before mentioned, and filled with oil or water for keeping rubbing surfaces cool. This is better shown in fig. 2. *B* circular disc, and *D* is a toothed wheel into the cell, at the centre whereof the steel disc, *B*, is inlaid and fastened, so as to be held on vertical plane, and so as to be carried round with slow revolving motion of wheel, *D*, which is sustained by means of prominent central boss, *e, e*, on opposite side of it, to that side on which disc, *B*, is fastened, which boss, *e, e*, is received in, and fitted to, corresponding circular cell, *f, f*, which may for the present be considered as immoveably fixed, with its centre somewhat eccentric to centre line of spindle, H, as is apparent in fig. 3.

The toothed wheel *D*, is capable of turning round in said cell *f, f*, as though it were mounted on the end of the horizontal axis, and revolving therewith in a vertical plane, and carrying the disc *B*, round with it in such motion, and there may be a horizontal centre pin at *g*, in centre of the said cell *f, f*, fixed to or part thereof, and fitted into the central hole of the wheel *D*, around its prominent boss *e, e*, applies with close contact against the flat circular border around cell *f*, *f*, and by the aforesaid fittings and contact over a considerable diameter, the wheel D, and disc B, are securely sustained in their intended vertical planes, and qualified to bear the endway pressure of spindle H, notwithstanding the eccentricity thereof to wheel D, as shown in fig. 4. The aforesaid slow-revolving motion of the disc B, and wheel D, is given thereto by means of the endless screw E, on the cross axis F, which is turned round by spin-wheel G, on the end of it, that wheel receiving motion from another spin-wheel N, on the end of another cross axis I, whereon is another screw wheel J, which is turned by the endless screw *j*, on spindle H. The aforesaid wheel-work and screw-work will give a very slow revolving motion to wheel D, and the disc B, compared with the rapid revolving spindle H; but the proportions of the said wheels and screws may be varied, and the endless screws, E and *j* (or one or them), may be made with 2 or 3 spiral threads, in which case the revolving motion given to disc B will not be so slow. And if the parts are constituted according to the drawing, so that the cell *ff* is not immoveably fixed, the degrees of eccentricity can be varied at pleasure, and the motion quickened merely by turning the lever handle K, which is fastened on the extreme end of the axis *k* in figs. 3 and 4, which axis is part of the metal of the cell *ff*, but eccentric thereto, as shown in fig. 4.

It is easily seen that the said axis *k* is fitted into a socket, perforated through the end of the box A, and flat vertical surface of the said end around that socket, affords a flat bearing for the flat vertical surface at back of the cell, *ff*, around its axis *k*. The socket for the axis *k* is somewhat eccentric to central line of spindle H, as shown in fig. 4, and by the position of the parts there shown, the eccentricity of axis *k*, in respect to spindle H, concurs with the eccentricity of the cell *ff*, in respect to its said axis R, for giving the full degree of eccentricity for disc B, in respect to spindle H, that the disc B, and of the end of the spindle H, will permit, as is shown in fig. 4. But if the handle K, and axis R, with the cell *ff*, were to be turned half-way round from their said position, fig. 4, then the eccentricity of the axis R in respect to the spindle H; and those of the cell *ff*, in respect to the axis *k*, would counteract or neutralise each other, so as to give little or no eccentric motion to the disc B in respect to the spindle H. On the handle K being turned to any intermediate position between the aforesaid extremes would give any intermediate degree of eccentricity as may be preferred. The axis R should be made less tight into its socket, and to fasten them by screwing a nut on the end of the axis. The lever handle K should have some adequate means of holding it fast in any requisite position. And whereas the motion so given to cell *ff*, in turning it with its axis R by the lever handle K, as aforesaid, would derange the position of the wheel D in respect to the gearing of its teeth in spiral threads of endless screw E, the cross axis F of that screw; and if the spur wheel G must be allowed to to rise and fall in its bearings, but it will be retained at its proper distance from the cross axis I of the other spur wheel N by means of two levers *r r*, formed by bearings for the cross axis F, which bearings will rise or fall freely with it, but will always keep it horizontal. Also, the endless screw E is fitted upon its said cross axis F with feathers or keys, so as to be capable of sliding along that axis F, end-ways thereon, but so as to be compelled to go round therewith, and the place the endless screw will occupy in lengthening of its said cross axis F is regulated by two bearings *t t*, which are fitted on axis F, so as to include the screw between those bearings, *t t*, as projected from the collar, *v v*, fitted around the outer circumference of the cell *ff*, and are collars made on two halves united by screws *x x*; the said circumference is concentric with the interior of the cell *ff*, and consequently with the wheel D; wherefore when the cell *ff* is turned round by the lever K, the collar *v v*, by its projections *t t*, will cause the endless screw E to rise or fall, together with the axis F, or move sideways along that axis with such compound motion; *t* will always preserve proper contact of its spiral threads with the wheel D, for turning the same round, as aforesaid. Claim first: for improvements in steam engines, which have hollowed piston rods and connecting rods in the hollow thereof; of making such hollow piston rods extend both ways form the piston, and passing through stuffing boxes in both ends of cylinder, in order to obtain an equal surface of piston for receiving pressure of steam, and impelling piston in both directions in cylinder, up, down, back, and forwards, at same time obtaining secure guidance of the piston in such motion, in consequence of long hollow piston rod sliding through stuffing boxes at both ends of the cylinder, also rendering joint at inner end of connecting rod accessible within the hollow piston rod; but no claim is made to extending of piston rod each way from the piston, and guiding such long piston rod by passing through stuffing boxes in both ends of cylinder, when that is done for the mere purpose of the guidance of the piston in its motion within the cylinder; but claim is only made when the long piston rod, which is so guided, is hollow, for the purpose of receiving the connecting rod within the hollow, as before described. Secondly, in improvements in disposing the valves of horizontal double-acting air-pumps, with the lower or foot valve directing beneath the upper or discharge valve, and holding the valve seats for both those valves fast in the proper place, and also guiding the valves in their rising and falling motions by means of one forced upright spindle.

IMPROVEMENTS IN GOVERNORS OF STEAM ENGINES.

CHARLES WILLIAM SIEMENS, of Finsbury-square, Middlesex, engineer, for "*Improvements in steam engines and in regulating the power and velocity of machines for communicating power.*"—Granted December 24, 1845; Enrolled June 24, 1846. *See Engraving*, Plate XII,

The first part of this invention consists in some further improvements in the chronometric governor, a patent for which was granted to Mr. Joseph Woods, of Barge-yard Chambers, Bucklersbury, April 18th, 1844.

Figs. 1 and 2 represent the improved chronometric governor, which is generally applied to steam engines. The differential velocity between the engine and a revolving pendulum P is obtained by means of three bevil-wheels, A, B, and C. The wheel A is firmly connected with the arm or crank E of the pendulum by means of the upright shaft K, and revolves always in concert with the pendulum. The under wheel B is fixed to the pulley D, which is driven by the engine with its uncertain velocity and in contrary direction to the motion of A. Both these wheels move in gear with the third bevil-wheel C, which runs perfectly free on its axis, and is also permitted to travel round the perpendicular socket *d*. It is obvious that whenever A and B revolve in contrary directions, but with equal velocity, C will also revolve on its axis, but will not change its angular position, while any difference in velocity between A and B will cause C to follow the direction of the faster wheel, which will at once alter the supply of steam, the double arm *m* being attached to the throttle valve T by means of the lever and connecting rod *l*. To maintain the motion of the pendulum a constant power is required, resembling that of a falling weight in an ordinary clock. This power is given out by the weight *w*, which tends to pull the wheel C permanently to one side, and this strain being borne equally by the wheels A and B, causes A, and with it the pendulum P, to revolve, while B, which revolves in the contrary direction to A, is constantly engaged to lift W back again in its proper position. In practice, it has been found that the power requisite to maintain the action of the pendulum is much less than that required to effect the movement of the valve, and the inventor now adopts the principle of driving the pendulum with an excess of power, which shall be neutralised by a friction apparatus when not wanted, and shall be allowed to act freely when the governor requires its assistance to move the valve. This is effected as follows: R is a ring of cast iron or other proper material, against which a surface of steel or other material *g*, revolving with the pendulum, is pressed by its short lever, a spring *s* being placed between the point of the rod and the steel rubber, to let the pressure come on gradually. It is evident that whenever there is an excess of driving weight, which causes divergence in the arc of vibration, the surfaces of the steel rubber and of the fixed ring will be pressed in contact together with a force exactly sufficient to produce the required amount of friction necessary to counterbalance the excess; and so soon as the pendulum falls back towards a smaller arc of rotation it will relieve the friction apparatus, and permit an increased supply of power to overcome the resistances of the valve, &c. A second spiral spring *t* is laid in the groove of the arm F, behind the point of the pendulum, for the purpose of never allowing the latter to drop quite in its perpendicular position, and also to facilitate its starting with the engine.

There is also described another mode of obtaining the differential velocity between the pendulum and the engine and a governor of a more powerful description, which is calculated to move the gates of water-wheels or the expansion gear of large engines, but the general principle of these governors is the same as we have already described, and we therefore omit them.

The great advantages of the chronometric governor over Watts's Centrifugal governor, or others which have hitherto been proposed, are—that the engine must always keep pace with an "independent" pendulum, which will travel only with its proper velocity according to its perpendicular length —no matter whether the engine has to overcome the maximum of her load or none at all; and another principal advantage is, that the adjustment of the valve is done at the very instant when the equilibrium between the load and power of the engine is disturbed; there is no variation in speed visible, even if the whole amount of load of an engine is suddenly thrown off, an advance of about $\frac{1}{30}$th part of the revolution of the fly-wheel being sufficient to shut the throttle valve.

The patent has been applied to engines at the Steam Flour Mills of Mr. Carpenter, Shad Thames; at the saw mills of Mr. Rosling, Southwark-bridge, and Messrs. Ransome and May, Ipswich, and several other places.

ELECTRIC CONDUCTORS.

WILLIAM YOUNG, of Paisley, manufacturer and dyer, and ARCHIBALD MCNAIR, of the same town, merchant, for "*certain improvements in the construction and means of manufacturing apparatus for conducting electricity.*"—Granted August 4, 1845; Enrolled February 4, 1846. *(With Engravings, Plate XII.)*

This invention of improvements in the construction of apparatus for conducting electricity consists of a new and improved method of manufacturing electric conductors. The electric conductors are formed of one or more copper, tin, or other metallic or mixed metallic wires, which may be covered with cotton, woollen, or linen thread, in a manner similar to those termed "bobbin wires," used in the manufacture of caps and bonnets; or the wires may be covered with threads in a plaited or braided form, by means f a braiding-machine; such description of covering being much stronger and less likely to be disturbed or rubbed off when passing through the machinery hereafter described, than the coiled coverings of the ordinary bobbin-wires, or any other description of covering hitherto employed for that purpose. As the liability of the wires to come into contact, and thereby disturb the electric circuit, is greatly diminished by braiding their surfaces, the patentees consider this mode of protecting the wires as one of great importance in the construction of electrical conductors.

The wires so covered are to be introduced into and enclosed within a tube or pipe, composed of lead or other similar soft metal; which tube or pipe is filled with asphalte, pitch, wax, resin, or other substance, being a nonconductor of electricity, and capable of being liquified by heat, and afterwards becoming concrete by cold.

The wires being covered with thread, as above mentioned, are prevented from coming into contact with each other, or with any adjacent conducting medium which might divert the course of the electric fluid; and the spaces between the covered wires being filled with pitch or other suitable nonconductor of electricity, as before mentioned, and enclosed in pipes or tubes of lead, or other soft similar metal, the wires will be effectually preserved in an insulated state, and protected from damp as well from other sources of injury.

The means of manufacturing the improved electric conductors will be best understood by reference to the drawings in Plate XII. Fig. 1, is an elevation, partly in section, of a machine for effecting this object. *a*, is a cistern or vessel, formed of iron or other suitable material, for containing the bituminous or resinous matters which are intended to surround the wires in the leaden pipe; *b*, represents a tubular or hollow rod or mandril, open to and descending from the bottom of the vessel *a*; which mandril is preferred to be made of polished steel, and fixed, by means of flanges and screw-bolts, to a triangular plate or head, *q*. *c*, is a tubular core at the lower end of the mandril *b*, also made of polished steel; and *d*, *d*, is a circular hollow die, resting on the top of the ram *e*. The ram *e*, is cylindrical, having a perpendicular opening through its centre; the lower part of the ram is enlarged at *f*, with a transverse slot through it, and is bolted firmly upon a triangular plate *s*. *g*, is a piston, working in the hydraulic-cylinder *i*, having a projection or enlarged diameter *h*, to be packed with leather or otherwise, so as to fit the cylinder *i*, accurately. This cylinder is of cast-iron, bored, and lined with copper, and is bolted to the ground; *k*, is a ring or cap-plate, over the end of the cylinder, embracing the smaller diameter of the piston *g*, which is to be properly packed; *l*, is a malleable iron cylinder, having a chamber *m*, within it, and an aperture to admit the sliding tubular mandril *b*; it is also provided with a small opening at *o*, for filling the chamber *m*, with lead or other soft metal. *p*, *p*, are pillars, fixed upon the plate *q*, and intended to support the cistern or vessel *a*; the plate *q*, has an aperture in its centre to admit the tubular mandril *b*, shown in the drawing. *r*, *r*, are three sliding-rods (two only are shown in fig. 1,) which pass through the snugs or ears of the plate *q*, and are fastened thereto by nuts; their other ends are attached in the same way to the plate *s*. These rods pass freely through a heavy circular plate *v*, which, by means of a ring-plate bolted to its under surface, supports the cylinder *l*; a ledge or belt being provided at *x*, to rest upon the inner edge of the plate *y*. *z*, *z*, are six iron pillars, with screw-nuts at their ends, for binding the plate *v*, to the cylinder *i*.

The covered wires which form the electric conductors *a*, are intended to proceed from reels, placed in convenient situations (but which reels are not represented in the drawings), and pass through the vessel *a*; the reels should be loaded with a weight or drag to keep the wires always at a certain tension.

The relative position of the hollow circular die *d*, *d*, with regard to the tubular core *c*, of the mandril, will be clearly seen in fig. 1. The core *c*, is screwed into the tubular mandril *b*, and is tapered off and terminates before it reaches the most contracted part of the opening in the hollow circular die *d*.

The mode in which the machine operates is as follows:—The wire or wires, covered as before described, are introduced into the machine through the vessel *a*, where they become coated with pitch or other similar material. They are then brought down through the tubular mandril *b*, the hollow core *c*, the hollow circular die *d*, and the tubular ram *e*, to the opening at *f*, where they issue from the machine. The asphalte, pitch, wax, resin, or other nonconductor of electricity, capable of being liquified by heat, and afterwards becoming concrete by cold, is put into the vessel *a*, and brought to a liquified state by means of heat applied to that vessel. The liquified pitch, or other similar substance, will descend into and fill the tube of the mandril *b*, and the hollow core *c*, and during its passage down the said mandril, the pitch or other matter will remain in a liquified state. The chamber *m*, of the hollow cylinder *l*, is filled with lead or other similar soft metal, introduced in a molten state through the opening at *o*. The metal in this chamber is to be forced therefrom by the action of the hydraulic ram, when in either a heated or cold state; but the patentees prefer to operate upon it in a heated though solid state, varying from 250° to 400° of Fahrenheit's thermometer. This degree of temperature may be preserved in the cylinder by any convenient means.

When the chamber *m*, is filled with lead or other metal, the said mass of metal will assume the form of a thick hollow cylinder or tube, of which the mandril *b*, and the core *c*, form the centre. The cylinder *i*, and piston *g*, constitute a common hydraulic press, and water being forced into the cylinder *i*, at the opening *w*, below, by means of force-pumps in the usual way, the piston *g*, will be made to ascend, and with it the ram *e*, and the whole of the superstructure attached to the plate *q*. As the ram ascends, it will force the hollow circular die *d*, against the mass of the lead or other metal in the chamber *m*, which, having no other outlet than the channel between the core *c*, and the hollow circular die *d*, the thick cylinder of lead in the chamber *m*, will be forced into the form of a small pipe or hollow tube, and descending through the tubular ram *e*, will be delivered finished at the opening at *f*, with the wires firmly secured and enclosed within it.

When the charge of lead has been pressed out of the chamber *m*, it is again to be filled with melted lead or other metal, to be operated upon in the same manner, and the charge repeated, until a proper length of tube is produced. The metal being hot when it is poured in, will amalgamate with the remaining metal of the previous charge, so that one continuous perfect tube will be formed. Previously to commencing the operation of forming the pipes, the wires must be carried down to the opening at *f*, and when the first portion of the pipe is produced, it must be made fast to the wires; the further operations will then draw down the wires from the reel or coil, through the pitch vessel *a*, and tubular mandril; so that the pipe or tube, during its whole formation, will always have the wire or wires and the nonconducting material enclosed within it.

The screws at each end of the rods *r*, and corresponding nuts, are intended for adjusting the mandril and die. The vacancy formed in the cylinder *i*, between the projection *h*, in the piston *g*, and the ring *k*, is to admit of water being injected through a small opening by force-pumps, for the purpose of accelerating the descent of the piston.

Figs. 2, 3, and 4, represent various views of another construction or arrangement of machinery, which is a modification of the one above described; for although the arrangement of the parts is somewhat different, the principle upon which both machines are constructed is the same, and the effect produced is identical in both. Fig. 2, represents the machine in vertical section. As many of the parts in both arrangements are the same, their situation only being changed, it has been thought unnecessary to give a detailed description of this machine; but similar letters of reference are employed to denote the corresponding parts. The hollow mandril in this machine is made of much greater length than that in the first described machine, and the position of the core and die is consequently changed, which is poured in at the top, by raising the ram or plunger *e*, out of the chamber. In this machine the hollow mandril and the die do not move up and down with the other moveable parts, but are stationary, and only so far moveable as to allow of their proper adjustment. The die *d*, is placed in a recess made at the bottom of the malleable iron cylinder *l*, and is secured therein by means of a plate *d**, bolted to that cylinder. Through the cover of the hydraulic cylinder passes the hollow mandril *b*, surrounded by a strong tube *a*, which is a prolongation of the piston *g*.

The ram *e*, is firmly bolted to the lower end of the piston or plunger *g*, and the hollow mandril *b*, which, at this part, is contracted in diameter, is passed through it. The lower end of the ram *e*, is furnished with a steel plate, which accurately fits the chamber *m*. The cylinder *l*, is suspended in a strong circular plate *v*, firmly secured to the frame work, and is prevented from moving from its seat by means of a ring *y*, which is bolted to that plate. *q*, is a circular plate, supported from the top flange of the hydraulic cylinder, *i*, *i*, by means of rods, and has an aperture in its centre, through which the hollow mandril *b*, passes; *j*, is another plate, supported above the plate *q*, upon vertical worm-shafts *a**, *a**, which pass through holes made in the plate; and to the centre of this plate *j*, the hollow mandril *b*, is secured in such a manner that by moving the said plate *j*, up and down, the hollow mandril is moved also in a corresponding ratio. The vertical worm-shafts *a**, *a**, each carry a toothed pinion *b**; and upon a horizontal shaft *c**, mounted in bearings on the plate *q*, are small endless screws or worms *e**, *e**, which gear into the pinions *b**. When the pinions *b**, *b**, are made to revolve, the worm-shafts *a**, *a**, will raise or lower the plate *j*, and, consequently, the tubular mandril *b*, to which it is secured. By this contrivance the distance between the core *c*, and the die *d*, is regulated, and, consequently, the thickness of the pipe is determined with the greatest nicety.

The mode of operating with this machine is very similar to that first described. The wires being enclosed in tubes or pipes, filled in the manner aforesaid, may be laid down or otherwise used, either above ground in the open air, or underground, or below the surface of water: and when so constructed, according to this improved method, will present outwardly the appearance of a common leaden or soft metal pipe. The improved conductors may be manufactured, by the machinery and means described, in long lengths, and may be rolled upon reels. If the electric conductors are to be used in great lengths on land, it is proposed to carry them on reels, on a wheeled carriage; and while the pipe is being laid down, one end is to be held fast, as the carriage proceeds in the direction in which the pipe is to be laid, so that the reel may revolve on its journals or centres, and thereby allow the pipe containing the wires to be unwound and delivered on the ground, without risk of injury, and with great facility. Should the conductors be required to be laid in water, it would be advisable to employ a floating vessel, propelled at a suitable speed, by drawing upon ropes or chains, made fast to the bottom or banks; or by steam-boat machinery, applied so as to regulate the speed.

When the electric apparatus is laid down or used on land, it may be laid in a trench made in the ground; and at regular or convenient distances, the ends of the pipes should be raised above ground, and placed in a cast-iron or other suitable case or box, provided with a lock or other means of safe keeping, so that the wires may be easily accessible to the examination of parties wishing to communicate intelligence by them. The ends of the individual wires may also be disconnected from each other in these boxes, and the circuit with the corresponding wires belonging to the adjoining tube completed, when required, by means of small pinching screws, or by causing the ends of the wires to dip into a hollow space, filled with mercury, or an amalgam of that metal, so as to produce metallic contact, in order that the conductors may be so joined as to form a continuous length to any extent, but capable of being disconnected when required.

For this purpose the patentees propose to employ an apparatus, shown in plan view at fig. 5, which represents the terminations of two pipes of soft metal, each containing three conducting wires *a, b, c*. The ends of these wires extend beyond the termination of the pipes, and are bent downwards into cups of mercury *g, h, i*. By this means the connection of the conductors is restored through the mercurial medium; that is, the conductor *a*, by its end being immersed in the cup *g*, communicates with the wire *d*; and the wire *b*, in the cup *h*, communicates with the wire *e*; and the wire *c*, through *i*, with *f*; connection is also made with the outsides of the pipes A, and B, by thick wires *k*, and *l*, soldered to the pipes, which are made to communicate through the mercurial cup *m*. This apparatus, placed at any desired part or parts of the line of communication, may be enclosed in a box *n*, and locked up securely.

The improved electric apparatus may be used not only as conductors for telegraphs, either by land or water, but also for firing mines, or other purposes for which electric conductors have been or may hereafter be employed. It is likewise proposed to use the leaden or other aforesaid metallic pipes or tubes, as means of returning the electric currents conveyed by the metallic wires enclosed in such pipes. Metallic contact is produced through the whole length of these tubes, so as to complete the electric circuit, either by soldering a piece of copper or other metal to each end of the leaden tubes, and bringing these pieces of copper or other metal into metallic contact through the mercury, or by other means, as above said.

When the conductors are used for electric telegraphs, these ends and the wires enclosed therein are attached to the wires proceeding from the clockwork of such telegraphs, in the usual way; but which may vary according to the construction of such telegraphs. If the conductors are to be employed for igniting gunpowder, a short piece of metallic wire, of small diameter, may be placed in any convenient situation, so as to form a part of the electric circuit; and if the electric current be sufficiently powerful, this small wire will be made hot enough to ignite gunpowder, when a current of electricity passes along the wires.

The patentees, in conclusion, state, that they do not intend to claim the adaptation of wires, surrounded with nonconducting substances, enclosed in tubes for electric conductors; but that which they do claim is, the construction and manufacture of electrical conductors, by the employment of machinery having a tubular mandril or hollow rod, through which wires may be drawn, whilst the leaden or other soft metal tube is forming, by pressure between a core and die; such wires being at the same time imbedded in pitch or other nonconducting material.

PROPELLING ON RAILWAYS AND CANALS.

William Hannis Taylor, of Piccadilly, gent., and Francis Roubiliac Condor, of Birmingham, civil engineer, for "*certain improvements in propelling*,"—Granted December 20, 1845; Enrolled June 20, 1846. (*See Engraving, Plate XII.*)

The object of this invention is to propel a train of carriages by means of electro magnetism in connection with the atmospheric principle, in the following manner:—A tube *a* is laid betwixt the rails throughout the whole length of the line, having two pistons *b* moving within it, similar to the present mode of working atmospheric railways, with this difference, that in place of forming the connection between the piston and leading carriage by means of an arm passing through the longitudinal opening. The inventors effect the above by means of powerful magnets *c* attached to one or more of the leading carriages of the train. On the top of the atmospheric tube *a*, which is provided with an opening of about three inches wide, there is firmly fixed a rectangular box of copper, *d*, projecting above the tube about three inches, so that the longitudinal opening is covered as it were with an inverted trough. Within this box there is a piece of soft iron, *e*, supported from the piston by means of a wood frame and arms, *f*. The magnets *c* are bent of such a form that the two ends or poles approach the sides of the copper box, or covering to the longitudinal opening, and fixed to the underside of the carriage; then being charged with the magnetic influence, by a galvanic battery, are attracted by the piece of iron *e*, attached in the manner before described to the piston, so that the connection between the carriage and the piston is effected by means of powerful magnets, in place of an arm passing through the longitudinal opening as heretofore.*

* The application of the above principle will be found in the specification of a patent granted to Mr. Henry Pinkus, in the year 1834.

CONNECTING OF BOILERS.

James Garforth, of Dunkinfield, Chester, engineer, for "*certain improvements in machinery, or apparatus for connecting of boilers, and other purposes*."—Granted December 10, 1845; Enrolled June 10, 1846. (*With Engravings, see Plate XII.*)

These improvements for connecting metallic plates for the construction of steam boilers consist in the direct application of the expansive force of steam to the dies for rivetting the plates together, and in the machinery or apparatus, whereby such force is brought into action. Fig. 1 is a side-view of an arrangement of machinery for rivetting metallic plates for the construction of steam boilers, and fig. 2 is a vertical section of the cylinder; *a, a*, is the frame work supporting the steam cylinder *b, b*, in which a steam-tight metallic piston *c*, is mounted upon the rod *d, d*, which passes through stuffing boxes *e, e*, at each end of the cylinder *b*; in the end of the piston-rod the die *f* is fixed, the other die *g*, being mounted in the pillar *h*, which is firmly secured to the frame-work. Steam being admitted through the entrance or feed-pipe *i*, it passes onwards through a common slide or other valve *k*, to the cylinder, and after having performed its office, is allowed to pass out through the pipe *l*, the slide valve *k*, being worked by hand by means of the lever *m*, so as to admit the steam on either side of the piston, as required.

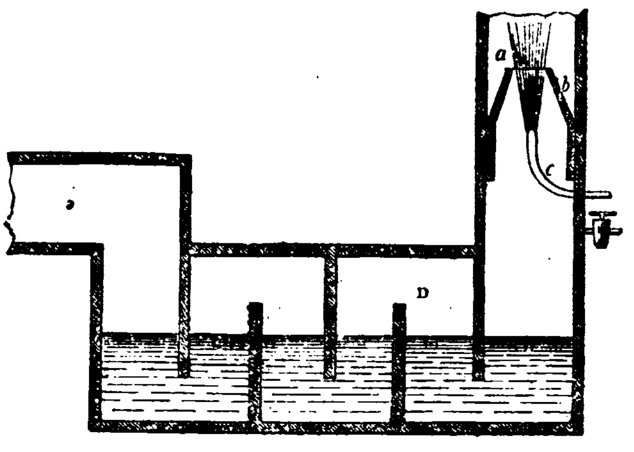
The operation of the apparatus is as follows:—steam of sufficient pressure being admitted by means of the slide valve *k*, on the left hand side of the piston *c*, it will force it, together with the piston rod *d* (to which is attached the die *f*), against the head *g*, which forms the end of the rivet *n*, between the dies *f* and *g*; thus firmly connecting the plates *p*, thereby producing a perfectly steam, air, or water-tight joint. The head of the rivet being formed at one or more blows as required, the intensity of the blow depending upon the area of the piston, the length of the stroke, and the pressure of the steam employed. The valve *k*, is then reversed, the steam admitted on the other side of the piston, which movement will withdraw the die *f*, when another rivet may be introduced and the operation proceed as before.

The inventor does not confine himself to the use of steam pressure, as the direct action of water, air, or any other elastic medium, may be similarly employed without departing from the principle of his invention. He does not claim as his invention the exclusive use of the several parts of the above machine, except it be employed for the purposes of his invention, which consists in rivetting metal plates by dies driven by the elastic force of steam, water, or other elastic medium as above described.

CHIMNEY DRAUGHT.

Henry Watson, of Newcastle-upon-Tyne, brass-founder, for "*Improvements in withdrawing air and vapours from furnaces or other apparatus, and in condensing and employing such vapours*."—Granted January 6; Enrolled July 6, 1846.

This invention relates to introducing a jet of steam through a cone fixed in a chimney, to create a draught and for withdrawing the air and vapours. Fig. 1, *e* is a section of a flue, with a cone *b* fitted inside, and made to



slide, so as to regulate the proper position for preventing a back draught. *c* is a pipe for introducing a jet of steam through the aperture of the cone, and for producing a partial vacuum below the opening; the inventor also shows how a chamber, D, to be used as a condenser, may be connected with the apparatus when a draught is employed for the purpose of reducing ores, such as lead. *e* is the flue, leading from the furnace. D, the chamber, half filled with water, and divided into compartments by partitions alternately dipping into the water. As the vapour passes from the flue *e* it will, the inventor states, on account of the partial vacuum created in the cone *b*, be made to pass through the water, and thereby be condensed and absorbed by the water.

STEAM SHIP PROPELLING MACHINERY.

JOSEPH MAUDSLAY, of the firm of MAUDSLAY AND FIELD, Lambeth, engineers, for "*Improvements in propelling and propelling machinery.*"—Granted Jan. 13; Enrolled July 13, 1846.

Fig. 1.

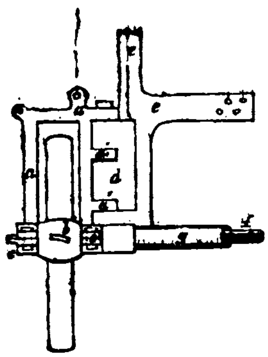


Fig. 2.

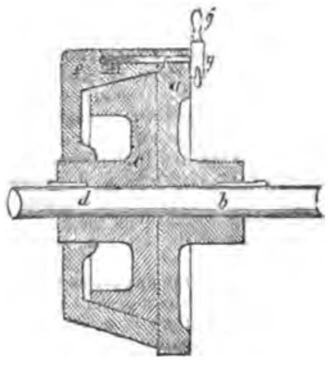

This invention consists in a mode of raising screw and other similar stern propellers, when the same are fixed abaft the stern-post. Fig. 1 shows the mode of effecting this object. *a a* is a rectangular framework of iron, which supports at its lower end a hollow shaft *b*, carrying the vanes of the propeller and working freely in the plummer blocks *c c*. The rectangular frame *a a* is provided with projecting pieces *a' a'* which fit into and are attached to a sliding piece *d*, in a similar manner to a hinge joint. This sliding piece *d d* is capable of moving freely upon a strong frame *e e*, which latter is firmly bolted to the counter of the vessel. *f* is the propeller shaft which passes through a hollow shaft or tube *g*, the propeller shaft being squared at its outer end so as to fit the hole formed in the boss or hollow shaft *b*, which hole is of the same figure. *h* represents a chain, one end of which is attached to the rectangular frame *a*, the other being attached to a capstan or windlass on board the vessel. When it is necessary to raise the propeller, the square end of the shaft *f* is withdrawn from the boss or shaft *b*, then, by giving motion to the windlass, the part *d* will slide upon the frame *e e*, carrying with it the rectangular frame *a a* and propeller. The advantages of this arrangement are stated to be, that the propeller may be placed lower down than heretofore, and consequently a larger propeller may be employed, moreover the water passing from the propeller will meet with less obstruction against the sides of the vessel, and which vessel will be less subject to that tremulous motion caused by the action of the propeller.

The second improvement consists in disconnecting the propelling shaft from the driving shaft, thereby allowing the former to run loose upon its axis when the vessel is required to be worked with sails only, or when she is laying in a tide way. In fig. 2, *a* is a circular plate of cast iron, firmly keyed on the outer end of the driving shaft *b*; *c* is a casting in the form of a frustrum of a cone, and is firmly keyed upon the inner end of the propeller shaft *d*; upon the periphery of this conical piece there is a hollow casting *e* turned accurately to fit the conical part *c*. On the periphery of the plate *a* there is cast three "snugs" or projections, through each of which is passed a bolt *f* (one only of which is shown in the drawing); at the outer end of these bolts there is a winch, *g*, or handle, having three projecting arms *g'*, so that one is always uppermost. It will therefore be seen by the above that by screwing the bolts *f*, and the part *c*, the propeller shaft *d* will be driven by the friction of the two conical pieces *c* and *e*, and by unscrewing the conical part *c* and propeller shaft will be allowed to run loose.

ATMOSPHERIC RAILWAYS.

CHARLES WHEELER, of Speenhamland, Berkshire, machinist, for "*certain improvements in the construction and working of railways*"—Granted January 22; Enrolled July 22, 1846.

The first part of this invention is for an improved form of rail for railways, shown at fig. 1, which represents a transverse section of a rail constructed of such a form as to present three different surfaces to the action of the wheels, that is to say, when one surface is worn out, another can be turned up, as will be clearly understood by the following description. *a* is a section of the rail, fastened down to the sleeper by means of cast iron blocks *b*; between the rail and the block a piece of felt is placed, or a key way may be formed in the blocks, as shown at *d'*, and a hard wooden wedge driven. The rails are further secured to the sleepers by means of a half round piece of wood *c*, upon which the rail is made to rest. The specification states that this description of rail may be made by rolling the bars of iron betwixt three rollers.

The second part of the invention consists in transmitting motion from the piston of an atmospheric railway to the carriage by having a flexible covering to the top of the tube, which is raised up and forced against a wheel attached to the leading carriage by means of a wheel attached to the piston.*

Fig. 1.

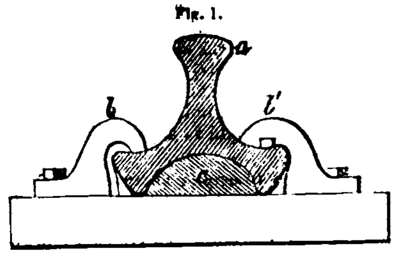

Fig. 3.

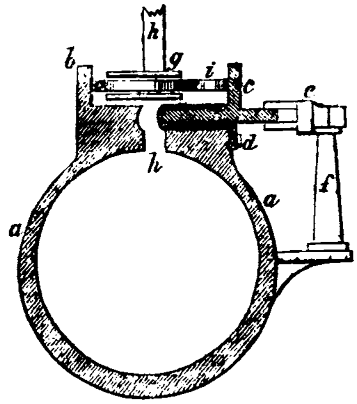

Fig. 2.

The third part of the invention relates to a mode of closing the longitudinal opening by means of a continuous sliding valve, shown at fig. 2, which represents a transverse section of the pipe and sliding valve constructed according to this part of the invention; *a* is the tube, which is cast with a projecting rib *b*; *c* is a sliding plate, also having a projecting flange similar to that upon the pipe; a number of these plates are hinged together with a rule joint, so as to extend the whole length of the line. Upon the underside of this sliding plate there is a piece of leather *d* firmly attached to the side of the pipe, which piece is brought over the longitudinal slit or opening by the inner edge of the plates *c*, the outer edge of such plates being acted upon by means of springs *e*, supported at intervals by pillars *f*, which have a tendency to force the plate *c* and leather over the opening. *g* is a framework of iron attached to the vertical arm *h*; this framework supports three anti-friction rollers which, as the piston travels along, forces back the plate *c*, so as to allow the vertical arm to pass, the opening being closed again by the action of the springs *e*. Fig. 3 shows a plan of the framework *g* and rollers *i*.

* This mode of forming the connection has already been patented two or three times over.

DECORATION OF HOUSES.

HENRI AUGUSTE BEX, of Great Titchfield-street, Marylebone, decorator, for "*A new method of drying, polishing, and colouring marble, stone, and certain other materials used in the construction or decoration of houses and other buildings.*"—Granted December 10, 1845; Enrolled June 10, 1846.

The improvements are: First, in polishing marble and stone by filling up the pores with plaster of Paris or marble cement; then rubbing them with hard stones, applying a thin layer of plastic before each rubbing; and lastly rubbing them with wax, or a mixture of wax and turpentine. Secondly, in polishing other materials used in the construction or decoration of houses by rubbing them with a varnish of gum lac. Thirdly, in dyeing and colouring marble, stone, and other materials used in the construction or decoration of houses, by wetting them with certain acids, salts, and colouring materials or their chemical combinations, by means of a brush or sponge.

The inventor then proceeds to describe the manner in which the said invention is to be performed. To polish marble or stone the surface to be polished is first rubbed with a piece of sandstone, and afterwards with a sandstone of a finer description, in same manner as is now ordinarily practised; the pores of the marble or stone are then stopped up with plaster of Paris mixed with a thin solution of gelatine and some colouring matter, to render it of the same colour as the marble or stone to be polished, till it attains the consistence of cream, or else marble cement mixed with colouring matter, till it attains same consistence, and is similarly coloured. These mixtures are then laid on respectively, as the case may be, with a brush, and afterwards scraped off with a wooden knife, taking care that all the pores of marble or stone are filled up. The marble or stone is then rubbed with a kind of sandstone called Charley Forest stone; the pores being stopped up, are rubbed with the stone, and after that with a piece of German stone, and finally with a piece of touchstone; before each of these rubbings there is laid on with a brush a thin coat of plaster of Paris or marble cement, mixed with water to the consistence of milk; and lastly, should the colour of the stone or marble be clear, a coat of wax, or mixture of wax and turpentine, is laid on and rubbed with a linen, cotton, or woollen rag, till the marble or stone becomes perfectly polished, but if the colour of the marble or stone should not be clear before applying the wax, or mixture of wax and turpentine, it is rubbed with linseed oil till the colour becomes clear, taking care to remove all the oil before the wax is applied. In addition to the above process, sometimes the marble or stone to be polished is rubbed with a piece of jasper, if a very brilliant polish is required. Other materials used in the construction of houses are to be polished in same manner as the marble and stone above described, till the rubbing is completed with the Charley Forest stone; they are then rubbed with linseed oil, taking care to wipe it off thoroughly, and then varnished with gum lac in the following manner:—Take a ball of wool, wet the surface of it with the varnish, and cover it with a linen rag. Then well rub the material to be polished, adding a little oil occasionally, if the varnish should not work freely. To dye and colour marble or stone, and other materials used in the construction and decoration of houses, the same system of acids, salts, or colouring matter is employed as generally used by dyers in dying cloths and other textile fabrics. The said acids, salts, or colouring materials, or their chemical combinations, are applied in a liquid state, over the surface of the material required to be dyed or coloured by means of a sponge. If the dyed or coloured surfaces are to have the same polish as the rest of the surface, the said colouring materials are applied before polishing the said substance, or when the process of polishing is only half finished; but if it be wished the dyed or coloured matter to be dead or unpolished, the colouring materials are applied after the process of polishing is completed. The certain other materials alluded to in his title are plaster, stucco, scagliola, and a species of stucco invented in France, and introduced by the inventor for the first time in England, and which is called *stuc à la brosse*. The claims are:—First, the filling up with plaster of Paris, or marble cement, in the manner above described, the pores of the marble or stone intended to be polished, and rubbing them with certain hard stones, as hereinbefore described; secondly, the polishing of certain other materials used in constructing or decorating houses, &c.; and thirdly, in dyeing and colouring marble, stone, and other materials, as above described, by wetting them with certain acids, salts, colouring materials, or their chemical combinations, as above described, by means of a brush or sponge.

GRAND BLAST AT THE DOWNHILL TUNNELS, LONDONDERRY AND COLERAINE RAILWAY.

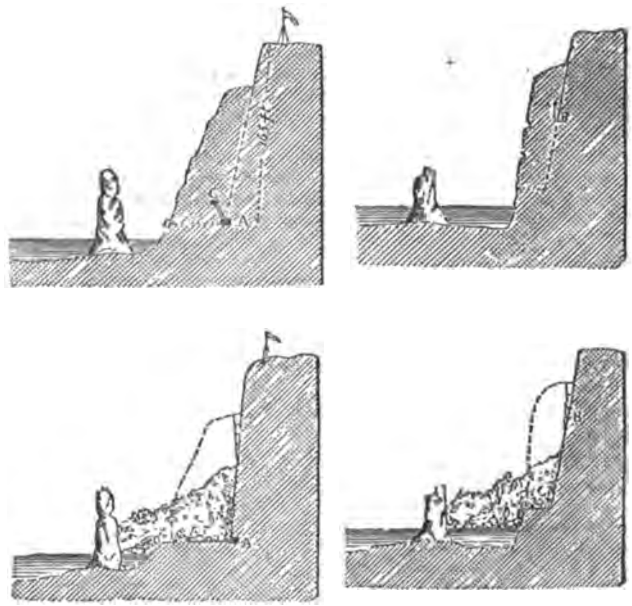
The novel nature of the undertaking proposed by the Londonderry and Coleraine Railway Company, has, from its first appearance before the public, invested that project with peculiar interest to scientific and the monetary world.

Lough Foyle, a deep indentation of the sea on the northern coast of Ireland, covers an area of about 60,000 acres. With the exception of the channel along the Donegal shore, leading up to the port and city of Londonderry, the tide in this lough does not generally rise more than six feet, and, at low water, a large portion of its area is left perfectly dry, exposing a slob formed of the richest alluvial deposit, capable of immediate conversion into valuable soil. The situation of the lough—almost land-locked, protected from the swell of the Atlantic by its narrow entrance, and sheltered from the prevailing westerly winds by the mountainous nature of the country on the Donegal coast—is such as at once to suggest the idea of facility for shutting off the sea, and reclaiming a great portion of the slob land. In the Session of 1837, an Act of Parliament, authorising this reclamation, was obtained, and two enclosures were made, winning from the sea about 4000 acres, upon part of which luxuriant crops have already been reared. In 1844, public attention became alive to the necessity for establishing railway communication between the important towns of Londonderry and Coleraine. The mountainous nature of the interjacent country, rendered a line inland impracticable. and the idea was conceived of combining the Railway and the Foyle reclamation, making one embankment serve for both. With this object a Company was formed; terms were arranged with the parties in whom rested the powers under the Act of 1837; and, in the Session of 1845, the Londonderry and Coleraine Railway Company obtained its Act of incorporation.

The length of line proposed by this Company is 30 miles, including a branch to the town of Newtown-Limavady—15 miles to be constructed on an embankment through Lough Foyle; and by which embankment about 22,000 acres of land will be recovered from the sea. Of this reclaimed land, 12,000 acres are set apart to cover the expenditure on the railway. The works are now so far advanced, that by the end of the present year the Directors anticipate being in a position to enclose and sell a portion of the land; and, as the works proceed, like portions may from time to time be enclosed and sold.

The line, after leaving Lough Foyle, proceeds eastward across Magilligan Point, and along the coast towards Coleraine. About seven miles from the latter town, and close to Downhill, the beautiful residence of Sir Hervey Bruce, Bart., it passes through the cliffs between Downhill House and the sea by two tunnels, one about 700 yards and the other about 300 yards in length. The works upon those tunnels have been some time in progress by the ordinary process of picking and blasting; but it being deemed necessary to expedite their construction, it was determined to effect the removal of the obstructing rock by one grand blast.

ROCK BEFORE THE EXPLOSION.



ROCK AFTER THE EXPLOSION.

We are indebted to the Illustrated News for the following particulars relative to an extensive blast which took place at Downhill, about 7 miles from Coleraine, on the 6th June last:—"The mass of rock which it had been originally necessary to remove was at the western mouth of the large tunnel, and measured nearly 60,000 tons, the material being the hard basaltic stone, in which the coast of Antrim and Londonderry abounds; a large portion of this rock had been previously removed by the common slow process already named. Having resolved upon the large blast, Messrs. Bromhead and Hemming, the contractors, formed a heading or gallery into the rock, from the side of the cliff, 50 feet in length: at the end of this, a shaft was sunk, 22 feet to the level of the railway, as seen at C A; and again another gallery at the bottom, running at right angles to the first gallery, and further into the rock, was made for 10 feet. At the end of this was placed the large charge of powder, 2,400 lb., shown at A. The whole was then well filled up, and tamped with clay and masonry, and the wires to convey the electric fluid from the battery through the charge were carefully arranged. The smaller charge, which was higher up in the rock, and which is seen at B, contained 600 lb. of powder; and the gallery B F leading to it was about 70 feet in length; this was also tamped in a similar manner to the larger one. The galvanic battery, which stood on a shed on the top of the cliff, was a very powerful one, consisting of 18 cells, each cell about 14 inches square.

The operations were conducted by Mr. Hemming and Mr. Webb, Superintending Engineer to the Contractor. Mr. M'Leod, acting under Mr. Robert Stephenson, the Engineer of the Company, was present, with Mr. Langon, and other civil engineers. There were also several royal engineers and scientific gentlemen who had come from different quarters of the country to witness the explosion.

At the appointed hour some little delay occurred in connecting the wires with the battery; but, at half-past three o'clock, the two poles were united, and instantaneously the bottom of the rock was seen to heave out for a moment, the mass of rock above stood, trembled, and, cracking into a thousand fissures, rolled into the sea beneath. A deep and hollow sound was heard, like distant thunder, but *no report*. The quantity of rock removed must be upwards of 30,000 tons. The effect will be seen by referring to the accompanying profiles or sections taken through the lines *a a b b*, in the front view, both before and after the blast. The result, in an engineering point of view, was perfectly successful, and reflects the greatest credit on the gentlemen superintending the operation.

The dotted lines show the quantity of rock to be removed. A is the larger chamber, containing 3400 lb. of gunpowder. c, the heading leading to it, which is 50 feet in length. B, the smaller chamber, containing 600 lb. of powder. A x, the line of least resistance—50 feet. From A to the top of the cliff—165 feet.

THE GAUGE COMMISSION.

Analysis of Evidence given before the Royal Commissioners appointed to investigate the subject of the diversity of Railway Gauges.

(*Continued from page* 214.)

Mr. Edward Bury: Is a manufacturer of locomotive engines, and has been such for 17 years. The heaviest engine made by witness has not exceeded 13 tons. 14-inch cylinder the largest yet made by witness; evaporating surface in proportion to the cylinder. Length of boiler increased from 8 feet 6 inches to 11 feet 6 inches. Space between fore and hind axle very considerably increased; interval 7 feet 6 inches. Witness considers that the speed now attained on narrow gauge lines as great as consistent with safety. The securities for the rails not sufficient to justify a higher rate of speed.

The transverse sleeper better than the longitudinal. There is a better chance of keeping the transverse sleeper right than the longitudinal sleeper; there is a great deal less packing with the transverse sleeper than the longitudinal sleeper; the under surface of the longitudinal sleeper is too great to admit of its being thoroughly and uniformly packed. Greater speed can be obtained on broad gauge than on narrow, because the speed depends upon the ratio of the stroke to the wheel, and on broad gauge a longer stroke and larger wheel can be had. The narrow gauge trains, however, can travel faster than is necessary or safe. If the Midland Counties were changed to broad gauge, the inconvenience to the London and Birmingham Company would be so great that they would be compelled also to change to broad gauge. Does not consider the rigidity of the rail essential to safety at high velocities; it would be better with a moderate elasticity in it. The best part of the Liverpool and Manchester Railway, and the most easily maintained, is that which occurs at Chat Moss, which is always elastic. The most difficult part to maintain on the Liverpool and Manchester line was that which went through Olive Mount, which is on a stone foundation. They have been obliged to take the stone out for a considerable depth under the rails and fill it up with ballast. The engineer of the Bolton and Manchester line was anxious to make that line perfectly rigid. He built a continuous wall, and put it upon a T rail; but that did not stand at all; it knocked everything to pieces; it was always out of order, and they have been obliged to change it. The rail itself ought to be rigid, and the foundation on which it is placed should be elastic. Does not think any of the rails that have hitherto been laid are heavy enough. Has no knowledge of the feeling of proprietors in the mineral districts with respect to broad or narrow gauge, but considers that the narrow gauge is more suitable to their traffic, because the curves can be made sharper than on broad gauge, and bring them closer to the pit's mouth. Prefers a wider gauge than 4 feet 8½ inches, which witness believes too narrow for the engines and carriages and machinery working on the rails. 6 or 8 inches' additional width would be amply sufficient. Does not at present use outside cylinders, but some are now being made. Can get sufficient power on the narrow gauge, but a more convenient and accessible machine, with greater range and capability, could be constructed with a little additional width of rail. If witness had to determine on the gauge for a country having no railway, should certainly not adopt the 4 feet 8½ inch gauge. Would not adopt the 7 feet gauge. Should adopt an intermediate gauge, as preferable for engines, carriages, and wagons. Strength of passenger carriages on London and Birmingham Railway considerably increased, weighing 10 or 12 cwt. more than when the line was first opened; this increased strength essential to public safety as well as to the durability of the carriage. Reserve fund appropriated to purchase of new engines. Stock deteriorated within the last half-year in consequence of being compelled to run the engines, &c., longer without the usual repairs, on account of the heavy traffic on the line.

Stock of Great Western Company valued at £534,000; of the London and Birmingham at £275,000, the latter doing the most work; difference accounted for by inferior size and expense of engines on London and Birmingham line. With the additional stock the expenses will come nearer the expenses of the Great Western Company. The 175 miles now worked with the original stock of the line. They have 93 engines and one borrowed from another Company.

Accidents from breaking of axles of rare occurrence; not one carriage axle broken within the last five years, and very few engine axles. The fracture of axle usually occurs in the journal; outside the wheel in the carriages, and inside the wheel in the engines. Engines frequently run some distance with a broken axle; have never had one so crippled as to be unable to get home; some have even taken out trains with a broken axle. The train taken off the line from broken axle in only one instance, when the front axle of the engine broke. Increased length of engine gives increased steadiness. Messrs. Sharp are manufacturing an engine with 18-inch cylinders; the cylinders are not placed outside the wheels, but inside, so that there is room for two 18-inch cylinders with the narrow gauge to be constructed inside the wheel with the crank shaft. Impossible to say what load an engine can be made to take on narrow gauge, but considers that for the ordinary traffic of the country, an engine on narrow gauge may be made of sufficient power to take at high speed both passenger and luggage trains. Present luggage engine on London and Birmingham line too small. Luggage trains often worked with several engines. The heaviest luggage train on this line was a train of 112 or 116 wagons, making upwards of 600 tons; for this train four engines were used.

Long trains much impeded by high winds. Has seen the transverse sleepers pushed out of their places, sometimes twisted like the letter S, by the expansion of the rail; this has occurred when sufficient allowance was not made between the rail for expansion. Average speed of express trains on London and Birmingham line 43½ miles an hour, including stoppages. They now use 13-inch cylinders; some of their engines for the express trains have been altered, by increasing the size of the boilers, an additional inch to the cylinders and three inches to the wheel. Does not think it safe to run a small train very fast; should prefer more weight on the engine to make it run steadier; when any of the royal family are on the line, always put more carriages on than are required for passengers, in order to steady the train. Has frequently travelled by express train on London and Birmingham; there is very little oscillation; thinks the express train steadier than any other because it is better screwed up; everything is in higher order. Outside cylinders not yet tried on this line; they were tried on the Liverpool and Manchester and condemned; the oscillatory motion objected to; the boilers, however, were shorter than they are at present; there was a greater tendency to the yawing motion. Decidedly objects to the use of carriages with shifting wheels on account of the difficulty of keeping the securities always right. Experiments have been made in the United States to allow wheels to adjust themselves on curves; they were soon abandoned, it being impossible to keep them in order. A very small increase on the narrow gauge would afford great accommodation in the construction of the engine. The difficulty of oiling and cleaning the narrow gauge engines a very great inconvenience, and can only be felt by engine-makers. They require more space for the tube of boiler, and a larger fire-box.

Mr. Benjamin Cubitt: Does not think an equal power can be obtained on narrow as on broad gauge. The narrow gauge does not allow width enough to get a fire-box large enough, and is cramped for width in getting strength for the working parts of the engine. Thinks it impossible to make so effective a boiler for narrow as can be made for broad gauge.

Has not particularly considered the relative advantages and disadvantages of outside or inside cylinders. There are about half-a-dozen outside cylinders upon the lines of which witness is superintendent. Total stock of engines about 120; all but 16 on 6 wheels. The Dover Company have ordered a large number of outside cylinders. Has ridden a good deal upon the outside cylinder engines. At first they travel as steadily as the inside cylinders, till they have been at work eight or ten weeks, and then they begin to get side play and oscillate a good deal. This motion increases with the wear. The repairs upon outside cylinder engines are not more costly than upon inside cylinder engines.

The repairs required on the outside cylinder engines.

Bodmer Engine								73	[illegible]

* April 14, 1845.—Taken into dock to have new tyres, axle-bearings, and general repairs.

† August, 1844.—Taken into dock for two new eccentric straps, and temporary repairs.

‡ April 21, 1845.—Taken into dock for new driving-wheels, new bearings in leading wheels, and general repairs.—July 10, 1845: Taken into dock for new bearings to trailing wheels.—July 22, 1845: Taken into dock for leading wheels keyed on to axles, and new axle boxes and bearings to driving-wheels.

In the narrow gauge inside cylinder engine there is scarcely sufficient space for the necessary repairs and cleaning; there is also a difficulty in the outside cylinder to get at the bearings, both to oil and to clean them, without lifting the engine. As a locomotive engine-maker, is in favour of a gauge of 5 feet 3 inches. There is at the New Cross station a new engine of great power, made by Bodmer; he has taken out a patent not only for locomotives, but for steam engines in general, for what he calls a compensating engine, as it works with two pistons in one cylinder, so that the connecting rods pull and thrust at the same time, which takes the strain off all the other parts of the engine, except between the cylinder and the crank. The length of the boiler is 10 feet, the cylindrical part of the boiler. The fire-box is as large as it can be got to suit the gauge. This engine has been tested against other engines and found more powerful than any other with one pair of driving wheels, because it is a larger engine, with a larger boiler, and larger cylinder; the cylinders are 16 inches in diameter, and the stroke is equal to a 30-inch stroke, being four 7½-inch cranks. It has taken 38 carriages upon an incline of 16 feet a mile, about

4½ miles long, at about 30 miles an hour, with a gross load of about 150 tons.

Cannot accurately ascertain the comparative locomotive cost of working goods trains and passengers trains upon this line, the accounts not being separately kept.

Locomotive Expenses of the Brighton, Croydon, and Dover Railways, compared with the Great Western Railway Company, for the half-year ending December, 1844.

The passengers of an ordinary train of 10 or 12 carriages could not be changed from one train to the other under 20 minutes. With engines on narrow gauge, even with outside cylinders, there is more difficulty in getting access to the axles to clean and oil them than in the broad gauge. This difficulty of oiling the axle depends upon the circumstance of the cylinders being outside, and not upon the breadth of the gauge. It is easier to do this with the wide gauge engines; on the crank axles the bearing is taken on the outside of the wheels; on the four-wheel engines the bearings are inside bearings, and there is a difficulty in getting the men to keep those bearings clean. If the gauge were increased from 4 feet 8½ to 5 feet 3, the weight of the engines would be increased from 15 cwt. to a ton. Average weight of engines on South Eastern Railway, about 14 tons; on Great Western about 17 tons. Considers that the general construction of the roads will admit of heavier engines being placed upon them.

Weight of rail upon the South Eastern line 65 lbs. a yard. The bearings average 3 feet apart upon a cross sleeper. The sleepers are triangular; they are four triangles cut out of a 13-inch square. The rails are fastened to chairs with wooden keys; and the chairs are fastened to the sleepers by wooden treenails. The boilers upon Great Western are not much larger than those upon the Brighton line. If witness had the control of the engines of the Great Western, should certainly make larger boilers. There is room to get sufficient strength and cranks, with inside cylinders; but the engine and the boiler have to be raised, which is a great objection. Would like to have the cranks more separated, and keep the boiler still the same height. To give the cranks strength, obliged to make the bearings shorter to get room for the cranks. The thickness of the side of the crank, which is perpendicular to the axis, 4 inches; some 4½. Does not think it necessary to make that thicker; the great advantage would be in getting the bearings longer. The eccentrics are reduced as much as possible. When they are very short bearings, they are apt to heat and get dry; then they cut away the journal, and it is reduced and made weaker. With the present construction of the South Eastern Railway, should venture to increase the speed by having much more powerful engines. The quickest train is upon the Brighton line, which runs from Brighton to London in an hour and a half; that is 50½ miles, stopping once five minutes. The distance is often run in an hour and a quarter; some parts of the distance cannot be run at 40 miles an hour, on account of the gradients; and other parts have to be run at more than that speed, in order to keep the time. There are 120 engines for the three Companies, working 166 miles. This includes the Dover, Brighton, and Croydon, and two miles of branch to the Bricklayers' Arms, and the branch to Maidstone.

William Cubitt, Esq.: The limit to safe speed on narrow gauge lines is the want of evaporating surface and space for the fire boxes, the want of solidity and perfection in the road, the want of base for engines or carriages, the want of greater strength in the rails, and greater security in connecting them with sleepers; many accidents have been caused by attempting to go too fast upon a bad road. And that danger is very much increased by increased velocity. A speed of 15 or 20 miles an hour may be safely attempted on a bad road, while double that speed would throw engines and cariages off the line of road. Attention to the state of the road has not kept pace with the improvement in the driving machine. Before increased speed is attempted that particular should be attended to. The perfection of the permanent way has been less thought about than almost any other part of railway mechanism, and that is the basis upon which it all rests. Does not think that the speed might be increased, without a corresponding increase of danger to the traveller, by adding to the width of the narrow gauge; considers the narrow gauge wide enough for safety at almost any practicable speed, but not wide enough to get the most perfect machinery for speed. An addition of 6 or 8 inches over the present narrow gauge is wide enough, perhaps, for all practical purposes of machinery of locomotive engines and carriages. A gauge of about 6 feet would be the best. Has often heard that an increase of gauge would involve the necessity for widening the tunnels; does not concur in this opinion; if the size of the largest loads is not altered, nothing need be altered but the gauge. Does not think that if they had carriages upon a wider gauge, they would wish to carry larger loads; in railway operations would rather adopt the same width, making the vehicles of greater length, which would produce greater safety and greater convenience than by shortening them, so as to produce greater width and greater height. The adoption of a wider gauge in tunnels would not restrict the room for workmen, as regards trains passing; the wheels are always far inside the outside of the trains, and so they would with the 6 feet gauge, because the loads are 8 feet; the only difference would be that the two inner rails would be nearer to each other, and the two outer rails would be nearer to the walls; the centre of gravity would be the same if the loads were no higher.

An increase of the width of gauge would not render it imperative to have a corresponding increase of the radius of the curves. An increase of the gauge would not render necessary a corresponding increase of the height of the driving wheel. Does not think that in reference to the number of miles run on the broad gauge, and the number of miles run on the narrow gauge, that there are fewer accidents on the broad gauge than on the narrow. The superiority of either gauge depends not upon the gauge, but upon the condition of the permanent way. Gradients are of less importance if the road is in perfect order. Rigidity in a road is preferable to elasticity in a road. With elastic rails, it becomes like driving over a series of points. If there be any elasticity at all, it is best to have it in the whole road, like having a perfect road laid upon a bog, as in Chat Moss, or any other soft ground, where the whole railway itself could, in a very great length, have a very slight elasticity. There is less cost in the repair of Chatmoss than any other part of the Manchester and Liverpool Railway on that account. It always will be so upon soft ground. If you have a good permanent way, thick enough and strong enough in itself, and lying upon a substratum, which has a little tendency to elasticity, it is most easily kept in repair. Cross-sleepers are better than longitudinal sleepers for keeping in repair. Any sleeper of a proper form can be packed, whether it lies longitudinally or transversely. There is a greater length of bearing to be obtained upon cross-sleepers than upon longitudinal sleepers. If we were to have a railway laid from end to end, all upon cross-sleepers, there would be a much greater length of bearings than upon a railway where it is all upon longitudinal bearings; and the greater number of sleepers we have the better the road will be.

Is not aware of the exact limits of contraction and expansion, by cold and heat, of a 16-foot rail; has known the road lifted up; has known it bent sideways by expansion; has never had time or opportunity to measure it exactly; it is a difficult thing to ascertain what the expansion is in certain cases; it can be done best off the line, by ascertaining the temperature of certain lengths of bar uniformly. Expansion and contraction on longitudinal bearings have a tendency to loosen the screws which bind the rail to the balk.

Break of gauge is of little consequence in reference to passengers, but becomes a great difficulty in transferring heavy goods. It becomes a matter of importance to devise the best, cheapest, and quickest mode of transhipment from the one gauge to the other, whether it be by removing the goods from one carriage to another carriage, or by moving the body of one carriage on to another set of wheels by mechanical power; it becomes a question of cost. The measure of the inconvenience is the cost per ton to do it quickly. The expense of constructing powerful lifting machines of little importance where the traffic is large; has laid out £130,000 to save about a halfpenny per ton upon the shipping of coals. Could put up apparatus to move 25 wagons in one minute, or in a couple of minutes, requiring the employment of not less than 50, nor more than 100 men. The cost of transhipment would be a trifle upon a long line, but a large item upon a short one. It is perfectly easy to make wagon frames and wagon bodies for a large trade that would go to any part of the country; the bodies must go quite through, and return again; the frames would keep on their own lines, and the wagons would simply drop into them. There would be no difficulty in constructing passenger carriages to move in the same way; if there is traffic enough to render it worth doing, there is no difficulty in doing it.

THE HOUSES OF PARLIAMENT.

Ventilation has taken the character of stagnation in its effect upon the progress of the Houses of Parliament; more especially those parts of the interior whose completion is soonest required—at least impatiently demanded. Talking and *Reiding* have considerably retarded operations. No one room is yet anything like finished,—or much more than merely sketched out,—though the main work, that of construction in the rough, is nearly terminated in the House of Peers and the royal approach to it. At present, the picture is merely drawn in and dead-coloured; therefore we pretend not—especially from such cursory inspection as ours has been—to judge of intended effects otherwise than conjecturally, and with due submission to correction for any misunderstandings into which we may have fallen.

To begin, then, with the royal entrance from the gigantic porch beneath the Victoria Tower:—the Scala Regia, which is partly lighted by lanterns in its vaulted and groined ceiling, ascends in a direction, as seen from the entrance, turning to the right or southwards, in two successive flights. We forgot to count the number of steps in each flight, which Lord Sudely found fault with as being too many for architectural dignity. But there is a precedent for more multi stepped, and certainly for loftier, flights, in what is, perhaps, as magnificent an example of a staircase as any we know of—viz., the *Parade treppe* in Gärtner's new building of the Bibliothek at Munich. This greatly exceeds in point of amplitude, splendour, and perspective display, what the Westminster staircase promises to be. In one respect, indeed, the latter is almost unparalled,—the *risers* being unusually low, and the *treads* broad; so that what, in moderation, contributes to elegance and convenience, is here carried to such excess as to be likely to prove an incommodity. It is not only somewhat fatiguing to walk up such very shallow and broad steps, but rather difficult to do so without seeming to stride or jerk along, or making two steps of each stair. Some little practising will be necessary for either ascending or descending majestically. Passing through the *shell* of the Victoria Gallery and another room, we enter the House of Peers, at the west, or throne, end;—the first glance at its ceiling, a wide expanse of gorgeously carved and gilded work is already striking enough. How far more imposing—almost bewildering—will be the first *coup d'œil* of this spacious and magnificent hall when completed in all its decorations—its walls arrayed in gilding and emblazoning, displaying a series of compartments of fresco below, with a corresponding range of richly painted windows (six on each side) above. Still, we have our misgivings: because, though casual visitors may be more than satisfied—even enchanted—"My Lords," themselves are likely to feel sated by the constant blaze of so much architectural and pictorial pomp. Such a sumptuously, not to say extravagantly, adorned hall, would be more in place within the walls of Windsor Castle, for royal banquets and festivities, than as a place for solemn debate on grave and anxious matters. Putting propriety of purpose out of the question, we entertain great doubts, too, as to the effect which such profusion of painted glass as is intended will have upon the fresco paintings. Besides that gleams of coloured light may occasionally fall from the windows upon parts of the mural pictures, quite different in hue from the colours on the latter,—will not the windows overpower the paintings, and cause them to look flat and dull, by comparison?—or can that inconvenience be remedied by exaggerating the colours of the frescoes, and painting them up accordingly? We may be allowed also to ask, whether another matter has been taken into consideration—because if it has hitherto been forgotten or overlooked, attention should be directed to it without further delay. Will not the effect and character contemplated for the "House" be, in great measure, lost at those particular times when the place will be chiefly used for business? After dark, the painted windows will not show themselves otherwise than as gloomy gaps and vacancies, occupying the upper half of the two side walls. A singular degree of brilliancy might, however, be obtained at night, by lighting up the house chiefly, if not entirely, from without, by means of gas burners on the outside of the windows. This would be further useful as helping ventilation. The plan appears to us to have, independently of its novelty, much to recommend it; should there be objections to it, not perceived by us, we yet hope that while they have their due weight, the suggestion itself will not be wholly disregarded, merely because it is a suggestion.—*Athenæum.*

PROCEEDINGS OF SCIENTIFIC SOCIETIES.

ROYAL SCOTTISH SOCIETY OF ARTS.

June 8, 1846,—John Beatson Bell, Esq., V.P., in the Chair.

The following communications were made:—

1. *Description of the machinery used, and of the manner in which the sand at the sides and end of the open-cutting was supported during the excavating and building of the works of the Edinburgh, Leith, and Granton Railway Tunnel in Scotland Street.* By Mr. William Paterson, F.R.S.S.A., Resident Engineer of the Tunnel. In this communication, Mr. Paterson described the machinery used, and the manner in which the sand at the sides and end of the open-cutting was supported during the excavating and building of the works of the tunnel in Scotland-street. A beautiful and accurate model was at the same time exhibited, representing the face of the tunnel, and the manner of disposing the beams to resist the pressure. There were also plans and sections of the works shown. The Society were greatly interested in this communication, which was clearly illustrated by the model and drawings. Referred to a committee.

2. *Description of a Patent Crane*, by David Henderson, of Renfrew, in which the important peculiarities of his improvements will be illustrated by drawings and a working model. Mr. Slight described this patent crane, distinctly showing the important peculiarities of Mr. Henderson's improvements by the aid of drawings and a working model. One of these patent cranes is at work in Mr. Slight's own works, and the valuable invention is coming into general operation in the west. In the ordinary crane as the Derrick rises the load also rises, and much time and labour are wasted; but the relative forces of the present have been all calculated by Mr. Henderson with mathematical accuracy, so that it combines great power and efficiency with safety. The barrel and wheels are so constructed as to afford a self-acting check; that is to say, although several tons weight were suspended, and in the act of being raised or lowered, the handle of the crane can be let go at once, and the machine remains in *statu quo.* Mr. Slight pointed out several other valuable properties of this invention, the principle of which consists in the Compensation Barrel, by which after the load is raised as high as necessary, it is then brought in nearly on a level, although the Derrick be raised. This of itself saves much time and labour.

3. *Description of a Revolving Valve for Locomotive and other Steam Engines.* By John Anderson, Esq. The principles and construction of this valve are entirely new. Instead of the reciprocating or alternating motion, so long in use, Mr. Anderson adopts a continuous rotary motion. The valve may be said to consist generally of two circular metal discs, connected together by a tube, placed opposite the ports of the cylinder. These discs are divided into two chambers, the one having communication with the steam, and the other with the exit passage. Into each of these chambers ports are cut so as to form, at certain parts in the revolution of the valve, a free passage, either for the ingress or egress of the steam, the disc for the upper part being so placed that the one may be admitting steam into the cylinder while the other is allowing it to escape. The whole valve works in a cylindrical case, having ports corresponding with, and opening into, those of the cylinder, the same as that of Medhurst's, but with this important difference, that the one revolves, while the other moves in a vertical direction. The revolving valve, Mr. Anderson states, possesses the following advantages:—

1. The valve, by its continuous rotary motion, effects a great saving in power, especially in locomotive engines, where the motion is very rapid.
2. The valve is devoid of pressure, and superior in that respect to the long and short D, or slide-valves.
3. The valve creates no loss of steam in the ports, as is the case in the short D, or slide-valve.
4. The valve wears equally, and can, at a comparatively small expense, be given any length of *lap* or *lead.*
5. The valve can be easily examined and packed when required.

COLLEGE FOR CIVIL ENGINEERS, PUTNEY.

It is very gratifying to those who take an interest in the advancement of practical science to find that a sound knowledge of the exact sciences is becoming more publicly recognized as a necessary part of the education of the engineer. Compared with the stupendous public works which have been undertaken during the last few years, the greatest engineering labours of the ancient world are as nothing: and when it is reflected that the lives of thousands may probably depend on the construction of these works with a due knowledge of the mechanical sciences; it becomes a matter of direct public interest that those to whom the task is confided should possess a *systematic* knowledge of their profession. That the importance of this knowledge is becoming publicly recognized, we have a gratifying proof in the condition of the College at Putney, and the results of the recent examinations there.

We have to regret that the limits of our space will not permit, at present a detailed account of the course of the examination, and an analysis of the printed examination papers now before us. We can do little more than record the names of the students who obtained honorary distinctions, and principal circumstances of the annual meeting, which took place on the 21st June, for the distribution of these rewards. The following is the list of prize-men.

MATHEMATICS.—1st Class, Stephenson.
,, Sharp.
2nd Class, W. Clark.
3rd Class, Coghlan.

CHEMISTRY.—Laboratory Class, Newsome.
,, Ward.
1st Class, Codrington.
2nd Class, Bennett.

GENERAL CONSTRUCTION AND ARCHITECTURE.—1st Class, Stephenson.
2nd Class, W. Clark.
3rd Class, Crump.

MACHINERY.—1st Class, Drawing Prize, Male.
2nd Class, ditto, Hawsen.
Examination, Willett.

GEODESY.—Trigonometrical Surveying, Stephenson.
Ordinary Survey and Plan Drawing, Coghlan.
Ditto, 3rd Class, Christie.
Military Class, F. Davidson.
,, the Hon. P. Feilding.

MANUFACTURE OF IRON AND GENERAL PRACTICE OF MACHINERY.—Pontifex.
Descriptive Geometry, Sharp.
French, Baldry.
German, Hansen.
Landscape Drawing, F. Davidson.

The chair was taken shortly after two o'clock by the Duke of Buccleuch, who called upon the Reverend the Principal to read the report detailing the examination. Of these reports we can say no more than they must have been satisfactory to the most sanguine supporters of the Institution. The certificates for prizes were given by the noble chairman to the students as their names were successively mentioned in the Reports.

The noble Chairman in the course of his address showed in very clear terms the fallacy of the notion that mere professional "experience," unguided by preliminary systematic education, was sufficient for the purposes of the engineer. He argued that modern engineering had made such advances and was now frequently applied to purposes so perfectly new and unprecedented, that cases must continually occur where the "rule of thumb," as it was called, would be of no avail. He took occasion also to compliment Mr. Cowie on the successful issue of his labous.

The Bishop of London, in his usual felicitous manner, eulogised the moral and gentlemanly deportment of the students. From living in the vicinity he had taken great interest in this subject, and had uniformly found that his neighbours concurred with him in giving the college this merit. Their testimony was of the greatest value because founded on impartial personal observation.

The Earl of Devon proposed and Sir Charles Lemon seconded a vote of thanks to the Duke of Buccleuch. Sir Charles Lemon observed that the enlightened sentiments of the Duke had never been more conspicuous than in his zealous support of the College, and his talents had never been better exhibited than in the clear views which his address contained of the results of the system pursued in the education of the students.

The following were among the noblemen and gentlemen present:—Duke of Buccleuch in the chair; Bishop of London; Earl of Devon; Earl of Denbigh; Sir C. Lemon, M.P.; Sir J. Duckworth, M.P.; Hon. R. Howard; E. Antrobus, Esq., M.P.; the Right Hon. the Lord Mayor; Major Olephant; Gen. H. Thompson; Col. Sykes; Capt. Moorsom; Col. Devereux; Dr. Arnott; J. C. Whiteman, Esq. Mr. Walker and Mr. Cubitt had both promised to attend, unless prevented by urgent business, and the Bishop of Oxford sent a letter regretting that buisness prevented his presence at the College.

A NEW THEORY ON THE STRENGTH AND STRESS OF MATERIALS.

SIR—Although I did not intend to answer queries, or discuss differences respecting the theory of the strength of materials, which I am advancing, until I should have the whole developed, yet I think it my duty to stop and more fully explain one or two points to which you have alluded in your last number. My theory is not founded on the idea, "that there does not exist in deflected beams what is termed a NEUTRAL LINE," yet I deny the existence of a *neutral* line, or a *neutral surface* as some writers term it. Your definition of the neutral line differs a little from that given by Barlow, Tredgold, Moseley, &c.; be good enough to look at Tredgold's definition again, I gave it in my first article. Moseley says, "One surface of a beam becoming, when deflected, convex, and the other concave, it is evident that the material forming that side of the beam which is bounded by the one surface is, in the act of flexure, extended, and the other compressed. The surface which separates these two portions of the material being that where its extension terminates and its compression begins, and which sustains, therefore, neither extension nor compression, is called the *neutral surface.*" If you look you will find that your definition of the neutral line differs a little from this also. You say that "the originators of the term *neutral line* stated that when a horizontal beam supports a transverse weight, the upper part of the beam exerts a thrust and the lower part a tension; and since these two portions of the beam exert opposite kinds of action, there must be in the beam some intermediate part which marks the transition from one state to the other—where, therefore, there is neither thrust nor tension." Now this is the truth, but not the whole truth; consider two sections in a beam deflected by a weight, one in the centre and the other anywhere between that and one of the supports; the compressions and extensions in these sections will differ in intensity, and if we suppose a fibre whose breadth is very small, dx, *if you please*, I say that the state of neutrality of this fibre, at one of these sections, differs in degree from that at the other, without reference to the action which increases or endeavours to increase the thickness of the beam at top and decreases it at the lower part, which action has been neglected by every writer on the subject. For argument sake, let the line which separates the thrusts and tensions of every section be a mathematical line, then the only change that can take place in this line is in its length and deflection; then ask yourself the question, as the beam becomes loaded, is not this neutral line, under one amount of pressure, longer and more deflected than under any less amount. However, my great difference with other writers is not about the neutral line or surface. Other writers might have established their theory independent of the thickness of the beam, for they state that no action takes place in the direction of the breadth, that is, in the direction of your axis of Z. I show that there does exist an action in the direction of Z. I say that if a body becomes extended, or compressed, its cross sectional area is diminished, or increased, or has a tendency to diminish or increase, although the cross sections present similar figures: I am now speaking of the elongation of bars suspended vertically, and sustaining a given strain in the direction of their length. Other writers go so far as to suppose that the cross section remains the same till the body be extended to twice its length;—of this matter I will speak by-and-by.

When you refer to fig. 3 of my last article, page 104, "he says," speaking of me, "that if a beam be deflected and a *slice taken from the upper part* of it, this slice has the same form as the whole beam, and consequently there is as much reason for assigning a neutral line to the slice as to the whole beam." You will find that I did not take a slice from the upper part, and that I said, "the same process of reasoning which points out a neutral axis in the whole, will point out a neutral axis in any portion of the body, no matter where it is situated." In this instance you will find that I attacked the reasoning employed by others. Lower down it is said, "For when he says that the form of the *thin upper slice* is an argument for the existence of a neutral in it, he makes the neutral depend merely on the form of the beam and not on the mechanical action of its parts." You will find that I said no such thing, nor made use of no such argument; what I said I will repeat; it follows immediately what I quoted above,—"in fact, every fibre may be said to be compressed on one side and extended at the other, while the whole or each is bent round a common centre, entirely outside the body." When I select a portion I do not take an upper slice, for I say, "Now let us take $gcdxtyqz$ (fig. 3, page 104), any portion of the beam, it is evident that the filaments in the upper part near dtq are expanded, and those near to xyz are compressed;" mark what I say,—"according to this reasoning there is a set of fibres between dtq and xyz which are neither compressed nor expanded; *hence*, each portion of the beam is entitled to a neutral axis, *which is relatively correct*, but each neutral axis is itself bent round a centre." I hope you do not mean to say "that the form of the beam is not influenced by the mechanical action and connection of its parts," for I think that it will not be denied that the mechanical action is influenced by the form, and also that the form is influenced by the mechanical action. I have got to the place where you say, "We proceed now to the direct arguments establishing the actual existence of the neutral boundary." Neutral with respect to what? Neutral with respect to thrust and tension? Neutral with respect to what degree of thrust and tension? You might as well try to upset the truths of the multiplication table as $\Sigma(X) = 0$, $\Sigma(Y) + R - \frac{1}{2}W = 0$, $\Sigma(Z) = 0$; and you might as well try to understand what the author of the work on the "Calculus," published by the Society for the Diffusion of Useful Knowledge, means when he describes the third differential coefficient, as to try to understand what writers on this subject mean by such terms as "the internal forces of the beam," "the molecular action of the forces in the cross section," &c.; or, in other words, the equations have never been satisfied. If $R = \frac{1}{2}W$, it is evident that $\Sigma(Y) = 0$, but how is $\Sigma(Y)$ made up? This would be of no consequence, only the thrusts and tensions of $\Sigma(X)$ are uninfluenced by it. You, or rather the writer of the article in question, having despatched $\Sigma(Y)$, says, "similar reasoning applies to the forces represented by $\Sigma(Z)$"; now this assertion is not correct. I have before stated (page 105, fig. 11) the nature of the action of the particles in the direction of the axis of Z, so I need not dwell upon the matter here; and although $\Sigma(X) = 0$ may be represented by the statical couple $+M, -M$, little is known with respect to their actual amount, and as the distance between their points of application vary, your equations

$Mb = \frac{1}{2}Wa$, although true, leaves us in the very same difficulty as $\Sigma(X) = 0$. As b is variable, it would have been better to have said $My = \frac{1}{2}Wa$. Indeed, in taking moments about A (fig. 2, p. 205), it would be as well to call the perpendicular let fall from A, on the direction of $+M$, x; and the perpendicular on the direction of $-M$, x'; then, $+M \times x$ added to $-M \times x' = M(x-x') = \frac{1}{2}Wa$; this supposes both forces to be directed at the same side of A; however, if one acts above and the other below, then we have $M(x+x') = \frac{1}{2}Wa$, but in both cases, the quantities between the brackets is the distance between the points of application of the forces. At first sight, the equation My, or Mb, or $M(x+x')$, or $M(x-x')$, $= \frac{1}{2}Wa$ would appear to involve but one unknown quantity; but it involves two, for there is as little known about M as there is about y. I cannot see for what purpose these equations were introduced, except to show, if we were able to do it, how the principles of statics might be applied to the problem under consideration; however, I can see no connection between them and what follows, but perhaps others may.

The next four paragraphs, beginning with "We have, therefore, the upper and lower parts of C D in &c.," at the bottom of the first column, page 205, contains very little more than different methods of stating the same thing, or some general expressions that would be true in almost any inquiry, such as, "We are, therefore, perfectly safe in supposing that there is some general law by which these variations of action may be represented, that is, that the amount of molecular force at any point of either side of the beam is a continuous function of the distance from some fixed point." You must not be offended, for I am now speaking plainly; to beat round the bush would take up too much space. Lower down, where you come to the conclusion, "Consequently there is no longitudinal action whatever at the neutral boundary." If you reflect for a moment, you must admit that this boundary might be elongated, for it is only capable of being elongated and deflected, without altering the thrusts or tensions, except with respect to their intensity, of which there is but little known.

For the present, I beg you will excuse these few remarks, hastily made, until I have developed the whole of my Theory, then I will be glad to enter into any explanation that may be required.

I am, Sir, yours obediently,

Oliver Byrne.

NOTES OF THE MONTH.

Wellington Memorial.—The newspapers announce the gratifying intelligence that, in consequence of a discussion in the House of Commons, the preparations for raising the statue of the Duke of Wellington to the top of the triumphal arch in Piccadilly will be discontinued.

Fitzwilliam Museum, Cambridge.—We learn also with great pleasure that Mr. Cockerell has obtained power to deviate from the original plan for completing the Fitzwilliam Museum, by substituting real marble for imitation marble in the internal decorations.

Jesus College Chapel.—Among the contemplated alterations is the substitution of an arcade of five lancets (according to the original plan) for the present Perpendicular window. A Norman triplet in the north transept will be displayed. The choir had formerly aisles extending as far as the present lancet windows; the northern aisles will be rebuilt. We are not quite reconciled to the destruction of any of the genuine architecture, but the restoration is superintended by Mr. Salvin, and is therefore in safe hands.

Ely Cathedral.—The restoration advances rapidly. All the plaster work is being ruthlessly destroyed. The great tower is opened to the second story. Two painted windows by Mr. Wailes have been completed. A painted window will be inserted in the lanthern at the expense of the members of the University of Cambridge *in statu puppillari*.

The French Minister of Public Instruction has informed the Ecclesiological, late Cambridge Camden Society, that a complete set of the works of the Comité Historique is placed at the disposal of the Society.

Standon, Herts.—A new Decorated church has been erected from the designs of Mr. Salvin.

St. Bartholomew's, Nettlebed, is being rebuilt by Mr. Hakewill.

Seamen's Church, St. Katherine's Dock.—This church, which will hold 800 persons, is in the Early English style. The design appears to be exceedingly faulty.

St. James's Church, Westminster.—A new east window has been painted for this church by Mr. Wailes. The colours are very brilliant and the jointing of the glass is managed so skilfully as to be scarcely seen from the interior of the church; but the designs have an appearance of confusion and the drawing is not very correct. Of course we need not state our opinion respecting the use of Corinthian columns as mullions, as in the case of this window. Among the decorations or desecrations is the painting of parts of the walls in imitation of marble.

Architecture in Edinburgh.—The *Scotsman* speaks highly of the architecture of the New Commercial Bank, from which the scaffolding is partially removed. The design and also the sculpture is by Mr. James Wyatt.

There is a project under consideration for connecting all Natural History Societies with the Linnæan. The latter will be the principal Society, and the others will be considered as sections.

M. Hallette, whose inventions connected with atmospheric railways have been described in this Journal and are now being experimented upon at Peckham, recently died at Arras. He was an eminent builder of locomotive engines.

The third centenary of the birthday of the Danish astronomer, Tycho Brahé, was celebrated on the 21st of June by the erection of a monumental bust under a triumphal arch on the little island of Hveen, his birthplace.

The second centenary of the death of Leibnitz has been celebrated with great pomp by his *alma mater*, the University of Leipsig.

At Paris, the Chamber of Deputies has voted £41,000 for purchasing ground required for the purposes of the Museum of Natural History.

The new papal government have withdrawn the old prohibition against the construction of railways in the papal dominions.

Painting on Lava.—This new process seems to be one of considerable importance as a substitute for enamel painting, on account of the large size of which the pieces of lava can be obtained. A large historical picture, painted on four plates of lava, which together have a surface equivalent to 10 feet square, has been completed for the church St. Vincent-de-Paul, at Paris. The advantage of lava for this purpose is, that being vitrious it receives vitrifiable colours without changing its form in baking.

The restoration of Malvern Abbey is completed.

The figures on the great gate of the cathedral of Senlis have been restored by M. Rabinet, sculptor, under the direction of the architect, M. Ramée.

The French Chamber of Deputies have voted a sum of money for the publication of the work by MM. Cotta and Flandin on the ruins of Nineveh.

It has been suggested that the fields north of the Model Prison at Pentonville should be converted into a park. This, if done at all, must be quickly; otherwise, there is every reason to suppose, from the rapid increase of buildings in this neighbourhood, that the ground will be soon built upon. A park in this locality, which is far removed from any of the existing "lungs of the metropolis," would be an incalculable benefit to the poor inhabitants.

Electric Clocks.—By means of the electric telegraph on the Edinburgh and Glasgow Railway, Mr. Bain has exhibited a clock of which the pendulum at Glasgow regulated the movement of the dial-wheels and hands at Edinburgh!

The *Presbyterian Church*, in Lower Gloucester-street, Dublin, has recently been completed, from the designs of Mr. D. Ferguson, a young and rising architect. This building is the first in the Grecian Doric order that has been erected in Dublin, with fine Irish granite, and the execution is highly creditable for a first attempt of the workmen. The Acroteria are perfectly new in this country, and have a very pleasing effect upon pediments too small for the support of statues. The lighting of this church is effected by a most economical plan, costing not more than half the expense of lighting in the usual manner with pillars and brackets. Mr. Ferguson holds the Mastership of the Architectural School of the Royal Dublin Society.

An Institute going a begging.—Under this title the *Athenæum* alludes to a circular issued by the Institute of British Architects, soliciting architectural essays from men of erudition and science. The paper in the *Athenæum* contains some valuable suggestions, to which we must refer next month.

Comparison of the economic properties of coals.—A most important series of experiments is about to be undertaken at the College for Civil Engineers, Putney, on the part of the Admiralty, in order to a comparison of the relative evaporative powers and facility of combustion of different kinds of coals. The examination will be conducted by Sir Henry de la Beche and Dr. Lyon Playfair. A enormous mass of information on the same subject is contained in a report published by order of the American Congress, which was noticed in our last volume, p. 242.

The French Geological Society meet at Alais on the 14th of September.

St. Mary's Church, Kidderminster, is to be restored, at a cost of £2,000.

The Isthmus of Panama Railway will be commenced, it is said, next November.

The Hungerford Bridge Terminus of the Southampton Railway.—Several houses are being cleared away for the construction of the viaduct from the Nine Elms station.

Bridge over the Mersey at Runcorn.—The Admiralty requires that the arches shall have a clear headway under their centres of 100 feet, and a waterway between the piers of 280 feet. If flat girders be substituted for arches, 250 feet between the piers will be sufficient.

British Museum.—Sir R. Inglis has stated in the House of Commons, that the works will be completed in three years time.

Geology.—A very curious theory has been propounded by Commander Morton respecting the columns at Giant's Causeway and Staffa. He asserts that molten lava in crystallising could never form blocks fitting into each other with sockets or joints; and that, consequently, the usual opinion that the columns in question are formed from molten basalt is untenable. He asserts that they are *petrified forests of gigantic bamboos*; and refers to the well-known fact that bamboos and canes, when growing, secrete silex. The divisions in the basaltic columns resemble in form and position the joints of growing bamboos.

Professor Donaldson invited all the principal members of the Architectural profession to a soiree at his house at Bolton-gardens, Russell-square, on Tuesday, 7th ult.; it was well attended, Several works of art were laid on the tables, and a sumptuous entertainment provided at the close.

Westminster Bridge.—It is reported that Mr. Walker and the committee have had several consultations respecting the condition of Westminster-bridge, and the general opinion entertained by them is that the present structure should be pulled down and a new one substituted. Mr. Walker has already drawn out plans and specifications for the new bridge. He proposes that a temporary wooden bridge should be erected, and the new bridge commence eastward of Ginger's Hotel.

Substitute for Gunpowder.—Professor Schonbrin has just presented to the Society of Natural History, Basle, a specimen of cotton prepared by him which is more inflammable than gunpowder, and explodes within a capsule. Several trials have been made of it, from which it appears that a small quantity, equal to the sixteenth part of an ounce, placed in a gun, projected the ball with such force that it perforated two planks at a distance of fifty-eight paces, and at another time, with the same charge and at the same distance, drove a ball into a wall to the depth of nearly four inches.

Coloured Glass.—Mr. Hoadly, of the Hampstead Road, has shown us several patterns of a new description of coloured glass borders which possess considerable elegance, and can be produced at a very moderate price, a handsome border with a ruby or blue ground and a silver and gold embossed ornament can be sold at 5s. 6d. per foot, and a ruby blue or gold ground with silver or white embossed ornament at 2s. to 4s. per foot.

Fortifications at Sheerness.—The new works continue to progress slowly and steadily. The scarp of the battery forming opposite the Dockyard gate is now being proceeded with. The musketry walls connecting it to the old works of Garrison Point on the one hand, and to the line of bastions extending from the Thames to the Medway in the other, are well nigh completed. Each wall is upwards of 120 yards in length, three feet thick, from 10 to 12 feet in height, and has loop-holes for musketry at every three and a half feet distance. A ditch 50 feet wide, and 15 feet deep, is to surround the battery. It is almost formed, and will communicate with that from the Medway, which is to be cleared out and deepened, and the bastions extending along it are to be heightened with the mud procured by the excavation. The following guns have been ordered for the new works: One 56-pounder, 97 cwt., 11 feet long, 17 eight-inch guns 65 cwt. each, 9 feet long—28 32-pounders, 56 cwt. each, 9 feet long—and 12 24-pounders of 20 cwt. each, 6 feet long—total, 58. The 24-pounders will be mounted on iron carriages, but all the heavier guns on wooden carriages with traversing platforms. Sixty-three guns of a similar description have already been received, and are to be mounted on the old works surrounding the garrison. The alterations and repairs there are progressing favourably, the pivots and tramways for the traversing platforms of all the 32-pounders being already laid down; the parapet has also been heightened along its whole extent. One or two companies of artillery are to be in future permanently stationed here, and new and extensive barracks are to be erected for their accommodation, the present being confined and incapable of accommodating more than 300 men, which is the average number of troops forming this garrison.

THE BASILICA AT ROME.

The *Times* correspondent of Rome gives us the following description of the Basilica:—The Basilic is the metropolitan of Rome. The original structure was commenced ten centuries ago, but the building was twice burnt down, and the Basilic, as it now stands, was begun in 1368. Several Popes, including Clement V., Urban V., Alexander VI., Pius IV., Sixtus V., and Clement XII., lavished enormous sums of money on it, so that, although the proportions are not so vast as St. Peter's, it is almost equal in magnificence, and certainly far superior to all other churches of the Eternal City. Severe taste will, however, condemn the gilded roof, though by the crowd it is very much admired; but where mosaic marble, painting and sculpture abound, the meretricious ornament of gilding should not be introduced. The bijou of the cathedral is the Chapel Corsini; it is perfection, and within that little space there is more to be found to satisfy the eye and exalt the mind than in any other part of the immense pile of buildings. The altar-piece is a mosaic, copied from a picture by Guido, executed with so much delicacy that you almost desire to touch the work to be convinced that it is not a painting. The bronze statue of Clement XII. is also admirable. The expression of the face is perfect; and every line traced by care and age is reproduced with the fidelity of nature. There are two groups of marble in the niches at each side of the bronze statue by Monaldi, on which it is said Canova studied intensely. There is a female figure in one which is almost the model of his Venus, but the neck, bust, and arm are far superior to anything that Canova ever produced. The mosaic floor is very remarkable, as well as the precious marbles, which are used with an unsparing hand; but the wonder of the place is a subterranean chapel, where the tombs of the Corsini family abound, and where a marble group of the Virgin and dead Christ are not inappropriately placed. Bernini is given as the sculptor's name, but I imagine that much of the fame which the group has acquired is owing to the purity of the material, which admits a little of trick in the exhibition, and to the place where it is situated disposing the mind to religious meditation. The man who shows the statue does so by the light of a small wax taper, and as he passes the light along the lifeless body of our Saviour it appears to be wax, not marble. The hands are positively transparent. The agony of life in the Virgin is finely contrasted with the inert weight of the corpse which hangs from her embrace; but I believe that the group, however beautiful, would lose much of its value if exposed to the open day. The late Count Somariva, at Paris, used to show Canova's Magdalen in the same manner; but good judges condemned him, as the eye never embraced the whole figure, but was carried from one littleness, such as the graining of the skin, which Canova introduced, to another. There is a chill of death in the subterranean chapel of the Corsini, and the sacristan who shows it not only covers his own head, but carefully recommends you to do the same. The ceremony at St. John de Lateran was limited to the celebration of mass, and the Pope returned to the Quirinal in the same simple manner that he left it.

THE CHANNEL SQUADRON—TRIAL OF STEAMERS.

On the 30th June, the steamers were ordered to try rate of steaming. At 10 a.m. the Retribution, Gladiator, and Avenger, started, full power, with a strong breeze six points on port bow. In two hours the Retribution gained on Gladiator 1¼ miles; on Avenger three miles. At noon altered course to wind on port beam, and tried until 4 p.m.—at each successive step of expansion gear—during the whole of this time the relative distances were perceived as near as possible as during the trial from 10 to 12. At 4, being about seven or eight miles dead to leeward of the Admiral the signal was made to prepare to steam to windward. Topmasts were in consequence struck, and everything got ready to join the ships to windward. At about 4·30 they started abreast. Retribution soon got the lead, although Gladiator stuck very close for a few minutes; but once clear of her, she soon shot ahead, beating her in the run about two miles, and Avenger four miles.

Gladiator and Avenger were each working up to 10 lb. the square inch, having tubular boilers Retribution can only work up to 6 lb., having the old common boilers.

July 1.—The Terrible having joined the fleet during the previous night, a signal was made to try rate of steaming with her. They accordingly started at about 10 a.m., with full power, the Terrible, with her tubular boilers, working up to 13 lb. the square-inch, and after steaming dead to windward, with a strong breese and heavy head-swell for three hours, she beat Retribution as near as possible half a mile an hour. Unquestionably she is a noble ship; but, nevertheless, I am inclined to believe she beat Retribution principally by the great command of steam generated by tubular boilers. Had both ships been fitted with similar boilers, probably the result would have been different. One thing by this trial appears to be clearly settled—that where two ships of similar tonnage, or nearly so, and equal horse power, but fitted with tubular and common boilers, are matched, the former must have the advantage in speed over the latter. This was very evident in the trial the day before with Gladiator, for with Retribution's immense engines of 800 horse power, over Gladiator's 450, the former certainly ought to have beat her double the distance, had they both been fitted with similarly constructed boilers. At 1 p.m. a signal was made to Terrible to steam with 6 lb. pressure only. At first Retribution gained rapidly on her, but as soon as this was perceived on board she shot ahead again. In short, this trial is not worth relating, it being almost impossible to keep steam at any exact pressure. A few shovelsful of coal, or slightest alteration of throttle valve, more or less, will always cause an alteration. In the evening they both banked the fires.

July 2, at 9 a.m., we tried rate of sailing on the wind, starboard tack. Terrible, under all plain sail; Retribution, with single-reefed topsails. At 11, the wind falling light, Retribution shook out first reefs. At 1·30 p.m., Retribution being about one mile ahead, tacked. At 3, having weathered on her opponent about three quarters of a mile, bore up and set port studding sails. Ran until sunset without any difference of sailing; then lighted the fires of two boilers and steamed all night. Terrible gained two miles all night. Arrived at Cove this evening, July 3, at 7 p.m. Found the squadron lying there.

MISCELLANEA.

Sculpture Machine.—During a recent visit in Boston we were shown specimens of the production of a wonderful piece of mechanism, which were, indeed, truly astonishing. They were miniature busts of Daniel Webster, Abtot Lawrence, and Levi Woodbury; being perfect facsimiles of their distinguished originals, and wrought out of beautiful American marble, and by a machine which has been invented by Mr. Thomas Blanchard, of Boston. This invention certainly establishes a new era in the art of sculpture, and promises to dispense almost entirely with the deep thought, and classic study, and indefatigable labour of the artist, in his efforts to put life and poetry into the marble, for nature, art, every thing tangible, can be copied by this machine, with a precision which defies the chisel, even when guided by the most skilful hand and directed by the most gifted talent. The machine, too, can be graduated so as to give reduced copies of any statuary, which shall, in their miniature, be perfect and exact copies of the originals in everything else but size; preserving every line, furrow, and dimple, and giving prominence to muscles and veins, and every particular lineament and feature, in exact proportion. By the same machinery, the most correct and perfect bas-relief profile likenesses may be cut, on the hardest material, and of any size required, from half an inch to full life-like size. We saw a strikingly exact cameo profile of Henry Clay, as perfect a head of that statesman as we have ever seen in any of the busts or casts to be found, and of the fashionable size for a lady's breast-pin. Among the specimens shown us, too, were the heads of several of our acquaintances, cut in cameo and ivory, the proper size for setting in pins, the first glimpse of which called before our minds the originals as readily as the most perfect daguerreotype or pencilled miniature would have done. We are assured that the best of Greenough's and Pera'co's productions, which have cost them years of study and effort, can be copied by this apparatus with most positive accuracy; and the block of shapeless marble put into its power will, in a few hours, stand forth a perfect copy of the most beautiful and animated statuary the greatest sculptors ever produced. And, what is most wonderful, this machinery may be readily graduated to increase or diminish the copy, so as to furnish a colossal or a miniature figure, with equal precision, and in all respects exact proportions.—"American paper."

Alligator Oil.—A letter from St. Augustine, dated April 12, says:—"I suppose that you may not have heard that we have discovered the utility of alligators. An alligator is found to be as valuable in his way as a spermaceti whale. An expedition has left this place for the river of St. John's, and the dark tributary stream of Black Creek, swarming with these hideous creatures, with the view of killing them to obtain their oil. The oil of the alligator is said to be better for lamps than even whale oil, and it is extracted from the animal in considerable quantity and without any great difficulty. For this discovery we are indebted to the Indians, who have been in the habit, for how long a time I know not, of extracting the oil of the alligator and using it for various purposes. It makes a fine transparent fluid and burns admirably. You know how many of these enormous animals are shot out of wantonness from the decks of the steamboats that plough our waters. I expect he eafter to hear of laws passed for their protection. Every time an alligator of 18 feet long is shot in the long grass of the river banks, or while he is swimming, a barrel or half a barrel of oil, as the case may be, is wasted. This should not be. We must allow them to be killed only at a proper season, when they are fattest, and not permit their destruction at the season when they lay their eggs. The alligator is a formidable looking creature, it is true, but he is generally harmless. His office is to prowl in the sluggish waters of this southern region, pick up what he can, and digest it into excellent oil for the illumination of our houses. Alligators will be hereafter esteemed as useful animals as pigs—perhaps more so, for their keeping costs nothing. The danger is, that now that the world has discovered what they are good for, their race will be exterminated."—'Montreal Times.'

Mammoth Locomotives.—The Great Western have just completed three most powerful locomotive engines, built upon the plan and under the superintendence of Mr. Brunel, assisted by Mr. Gooch, the superintendent of the locomotive department. The dimensions of the Great Western engine (the leviathan of locomotives) are as follows:—Diameter of driving wheel 8 feet; cylinder, 18 inches; stroke, 24 inches; boiler, between 15 and 16 feet; weight of engine, 36 tons, without water; weight of the tender, without either coke or water, 10 tons; making a total of 46 tons. This splendid engine, built for passenger trains, drew a train weighing 136 tons up the incline at Wootton Bassett, with as much ease and as fast as one of the smaller engines would a passenger train. The engine Queen is likewise for passenger trains, and was built at Swindon: Driving wheels, 7 feet diameter; stroke, 18 inches; cylinder, 16 inches; boiler, 14 feet; weight of engine, without water, 25 tons; weight of tender, 9 tons, without coke or water. The above engines, when their machinery get into perfect order, are intended to be employed in propelling the express trains. The other is a luggage engine, the Premier, having her six wheels of 5 feet diameter connected. The dimensions of this locomotive are in other respects similar to the Great Western passenger engine. The Premier is decidedly the most powerful employed on the broad gauge, surpassing in strength and speed the Hercules engine, which propelled 406 tons on the experimental trip with the gauge commissioners.—A new and powerful locomotive, the Goliah, was lately tried on the Sheffield, Ashton-under-Lyne, and Manchester Railway. It is the largest crank-axle locomotive engine ever built. The cylinders are 18 inches in diameter, with two feet stroke, mounted on six wheels of four feet six inches in diameter, all coupled, so that they will not be liable to slip in wet weather, or with a heavy load, as is often the case with those constructed upon the present principle. The engine is calculated to take a load of upwards of 1,000 tons, on a level, at the rate of 20 miles an hour. It has given every satisfaction to the company, who have nine more engines of a similar description in progress of building at the works of Messrs. Sharp, Roberts and Co.

LIST OF NEW PATENTS.

(From Messrs. Robertson's List.)

GRANTED IN ENGLAND FROM JUNE 27, 1846, TO JULY 23, 1846.

Six Months allowed for Enrolment, unless otherwise expressed.

Joseph Storer, of Stanhope street, Mornington crescent, musical instrument maker, for "Improvements in organs, seraphines, and other free reed instruments, part of which instruments are applicable to piano fortes." (A communication.)—June 27.

John Davie Morris Stirling, of Black Range, North Britain, esq., for "certain new alloys and metallic compounds with a method of welding the same and other metals."—June 29.

Francois Stanilas Meldon de Sussex, of Millwall, Middlesex, manufacturing chemist, for "Improvements in the manufacture of soda and potash."—June 29.

Thomas Lane Coulson, of Assington Hall, Assington, Suffolk, esq., for "Improvements in the construction of chairs."—June 29.

Charles Payne, of Whitehall wharf, Cannon row, Westminster, gentleman, for "Improvements in preserving vegetable matter."—June 29.

William Mill, of Newhall street, Birmingham, manufacturer, for "Improvements in instruments used for writing and marking, and in the construction of inkstands."—June 29.

Moses Poole, of London, gentleman, for "Improvements in regulating the velocity of steam engines." (A communication.)—June 29.

Joseph Moreland, of Old-street, Middlesex, copper still and boiler setter, oven builder, constructer and designer of furnaces generally, for "Improvements in setting and fixing coppers, stills, and boilers, and in the construction of fur aces."—June 29.

William Smith, of the city of London, gas meter manufacturer, for "certain Improvements in gas meters."—June 29.

Anto'ne Perpigna, of Paris, advocate, for "Improvements in regulators for qualifying the actions of mechanical powers." (A communication.)—June 29.

John Tatham, of Rochdale, Lancaster, machine maker, David Cheetham, of the same place, machine maker, and John Wallace Duncan, of Manchester, gentleman, for "certain Improvements in machinery or apparatus, to be used in the preparation and spinning of cotton and other fibrous substances."—June 29.

Joseph Seraphin Faucon, of Rouen, in France, banker, for "Improvements in combining materials to be employed in fulling cloth."—June 29.

Sir James Caleb Anderson, of Buttevant castle, Ireland, baronet, for "certain Improvements in obtaining motive power, and in applying it to propel carriages and vessels, and to the driving of machinery."—June 29.

Thomas Parkin, of Hoxton, in the county of Middlesex, engineer, for "Improvements in the means of giving motion to locomotive carriages, with or without bearing wheels attached to them, and in the construction of ways, passages, and roads, on which the said carriages are to travel."—June 29.

Charles Clark, of Cornhill, City, merchant, for "certain Improvements in the pyro-hydro-pneumatic apparatus for generating, purifying, and condensing, steam and other vapours, and for obtaining vegetable extracts."—June 29.

James Hastings, of Havre, in France, for "an Improved machine for making bricks, tiles, quarries, and cornice ornaments."—June 30.

William Clarke, of Hoxton, Middlesex, machinist, for "certain Improvements in weighing machines, steel yards, and scale beams."—June 30.

James Thompson, of Liverpool, engineer, for "certain Improvements in machinery or apparatus for obtained motive power, part or parts of which improvements are applicable to other useful purposes."—July 6.

Peter Ward, of Oldbury, county of Worcester, chemical manager, for "Improvements in the manufacture of certain salts of soda and magnesia."—July 6.

Richard Wright, of Hermitage-terrace, in the parish of Bow, sugar refiner, for "Improvements in refining sugar."—July 6.

George Downing, of Birmingham, steel pen tool maker, for "a certain Improvement in the manufacture of penholders."—July 6.

Frederick Ransome, of Ipswich, engineer, and John Crabb Blair Warren, Little Horksley, Essex, clerk, for "certain Improvements in the manufacture of bricks, tiles, pipes, and other articles composed of plastic materials, and in the preparation of plastic materials to be used for such purposes."—July 6.

John Palmer De la Fons, of Carlton-hill, St. John's Wood, in the county of Middlesex, Esq., for "Improvements in the manufacture of locks and other fastenings"—July 6.

William M'Gary, of Hoxton, Middlesex, for "Improvements in lamps, lamp glasses, candles, and shades."—July 6.

Thomas Woolley, of Nottingham, piano forte manufacturer, for "Improvements in piano fortes."—July 8.

Robert Beart, of Godmanchester, in the county of Huntingdon, farmer, for "Improvements in tiling land."—July 10.

William Middlemore, of Birmingham, manufacturer, for "a certain Improvement, or certain improvements in saddles."—July 13.

William Seed, of Preston, Lancaster, machine maker, for "certain Improvements in machinery or apparatus for preparing, slubbing, and roving cotton, and other fibrous substances."—July 14.

George Knight, of Southampton, wine merchant, for "certain Improvements in excavating and dredging; also in the formation of permanent and temporary harbours, canals, bridges, docks, and other similar works, and in the apparatus to be employed therein."—July 14.

Odert Gripenberg, of Finland, Russia for "Improvements in machinery for sowing grain and other seed."—July 14.

William Watson Pattinson, of Felling, near Gateshead, Durham, manufacturing chemist, for "Improvements in the manufacture of chlorine."—July 14.

Charles Frederick Bielefeld, of Wellington-street, Strand, papier maché manufacturer, for "Improvements in the making of moulds or dies used in the manufacture of papier maché, and other matters, and in moulding or forming articles from certain plastic materials."—July 14.

Gustaf Victor Gustafsson, late of Sweden, but now of Warren-street, Fitzroy-square, engineer, for "certain Improvements in steam engines."—July 14.

Lawrence Hill, jun., of Glasgow, civil and mechanical engineer, "for Improvements in the manufacture of iron for building ships and boats, and other vessels; and in the construction of ships and boats, and other vessels; and in instruments, machinery, and apparatus to be used in the said construction. (A communication.)—July 14.

Sir Samuel Brown, Knight of the Hanoverian Guelphic Order, and Captain in our Navy, of Blackheath, for "Improvements in railways and carriages to run on railways, and in the construction and arming ships or vessels."—July 14.

David Yoolow Stewart, of Montrose, Scotland, for "Improvements in moulding iron and brass."—July 14.

Thomas Symes Prideaux, of Southampton, gentleman, for "Improvements in machinery for excavating."—July 15.

William Thomas, of Cheapside, London, merchant, for "certain Improvements in frames, locks, and fastenings for carpet-bags and purses, parts of said improvements being applicable to all other locks."—July 15; two months.

Thomas Bouser, of Merton, Surrey, and Edwin Walker Williams [illegible] Pettit, of York-road, Lambeth, civil engineer, for "certain Improvements in machinery for tilling land."—July 15.

William Shurman, of the town and county of Nottingham, hosier, for "certain Improvements in the manufacture of gloves, stockings, and other hosiery goods."—July 15.

James Napier, of Shacklewell, in the county of Middlesex, operative chemist, for "Improvements in smelting copper ores."—July 20.

John Boyes, of Mincing-lane, gentleman, for "Improvements in machinery for thrashing and winnowing grain and seeds."—July 23.

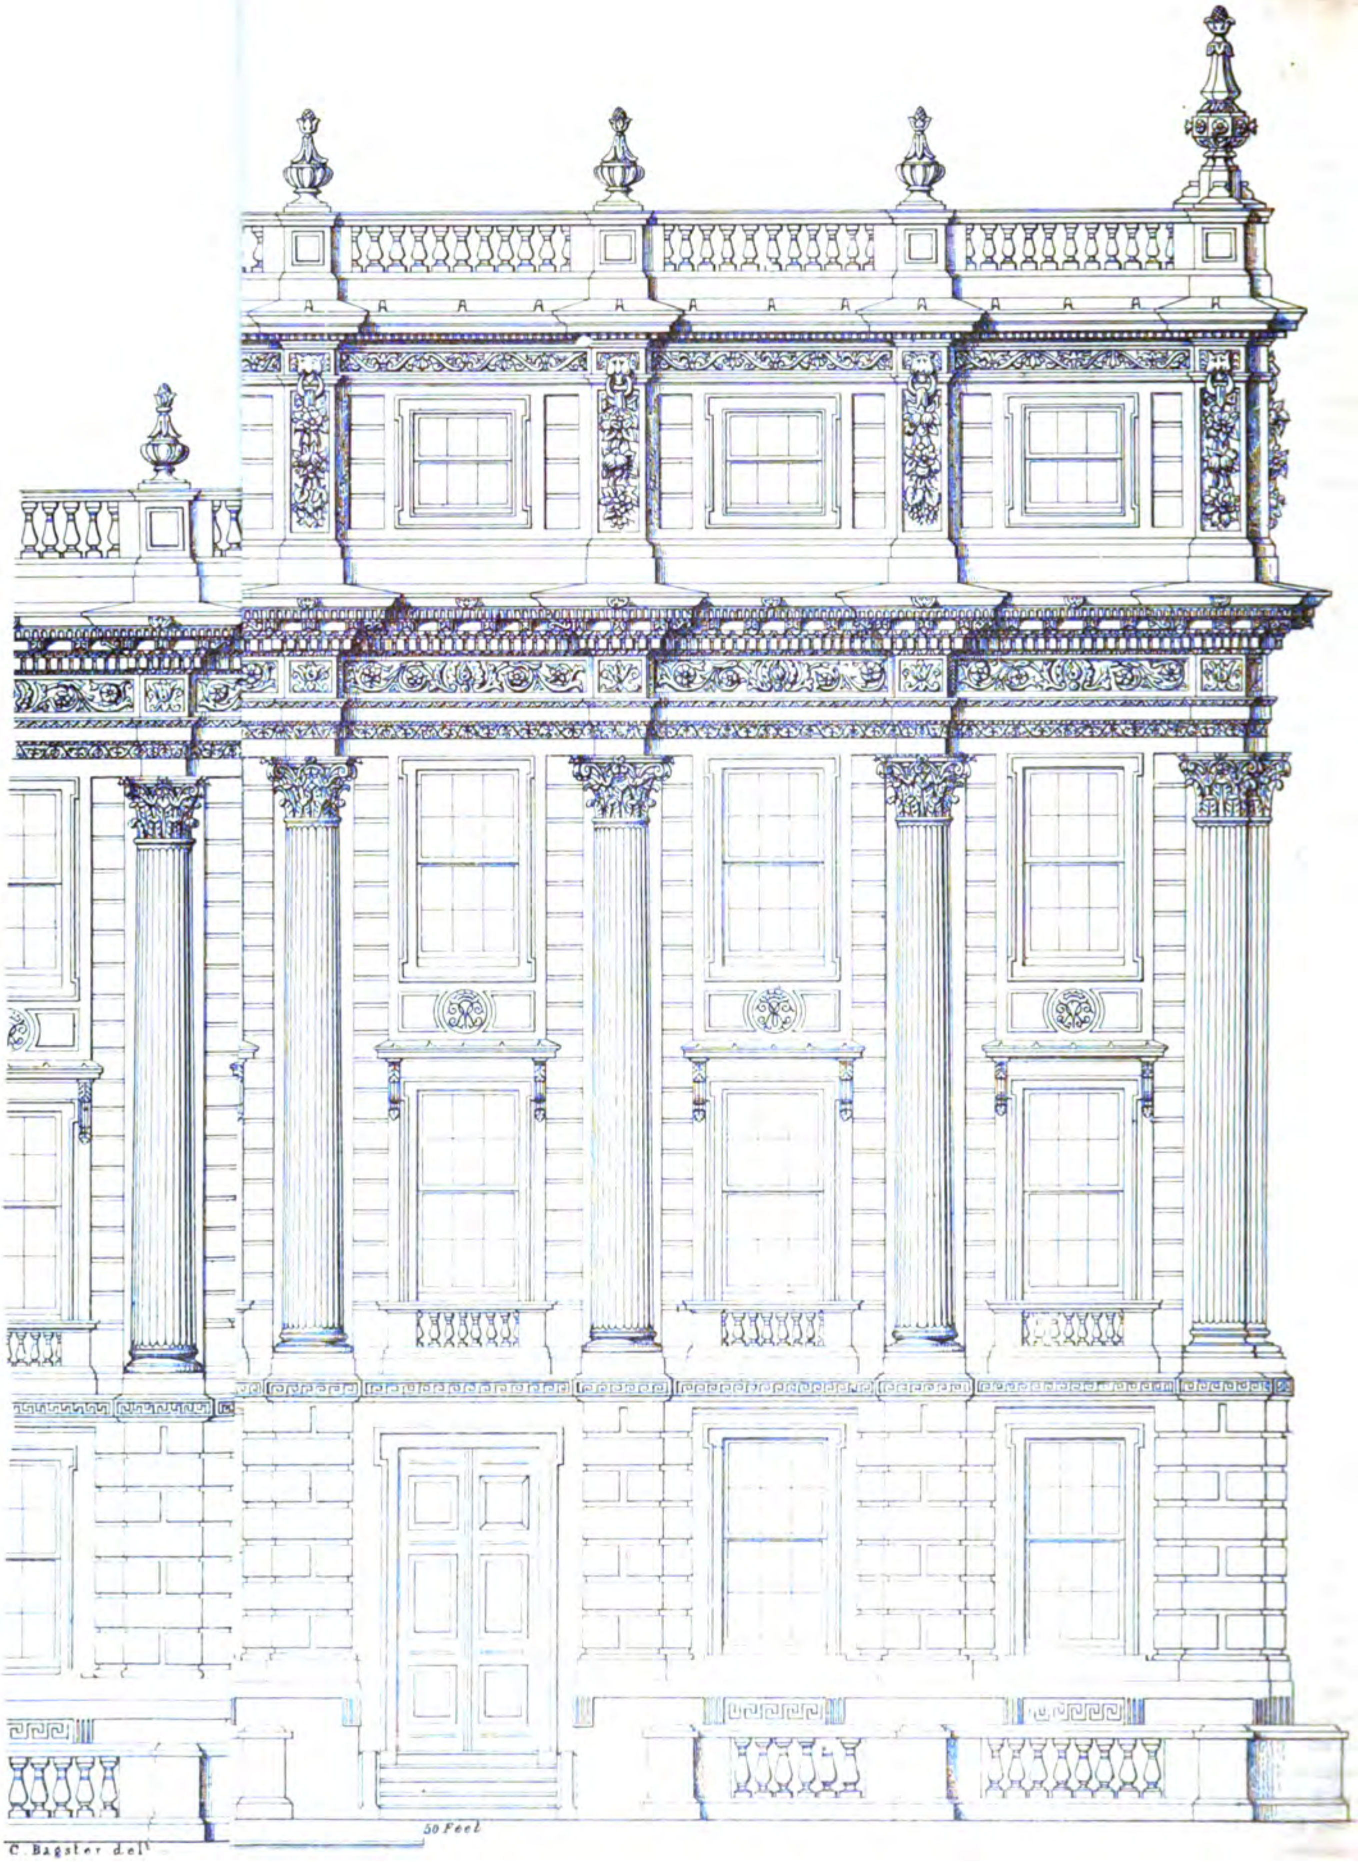
Augustus William Hillary, of No. 66, Cadogan-place, Chelsea, at present residing at No. 146, Avenue des Champs Elysees, in the city of Paris, esq., for "Improvements in the manufacture of gas."—July 23.

CORRESPONDENTS.

"A Working Mechanic."—The improvement of the hydraulic press is very ingenious, but the small end of the pump piston must work in the air: for if it work in a reservoir containing water, the water will be forced through the upper compartment into the main cylinder, and consequently the quantity of water pumped in at each stroke will equal the sum and not the difference of the volumes of the two parts of the plunge. If our correspondent will allow us to make the necessary alteration, the description shall appear next month. If we understand the action of the Archimedean air pump, the mouth of the spiral tube must alternately rise above and sink below the surface of the mercury. But as the exhaustion advances, the mercury would be elevated, till the mouth of the tube became wholly submerged.

From press of matter, the Reviews and several communications are unavoidably postponed.

ERRATUM.—Page 223, col. 2. The name of the architect of the New Post Office, at Hamburgh, misprinted "M. Charles Teusseuf," should be "M. Alexis de Chateauneuf," author of "Architectura Domestica," a work published in this country in 1839.



HALL.

HOME OFFICE, BOARD OF TRADE, &c., WHITEHALL.

(With an Engraving, Plate XIII.)

Twofold interest attaches to this subject because, as it exhibits a rifacciamento—a *re-dressing*, so to call it, of the former exterior, while the structure itself remains in other respects nearly as before, we have to consider not only the building as it now presents itself, but also what it has replaced. We have, besides, here a very remarkable case,—that of a building of quite recent date being subjected to complete alteration; while many others that might be materially improved by a much slighter degree of it—some of them even by a few corrections, remain in *statu quo* with all their blemishes: let us hope therefore that the example thus set will not be thrown away. Sir John Soane himself, we dare say, would not greatly have relished the idea of his "Board of Trade" coming to a *second edition* after his death; more especially as it was, with the exception of the "Bank," his principal and best work: but his design is now expunged, and what is more, after other things will have disappeared—as will shortly be the case—the front of his own house in Lincoln's Inn Fields will remain and be preserved intact to posterity as a monument of his taste. Hardly could Soane have conceived it to be at all possible that any thing which he had done should pass away, or else he would doubtless have ensured the perpetuity of his designs and ideas by means of the graver. It is true he did publish many of them in a folio volume, but they are so incorrect and exceedingly rude in execution, many of them of such paltrily diminutive size, and altogether so insufficient and unsatisfactory, as to be in some respects worse than nothing—more injurious to his reputation than the contrary. Were they to be judged of from that work alone, it must hereafter be thought that at the time of its production, both architectural drawing and engraving were at the lowest ebb in this country, since with all his wealth, and also his solicitude about his works, Soane could find no artists capable of doing them justice.—And here we may just remark *en passant* that engraving might almost as well be extinct among us, for any advantage that is now taken of it by English architects, wo hhave executed structures, that if adequately represented would obtain for them celebrity where their names are now not so much as heard of.

In the volume above alluded to, there is a plate containing several variations or different ideas of the design of the "Board of Trade," including the one adopted, but they are upon so preposterously small a scale (attached scale there is none)—the entire height, 54 feet, being only $\frac{9}{16}$ of an inch,—that they are mere diagrams, from which no more can be made out than the general composition, and the number of columns and windows. There would have been no harm in giving that plate, had there been also another showing the executed elevation at large, or rather only so much of it as could be shown on the largest scale the size of the plate would admit of; whereas now only the mere skeleton of, the elevation is there given, all its lineaments being suppressed. In the "Illustrations of the Public Buildings of London," again, it is shown very unsatisfatorily,—only a small outline *perspective* view; wherefore we purpose to record it faithfully next month in another engraving, in like manner and upon the same scale as the present one of Mr. Barry's new front to the Board of Trade.

Were there nothing else satisfactory, it would be so to know that the building will now forthwith be carried on northward as far as Dover-house, and the entire façade at length completed, as perhaps it would have been done before; had it not been for a most strange oversight in setting out the line of front, owing to which the North Pavilion could not have been erected without advancing considerably upon the pavement. Therefore if that really was an oversight on the part of Soane—and we can account for it no other way he has been punished for it, since the consequence of it may have decided for remodelling the façade in order to get rid of the advanced hexastyles at its extremities. Besides which, even had there been no obstacle to completing the building according to Soane's design, it would, when so extended to half as much again in length, have looked still lower than it did: whereas now there will be better proportion in the ensemble, and the entire façade will form a noble mass,—one that will show admirably well in itself, but which will perhaps overpower that little architectural gem Dover-house, and will certainly cause the Horse Guards (that is, its street front) and Admiralty to look more indignified than ever. In one respect, indeed, the contrast is an agreeable one, inasmuch as Mr. Barry's new piece of architecture shows, as compared with the two last-mentioned structures, the very great improvement that has taken place all at once in the quality of official and government buildings, which have hitherto been mostly made jobs of, and instead of conducing to the advance of taste, have in some instances been quite discreditable to the nation. The National Gallery stands a monument of the wretched system of doing things of the kind by halves: either a great deal too much was there attempted, or a great deal too little done; and should any thing more now ever be done to it, the expense will be very much greater than if it had been done properly at first, for there will be much to correct as well as to supply.

In the present instance every thing has been done most liberally: we have got, not as repeatedly before, what might have been good, or a good thing spoilt, but a really excellent one—a very superior example of its particular style, one that is thoroughly studied, and which therefore both deserves and cannot fail to become an instructive study and authority. While elaborately ornate it is marked by such refined taste, that rich as it is, it is the very reverse of tawdry. Numerous as the details are, there is not one that seems to have been neglected, or not to have been carefully considered by the architect. The whole and every part appears to have been done with relish —with true *gusto*,—without which, what is called art is only manufacture. If there be any thing which we could wish had been otherwise, it is, that the heads of the second floor windows had not been carried up quite so high, because they now break into the line of the lower edge of the capitals of the columns, which if not actually objectionable, is what is much better avoided; and no doubt Mr. Barry would have done so, had he not been over-ruled in that particular.

It is quite unnecessary for us to enter into a minute architectural description, because the engraved elevation, from Mr. Barry's own drawings, is upon such a scale that even the details are shown sufficiently distinctly,—an advantage that very far outweighs that of having the entire front represented in a plate of the same size. Had there been a marked central feature—one principal in the composition, the case might have been different; but as there is not, it being the extremities alone that are distinguished from the rest, and that only by the addition of an attic, both the composition itself is clearly enough made out, and the character of the whole intelligibly conveyed by as much of the elevation as is here represented,—which is rather less than half, there being thirteen windows on a floor, between the two end pavilions. To remove all doubt as to one point, that might otherwise be felt by those unacquainted with the building itself, we should observe that the middle compartment resembles the others, there being not even so much as an entrance there to mark it out at once to the eye as the centre. Perhaps a doorway there, of more ornate design than the others, either in addition to the four present ones, or as a substitute for the two in the middle division of the façade, might have been an improvement, but Mr. Barry was obliged to conform to the number and situation of the entrances determined by Soane's plan. There is also one peculiarity which has been forced upon him, in order to accomplish the raising of the columns to the level of the first floor; for they are placed upon projecting breaks or piers in the ground floor, that serve as pedestals to them; had not which been done, the thickness of the wall there must have been very greatly increased. While these breaks below produce a certain degree of variety and richness, they are in conformity with the treatment observed for the order itself, whose entablature is now made to break over the columns, and thereby, itself conforms to the treatment of the order, both the columns and their immediate portions of the entablature, being "*engaged*." Whether such effect has been an intentional or incidental result, this continuation of breaks upwards, throws a strong expression of verticality into the design, more especially at its extremities, where the vertical lines are prolonged by the attic pilasters, and their breaking cornices, and after being further carried on by the pedestals in the balustrading, terminate in the pyramidal vase-shaped acroteria.

The character of the rustication for the ground floor or basement of the order, has moreover been influenced and determined by the necessity for breaks in it, below the columns, it being thus reduced to nearly horizontal channels alone, with only a single vertical one in the alternate courses of each pier: what is here done however explains itself, and the effect is very different from that monotonous and *plank*-like appearance (without any indication of bond in masonry) which takes place when horizontal channels alone are continued uninterruptedly on the surface of a wall, without any jointing. In both the order itself and the attic, the rustication is treated with some degree of novelty, the channels not being continued quite up to the columns, but stopping against the edge of a narrow plain surface; whereby the rustics themselves are let into a sort of upright panel, not wider than half the diameter of the columns. And the panels thus formed, appear very much to assist the expression of verticality, which we have pointed out. We hardly need call attention to the development which Mr. Barry has given to his attic,—rendering it not a mere addition or excrescence to the order, but identifying it with the latter in point of luxuriant richness, and thereby rendering those portions of the design crowning ones in it,—parts which are to the general mass—what its capital is to a column, or its cornice to an entire order. The example of an attic, which he has here given us, is compared with the things of the kind we are accustomed to, what the *cornicione* in his Club-houses is to the meagre shelf-like cornices in that lean starvation style which so long prevailed in every style we affected. Barry will have given *embonpoint* to our architecture.

Leaving our readers to note for themselves minor specialities of design, which if their attention has been at all excited by what we have said, they will no doubt do, we will merely add that the north pavilion (the one shown in the engraving, and which is for the Home Office), together with the two adjoining compartments, has yet to be built, and will, we understand be commenced almost forthwith. When the entire front is completed, it will extend 296 feet, and be 56½ feet in its general height, and 67½ at its extremities.*

The structure is not only admirably finished up, but all of a piece throughout, every part that is at all visible, being strictly in accordance with what is completely seen. Thus the West side 'of the attic of the South or Downing-street pavilion, is finished-up like the others, although seen only partially above the adjoining buildings; for Barry does not countenance that miserable system of *pinafore* design, which leaves the end of a building—that is, as much of such end as really shows itself—whether intended to do so or not—quite bare and unfinished; as is the case with Inigo Jones' Banquetting House, just by, which as there is no probability of its unsightly ends being shut out from view by other buildings erected against them, ought to be completed externally. Unless that be now done, it will cut but a poor figure in comparison with Mr. Barry's new work on the opposite side of the street. The South-east view of the latter presents a striking contrast to the South-west view of the other, whose South end is a mere brick wall; whereas the South end or elevation of the Downing-street pavilion (the Council Office), is precisely similar to the East one (therefore to the one shown in our engraving), with the slight difference, that there are five windows to the ground floor, there being no entrance on that side.

If there be much to excite admiration in the building, there is also something to excite surprise, for surprising it is or would seem to be, that so superior a piece of architecture should have risen up almost all at once without any flourish at all of newspaper trumpetings, while the most vulgar nonsensical fuss is made about the most trumpery buildings imaginable, merely because somebody or other who is a somebody, performs the farcical ceremony of "laying the first stone," as it is called, to the great edification of all the nobodies who *assist* on the important occasion.

CANDIDUS'S NOTE-BOOK. FASCICULUS LXX.

"I must have liberty
Withal, as large a charter as the winds,
To blow on whom I please."

I. As Wightwick vows to go, D.V., to Naples and eat macaroni there, it is to be hoped that he will not forget to bring back with him some pen-and-ink sketchings—and if he like, some pencil sketches, too, of the recent architecture of that city. There is sufficient *pabulum* of that kind for his pen,—the church, for, instance, by that un*Naglerized* nobody, Bianchi. And let him portray that and whatever other buildings he speaks of, *architecturally*, so that we may be able to make out a tolerably distinct image of it, not a mere formless, shapeless Ossianic spectre. Let him take a lesson from the novelists:—they after all are the people for exact and conscientious description; they are content with nothing less than that of giving us a complete inventory of a heroine's "*personals*," noting every item separately,—though with all their exactitude they never inform us of her exact weight—the weight of a mortal "sylph." As to Vesuvius, we can very well dispense with any remarks on that *from* Wightwick; so let him eschew speaking of its crater—that *bore* of tremendous calibre,—or we shall wish that he had fairly jumped into it, and like Empedocles, distinguished by extinguishing himself within it.

II. It is curious that we should be indebted to a Cookery book for a detailed plan of the kitchen offices in the Reform Club-house. M. Soyer has supplied a leaf that was very much wanted in architectural lore, for those who have published plans of town mansions, have never revealed t us the complex *arcana* of their below-ground territories, but have literally passed over them, as matters altogether beneath them,—*low*, vulgar, and *infra dig*. Yet the arrangement of the numerous separate rooms requisite for an extensive domestic establishment, within the basement of a town residence, calls for the exertion of more than ordinary ingenuity and contrivance. A collection of a dozen basement plans, minutely detailed and explained, would form a series of valuable and useful lessons. There then, is an idea at once for a publication of entirely new character. So let some one now take it up. But no,—nothing will take or go down with the profession or the public, that does not address itself to and flatter the present church-mania, and the passion for studying Roman Catholic "*rubbish*." What with churches, church furniture, and church upholstery, on the one hand, and with railways on the other, the demand for architectural publications of any other kind, seems to have ceased. Archæology is all very well in its place, as the *handmaid* to architecture, but it has of late given itself such airs, and domineered at such rate, that it is time for it to be taken down a peg, and not be suffered to keep poking all sorts of paltry old trumpery in our faces, and insist upon our admiring hatched-faced saints, and angels with dislocated limbs.—Let us escape to the kitchen.

III. Talking of escaping to the kitchen, reminds me that the kitchen itself has completely escaped the attention of that great architectural encyclopædist, Gwilt. Even so; his fat Falstaff tome contains nothing whatever on the subject of kitchens and their accessories, and the multifarious apparatus belonging to them; an omission the more remarkable considering how much stuff—stuffing I mean—he has crammed into his book, that one would never think of looking for in it. He has indeed given the word "kitchen," a place in his Glossary,—and very properly, it being so strictly technical a term, as to render explanation of its meaning, indispensable,—indispensable at least for the information of those over-and-above genteel young ladies in middling life who are presumed never to have entered a kitchen, or to know what sort of operations are carried on in one. It is only thus that the insertion of such a word can be accounted for, while so many strictly architectural terms which are not to be found in general dictionaries, or even in encyclopædias, are omitted. Nor are omissions of the last-mentioned kind the most remarkable of all in Gwilt's book, because he has chosen to omit Rickman's well known work in the list which he gives of publications on Gothic architecture. I say "chosen" to omit, because it is not for a moment to be supposed that he was ignorant of the existence of a work which besides being exceedingly useful as a synopsis or catalogue of English structures in that style, is continually referred to as an authority. There are besides what look very much like instances of *intentional* forgetfulness, in regard to other publications, which though not mentioned by him were as well or better entitled to such *distinction* as very many of those which obtained it. That on Barry's Travellers' Club-house, is of sufficient merit if only on account of the examples of Italian detail given in the plates, to have been worthy of a place in the list of works on Italian architecture; and its non-insertion is all the more remarkable because Gwilt himself points out for particular admiration, and as example in which "the principles of that style are so admirably developed," the façade of the Palazzo Pandolfini, to which the Clubhouse above-mentioned bears a more than casual general resemblance. Possibly, however, Mr. Gwilt never saw or heard of the book; and if so, he will thank me for pointing out both that and Rickman's, that he may insert them accordingly in the next edition of his valuable Encyclopædia.—Apropos to Rickman,—the German *Nailer* (Nagler) has not nailed him in his Lexicon, though he has nailed up there an immense number of obscure or else quite forgotten names—some of them the smallest of the small-fry artists. Well then, all the more industry and greater research does it show to go and pry about with a farthing candle, and peep into all the crevices and crannies of tenebrous obscurity, and turn out the poor little things that lay there ensconced.

IV. The "Times" has been very pleasant à la Punch, on that *Nash*ional calamity, Buckingham Palace, which it is now discovered is hardly habitable, neither Nash nor George IV. having any idea that royal nurseries could ever be wanted within its walls, and not nurseries alone, but apartments for a whole colony of tutors and preceptors. As to a mere nursery—that is already provided, there being nothing more required than to make use of the "Garden Pavilion" for such purpose, for which indeed it appears to have been actually intended, it being so very pretty, all covered over with "nice darling little pictures"—exactly what a royal baby-house should be, with a kitchen and other "conveniences" attached to it,—a proof that it was built not only for show, but for service. The idea of so making use of it, was perhaps abandoned, because it was found not sufficiently large for the purpose; yet surely it is just as easy, and would be as CHEAP to build additional rooms out behind it, as to enlarge the palace itself. If Mr. Blore will take this hint—and he ought to jump at it—it will spare him a great deal of pathos, and perhaps no less perplexity also, since perplexed he, no doubt, will be to patch up decently the Park front of the Palace, on which side it is proposed to add another range of buildings, filling up the space between the wings, and enclosing the open court in front. In doing merely that, there will be no particular difficulty; but unless the wings themselves—the ends of them at least are to come down, and to be taken into the new East front, either what comes between them must be accommodated to them—made of a piece with them, in which case the architecture will be just as mesquin as at present, or the whole will be more or less a piece of patch work. It will be necessary also no doubt to advance the new building before the present line of front, and continue the wings also for the same distance, because unless that be done, what will then be an inner court will be smaller than the present open one; besides which the side elevations of the wings towards the court must either be altered accordingly, or their regularity would be destroyed;—as may be seen by one of the plates of plans and elevations of the Palace in the improved edition of the "Public Buildings of London,"—which, if never looked at before, are likely to be so now, out of curiosity, and in order to judge what contrivance can do for improving the building.

V. Whether Blore be a great master as to contrivance, I know not, but it may be questioned if he be exactly the right *B* for the occasion, or likely to improve the architectural quality of the Palace. What I have seen of his, is marked by littleness and feebleness of manner; and though he has had some favourable opportunities—Lambeth Palace for instance, he has done nothing at all of a superior kind, nor is any work of his ever quoted as manifesting more than ordinary talent. In one respect he is a copyist of Sir Robert Smirke, for like him he has a horror of exhibiting at the Royal Academy, and exposing any of his designs to the profane gaze of the multitude. Pity that such architects can not keep their buildings as well as their drawings secluded from public view.

VI. There is one notable inconsistency in what is rumoured relative to the alteration of the Palace:—the works, it seems, are to be carried on with all possible dispatch when once commenced—the necessity for which is sufficiently apparent, and yet only £30,000 per annum is to be voted for the purpose, although £150,000 is the estimated expense—at present, and if there has been any miscalculation at all in the matter, it is easy enough to guess on which side the mistake will be found to lie. But I forget,—the Pavilion at Brighton is to be sold towards paying expense—of taking it down, perhaps, unless some railway millionaire should happen to take a fancy to it, and offer to give a good round sum for it,—about a tenth of what it has cost first and last. Yet that would be horrible!—only think of some mushroom man of money installing himself in the pet *place* of George the Fourth. Poor George! poor Nash! poor Soane! methinks I hear the ghosts of all the three abusing "Posterity" for its villainous taste, and for committing such deadly havoc with their works. Carlton House gone, George III's Gothic Palace at Kew gone, the Pavilion going; Soane's "Board of Trade" so metamorphosed that it does not know itself, the Scala Regia going, "my Law Courts," too, going—about to be knocked down, though not by George Robins' hammer, and now Buckingham Palace to be improved!—improved indeed! as if what the newspapers, at the time of its being built, and John Britton also spoke of as an august metropolitan palace becoming the dignity of a British sovereign, could possibly admit of improvement. Oh dear!—but it is all owing to the March of Intellect.

VII. One comfort is that it will now be more work for the "Silver Trowel," as no doubt the first stone of the new front of the Palace will be laid with all due pomp and ceremony, if only for the benefit of the newspapers, which invariably take prodigious interest in such operations. Prince Albert must by this time be quite a proficient in the art of handling the trowel, if in no other; but his Royal Highness seems more ready to lend a hand that way, than at all to care what the buildings themselves will turn out. There is a little pigmy—I might almost say piggish or priggish—thing growing up in Oxford-street, the first stone of which was laid by the Prince on the 16th of last June—happy and memorable day!—but all the other stones after that first one have changed into bricks, which are to be compoed over; and whatever it may turn out in other respects, the front will be a most minikin affair. Moses—Minories Moses, I mean—will turn up his nose at it, as a thing that he could easily stow away in his own shop. Of course the Prince did not see the design, or he would have employed the trowel differently from what he did, by plunging that instrument into it. Hard work that some first-stone-laying, considering the precious balaam that must be listened to on such occasions. However the Prince is relieved from the drudgery of *Cabinet*-making.

ARCHITECTURAL RECOLLECTIONS OF ITALY.

By Frederick Lush.

(*Continued from page 231.*)

"Architecture (where it was not a mechanical art dependent on mere convenience, and upon the rule and plummet) was an emanation of the arts of design, and consequently, in everything that regarded its more liberal concerns, its beautiful and majestical effects, as a whole and parts, it was the pure offspring of drawing or modelling, and absolutely and solely depended on the composition of forms, and the compositions of chiar'oscuro and relievo which those forms produced."—Barry's "Lectures on Painting."

The most important constituents of beauty and grandeur in architecture are mentioned in the above quotation. They can only manifest themselves in art in proportion as that mind is imbued and acquainted with the principles of beauty which we find are requisite for the painter, and by which alone the architect is distinguished as an artist who thinks and feels, from the mere mechanic who measures and builds. How necessary then it is to possess these principles will be very apparent. Architecture, as a fine art, must be judged of by its agreeable effects and expressions—a cultivated eye or mind being the arbiters in these results. But the architect must need have a strong perception of several painter-like qualities—of the composition of beautiful forms, chiar'oscuro, and relievo—before he can give that expressive character to his works which fills and elevates the mind, in the same manner as poetry and painting. To accomplish this end is the chief glory and ambition of the architect. But to what motives and to what ignorance are such noble ends too often sacrificed?

This art being in its nature so *utilitarian*, necessarily demands an acquaintance with those general principles of art which, combined with its *utility* and *fitness*, may afterwards invest it with that poetic character which all works must have whose ultimate and grand object is to affect the imagination. The Italians, at the revival of art, who applied the principles of painting, i. e., drawing, harmony of light and shade, &c., to architecture, eminently succeeded in this particular; but their works, and the effects they produce, could never have been created but by this combination. Were proofs wanting, look at Michael Angelo—perhaps the grandest painter, one of the greatest architects; look at St. Peter's and his other works. Then Raffaele, greatest in expression and beauty as a painter, is he not elegant and beautiful in his architecture? Villa Madama and other buildings may occur to the reader as illustrations of this truth. Again, what is more elegant, simple, and lovely, than the Campanile of the Duomo, at Florence? And was this not the work of a painter, and when painting was in its early days of purity? Yes; Giotto was great both as a painter and an architect. And why are the works of such masters never forgotten when once seen; that even in presence of them they seem as if they had been called up by enchantment; and that at an after period they so frequently come before the imagination like dreams? Why, but because of their extraordinary and powerful *effect*; because of that beauty and grandeur in composition, which give life and intelligence and poety to building. They well knew that architecture required to be distinguished by such forms, such magical effects, such prominent bulks in the grand mass, as would produce this, and with it a most lasting impression. Where such thought and mind is evidenced in the works of the Italians, there is ample atonement for their defects, which are numerous; just as in the earlier paintings fine feeling and expression, make us forgive every anachronism and absurdity.

The noble group of buildings in that solemn square at Pisa, the cathedral, baptistery and campanile (whose beauties we owe more to painters and sculptors, than architects,) whether each is viewed as a whole or in detail, are further instances of the incalculable benefit architecture derives from a thorough understanding and practice of the union of the principles of the sister arts. Very many other names might be brought forward and examples mentioned to show that these men, when they took upon themselves to build and adorn, possessed a painter's perception of beauty. Each brought to the task and ennobled his design by applying the principles of painting and grounding it not so much on antiquated rules and precedents, as on the eternal laws of taste, harmony, and proportion existing in the mind; who, from the enlarged and comprehensive view he had of art, knew more than the subject demanded when he commenced the work; felt the nature of the idea his building was made for; saw his work was made for the place, and took care the place was adapted to his work.

Now, the neglect of these principles of painting among English architects is, with some few exceptions, the main cause, we think, of bad architecture, want of originality, &c., and one reason why we observe the art so often degenerates into a mechanical trade. We seldom see originality,—and where it does occur, there is little taste; and beauty is another word for the evidence of the existence of pictorial faculties, and indicates or reflects a mind that is conversant with the beautiful forms in nature.

Those principles (referred to by Barry) of uniformity and variety which must be pursued in the arrangement and construction of all forms which enter into the composition of buildings—are executed with the greatest success by him who is most capable of conceiving and delineating fine forms—and this power of drawing is very much neglected by the English student.

I of course allude to the study of the human figure, for all drawing implies a knowledge of that, and deserves first consideration, as it is this alone which is the best means, in the first, as well as in the last step of the art, for cultivating the eye and filling the mind with ideas of beautiful form, which facilitate and ennoble design, composition, and all the effects of chiar' oscuro resulting from them.

The prevailing practice is to begin with architectural inanimate lines, and copy ancient examples, before any part of the human body or even ornament is attempted to be drawn: the one has a vicious tendency—cramping both the hand and intellect; and the neglect and ignorance of the latter makes the power of adding the beauties of ornament, the foliated capitals, the enriched friezes, &c., at first an unconquerable and disgusting difficulty to the tyro.

Without a knowledge of the principles of design, we cannot give that contrast, elegance of line, and variety of form which, bearing in mind the purpose of the building, add to its beauty. A knowledge of chiar' oscuro will enable the architect to combine the various parts of his work with such general effects that, while every part may be beautiful in itself, such beauty will be but a part to increase the ensemble of the whole building. "It is he alone," as Barry says, "who, from the sure and expansive principles of composition and chiar' oscuro, can pursue beauty and sublimity in a thousand different ways; whilst, without these essential requisites of design, men are but mere builders, and must unavoidably copy or plunder from the works of those who are gone before them; and in either case, the absurdities that may result from the difference of climate, local situation, and from ill-according particulars, however beautiful in their own original proper arrangement, are too obvious to be mentioned."

But a knowledge of chiar' oscuro will prompt him to dare to give relief and power to his work as he can combine light with shadow, and play with relief till his idea of effect is fully carried out. In our old Gothic cathedrals, what richness and variety—what effect! how powerful they look, and eloquent and grand they are! In the numerous churches that have been erected in imitation of them, we see, with only a few exceptions, in their effects, the deficiency of architectural spirit and talent in their authors. In general what sameness—how barren and unmeaning they seem! as if they had tottered out of their places—and could not stand there long. So far short do they come of those glorious models of the 13th century—such meanness is there instead of profusion—such saving instead of cost—such reduced proportions and littleness of manner—that although the Gothic may be more appropriate to our Christian churches than the Classic Roman, there is far more beauty and skill observable in the spires of Sir Christopher Wren, than in those of the modern Gothic builders. The skill displayed in the construction of the spires of Wren, and the ingenuity with which he applied the ancient orders to the modern Campaniles, for which he had no authority, deserve our admiration. They exhibit, too,—many in an eminent degree—the principles advocated in this paper. We observe such simplicity, yet such variety—such a fine relief and "making out" of the parts, and to an extent which in vain we look for in the flat modern Gothic towers, &c.

It is a knowledge of these principles—valuable in their application to every branch of art, but more especially to architecture—that is the source and inspirer of originality. Hence the old Italians, though little professing architecture, possessed qualifications which raised and ennobled it; their inventions are steeped in beauty, for they were drawn from the infallible principles which guided their practice. And the opinions upon architecture as a fine art are always to be accepted and preferred before the judgment of architects, why then separate from their profession a knowledge of painting.

STAINED GLASS WINDOWS.

St. James's Church, by Mr. Wailes.—Woolwich Church, by Mr. Headley; from a Cartoon, by Mr. Corbould.

The two new windows lately completed, in the opposing styles—modern and ancient—which now engross so much attention, afford a good opportunity for instituting a contrast between them. The ancient window, or rather, series of windows, at St. James's Church, Piccadilly, consists of an upper and lower range of compartments, separated by a deep entablature. In each range are three lights, divided by columns: the painted glass with which each light is filled exhibits a scriptural subject contained in a panelled centre or medallion, which is surrounded by a wide border of mosaic work, with an additional circular mosaic ornament introduced in the lower part of the upper centre compartment. The drawing, though superior to that of many of Mr. Wailes's former productions, is very inartistic,—the arms and legs appear to have been stuck on, as though the painter had copied some Dutch doll, made to scale, and wrapt round with cloth of various hues, for a model. The flesh tints and other colouring must have been done from some of those Italian glass paintings frequently seen decorating (!) many of our agricultural labourer's cottages—they exhibit about the same taste. The Mosaic work has little pretension to consistent design; it is distinguished by all the beautiful "regular irregularity" of the kaleidescope, and could not, we should have thought, by any chance have been executed in any other way,—the colours are so varied and the pattern so heterogeneous.

As we happen to be a little in the secret, we may perhaps be excused in explaining how this competition was managed. We believe it to have been all fair and above board at first, and that many of the committee did, after looking many times over the several designs, choose one, extolled it, and were delighted with its originality, grandeur of conception, and extraordinary talent. It was but a sketch—but we all know what the sketch of a good artist is,—and they determined to make it their own. It appears, however, that after the committee had come to this resolution, they were informed by the Bishop that he liked not this modern style of glass painting—that it must be ancient "for his money;" mosaic work, with figures and all that sort of thing; which he thought the best adapted to this window;—and then, by some extraordinary argument, dictation, or power of patronage, did he win over this said committee to his views, and the result now appears to stain, not the window only, but the character of England, as a nation of taste.

The sketch first chosen we have seen, and pronounce it to be, in our humble judgment, one of the best conceived designs we ever beheld, either from ancient or modern painter. The lower part was the removal of Our Saviour from the Cross, and a cross on each side for the thieves. The principal cross and figures would have occupied the centre compartment, and one of the other crosses, with the thieves and subordinate figures, the sides;—but although thus separated, the subject was so well managed and balanced, as to appear one picture. The whole was treated as a night scene, and lighted up with burning fuel in vessels with long handles, held by attendants; giving a sombre and grand effect to the solemnity of the scene. The upper windows would have contained the "Wise Men's Offering," consisting of splendid figures of all nations, attending on camels with canopied seats, and other display of Oriental magnificence, seldom before embodied in one picture. These would also have occupied the three upper compartments, as one picture. Thus would have been exhibited the Birth and Death of Our Saviour, treated in a bold and original manner, and, from the well-known talent of the artists, could have been executed in a way that would have revived the art of glass painting, and have been a proof that there are *now* those who can produce better things than ever ancients did, and redeem the art from its present degraded state. This sketch was by Mr. Corbould, and was to have been painted on glass by Mr. Hoadley, from Mr. Corbould's cartoon, who would otherwise have assisted in the progress of the work.

The St. James's window has been in contemplation so long back as thirty years, when Mr. Backler was actually commissioned to make a design from the Transfiguration by Raffaele, and was engaged to execute the work, but by some unforeseen circumstances has been unfortunately delayed to this day to give place to another, who declared himself incompetent to paint the window in the style required, but was nevertheless chosen for that purpose!

We do not so much complain of Mr. Wailes,—he would have been to be pitied, had he not pocketed the good round sum of 1,000*l*, for his labours, which may, in some measure, cover any little annoyance he may receive from the indignation of the public; but we do blame the committee, without the least reserve, for allowing themselves to be seduced from the right path and dictated to in a matter of such importance; for it is not the St. James's window alone that may be subject to this degradation,—but the tendency to imitation is so strong in this country, that many other parishes will follow this vile example, for although many excellent examples of painted glass have been done of late years in distant parts of the country, yet this abominable trash, called Mosaic work, is still patronised and selected by a committee who, of all others, from its position in society, should have known better.

The pleasing effect of old stained glass, we well know, is not always caused by good drawing; on the contrary, it is produced by harmony of colours and a mellowness obtained by time. This gives that richness and beauty so much extolled in ancient windows; but it is no argument that bad drawing should be used; as it stands to common sense, that were the subjects better treated, the beautiful effect would have been greatly enhanced and the educated eye would not have been subject to the disgust now experienced on viewing the caricatures so often seen on old glass. Let any one attempt to decipher the subjects of many ancient windows, and he will find it as great a difficulty as transposing an Egyptian hieroglyphic.*

The Woolwich window, painted by Hoadley, is in the pictorial style, from a cartoon by Corbould. By a singular coincidence, these are the same artists who were to have executed the St. James's window, if the committee had not been deterred from their good judgment by the ecclesiastical dignitary. This window is 14 feet high and 6 feet wide, circular headed, and contains but a single figure—that of Christ bearing the cross, with a wide border and pedestal beneath, the latter having been judiciously designed to shorten the window and give the picture a better proportion; upon this the emblems of the palm branches are introduced with the touching motto—"CHRIST bearing His cross went forth." The figure is colossal, being at a great height and generally viewed from a distance; the features of the face depict sorrow and suffering, and the hands and arms are well executed and doing duty—not mere puppets to the figure, as at St. James's; the drapery is broad, and allows of a depth and mass of colour which give dignity to the picture, exhibiting those splendid ruby and purple tints said, by the ignorant, to be lost; the border judiciously introduces the passion flower, well executed and entwined in scroll work.

There is a grave solemnity about this single figure that strikes the beholder with religious reverence, at the same time there is a pleasing harmony in the colouring and design of the rich border, which relieves the principal composition. It is a contrast—and a bold one too—to that style we have just denounced in the St. James's window, and so much admired by ecclesiastic patrons of the art. We would seriously advise these gentlemen to look "upon this picture and on this," and try for once to clear their vision, so as to distinguish gold from tinsel, art from kaleidescope, talent from mechanism, and then decide whether 'twere better to remain in ignorance or to recant those bigotted notions they have heretofore so strongly held, and, although at the eleventh hour, to assist this degraded art, and make it one worthy of an intelligent nation.

* At the time of the Revolution, many of the painted windows in our cathedrals were taken down and packed away in hiding places, to be secured from the violence of the Puritans. When the glass was subsequently replaced in the windows, the work was frequently confided to those who were imperfectly acquainted with the original design, and therefore unable to reproduce it accurately.

ARCHITECTURAL IMITATIONS.

—— *esse quam videri malebat.*

In the introductory note to the present volume it was stated that our architectural criticisms would be based on the doctrine of faithfulness in architecture; and accordingly in the paper immediately following, the practise of using imitative materials in building was discussed and condemned. It was hoped that this and similar papers, if they failed of producing absolute conviction, would at least preclude the chance of our views on the subject being misapprehended. It appears, however, from some observations in our last number, that this hope was ill-founded, for we are by a side-wind accused of uttering sentiments which, if legitimately carried out, would lead to a condemnation of the use of gilding in architecture.

Gilding, as ordinarily employed, is not a deception. No one who looks at the gilded boss of the vaulting of a church-roof is deluded for an instant into the idea that what he sees is solid gold. Not only is he not deceived, but there is no attempt made to deceive him; for the position of the boss among other stones sculptured in a similar manner, and many of them painted of different hues, plainly shows that the gilding is nothing more than a means of giving to the stone a beautiful colour. When however gilding is used to make the substance beneath it seem to be solid gold, it becomes at once a paltry contemptible deception. The flashy gentleman (or gent) who wears gilded rings will generally prove, like his jewellery, a counterfeit: not in outward appearance only, but in education, feeling and language also, he will be found to be a gentleman in semblance alone.

What matter, it is asked, though the beauty which invests works of art be only skin-deep? If it be *no* matter *at all*, why then should stone and marble and costly woods be *in any case* preferred to less expensive materials? If the deception can be practised to perfection, why should we have the least preference for the reality? But as a matter of fact we *have* that preference —there is not an architect in England who would not always, if he could afford it, use real stone rather than the most perfect counterfeit. The existence of this feeling proves that the mere excellence of the counterfeit does not remove *all* objection to it—that the imperfect nature of the deception is not the *only* argument against its employment.

Let us suppose it to be discovered hereafter that the noble piers of the nave of Canterbury Cathedral are not Portland stone but Portland cement, and that the shafts of the Norman choir are not Petworth marble but stucco overlaid with black varnish, and that the beautiful foliated ornaments of the crockets, pinnacle-work, &c. were not sculptured by the hands of skilful artists, but were run in moulds by common workmen—would our admiration of the building be increased or diminished? Why should it be diminished? The imitation was perfect; we have supposed it to remain for centuries without being discovered, and though the beauty be only skin-deep there was no outward signs to reveal that circumstance.

Or to take a commoner illustration—the descriptions of public entertainments usually enlarge on the magnificence of the display of gold and silver plate, and the splendour of the jewellery work by the guests. Would the description be more or less glowing if it were found that what seemed gold or silver was merely electro-plated, and that the diamonds were only paste? Why should people care to have the Hall-mark on their dinner-service? Britannia metal is exactly the same colour as silver.

But we are told that it is no argument against deceptions, that they are "apt to be paltry." This may be disputed—for if all the paltry imitations were got rid of there would be scarcely any left to dispute about. And is it not obvious moreover that those who practise paltry imitations will shield themselves under the sanction of those who defend more costly deceptions? So that in fact these defenders are in fact fairly chargeable with providing excuses for the most miserable expedients of sham showy architecture.

Let us consider for a moment what are the imitations most generally practised. By far the most common of them is the expedient of smearing over the honest bricks actually employed in the construction of a house with a coating of plaster, on which vertical and horizontal lines are drawn with the point of the trowel. It may be fairly assumed that at least half of the newer houses in London are ornamented in this way. Occasionally the lines, especially inside churches, are drawn in black lead! What miserable expedients are these? Can any one for a moment be induced to suppose that a few thin black lines represent the joints of real masonry? They show all the intention of deceiving, but are too clumsy to effect the deception. Another favourite expedient is to paint the stucco of a uniform colour, and then *spatter* it over with spots of dark paint, by means of which it is supposed to assume the appearance of granite.

It may be assumed that no one sincerely desirous of maintaining the dignity of architecture as a noble art will defend these wretched juggles. But the condemnation rests not merely on their unsuccessfulness, for then a thief by parity of reasoning ought not to be punished unless taken in the fact The true ground of condemnation of all architectural deceptions, whether successful or unsuccessful is that they "partake more of mere manipulation than of art." They tend to substitute the workman for the artist, the builder for the architect. Unless, as has been well observed by the *Builder*, the *skilful* hand be apparent, the result is disappointment rather than delight. It is to this consideration we must refer for the cause of the failure of all the save-trouble expedients which have so long exercised their pernicious and debasing influence upon architecture and the other fine arts.

But there are many other arguments against that class of save-trouble expedients which we are more particularly considering. Imitative ornaments are necessarily inconstructive. A pillar or pilaster of stucco *must* be stuck on for show—the material has not sufficient cohesion to be useful in resisting either vertical or lateral pressures. Again, there is a practical tendency to evil in the system of imitative decoration, which if it be not an actual part of it, results certainly form it—namely, the introduction of redundant and inappropriate ornaments. The facility of being showy is certain to be abused: the temptation is too strong to be resisted by those who make the common mistake of confounding architectural beauty and elaborate enrichment. Accordingly we find plaster-architects bedizening their work with a crowd of ornaments as ridiculous for their number as their inapplicability. A building with showy bits of plaster thus stuck over it reminds one involuntarily of a village landlady tricked out in her myriad of Sunday ribbons.

They who defend deceptions in building should remember that for the sake of consistency they should be prepared to vindicate *all* such deceptions if well executed. If an architect wish to introduce more windows into an external elevation than is convenient for the internal arrangement of the building, why may he not *paint* resemblances of those windows on the external walls? The deception might be managed so well that it would scarcely ever be found out. The ornament would be only skin-deep to be sure; but what of that? Why should not the great doors of a cathedral be of deal grained and varnished to look like oak. Why should not the timbers of the roof of Westminster Hall be painted so as to appear elaborately carved? or why should not the parapet of the external roof be painted to look as if panelled or perforated? The triglyphs of a Doric order might be *drawn* in their proper places instead of being sculptured there, and the more inaccessible columns might have the flutings painted upon them. This seems the legitimate development of the the theory of architectural deceptions.

It is gratifying to those who are anxious for the advancement of architecture to find that the importance of faithfulness in architecture is being every day more distinctly recognized. The rapid growth of this doctrine even the last year or two is a most favourable indication that art is not to remain for ever in its present degraded condition. Every periodical which treats on subjects of art new recognizes this principle of criticism, and contains correspondence which proves that the detestation of plaster Gothic and plaster Grecian is becoming pretty generally diffused. Of course those who have long practised or defended these kinds of architecture are very angry at having their favourite tenets cut up by the roots: but they will generally acquiesce when they find the tide of opinion too strong for them and silently adopt the principles which they find it in vain to oppose. Those few who have too little wisdom or too much obstinacy to yield to the dictates of improved public taste will be left behind to enjoy their own opinions in undisturbed solitude.

NEW METROPOLITAN CHURCHES.

All Saints, St. John's Wood.—The new church which has been recently erected in the Finchley Road, St. John's Wood, from the designs of Mr. T. Little, is, as regards the exterior architecture a great improvement upon the churches built in and about London ten years ago. The general character of Mr. Little's design is an unpretending simplicity, which if it do give opportunity for the display of much original genius, at least precludes the occurrence of gross defects.

The plan of the church is nearly a parallelogram—a nave and two aisles, with lean-to roofs, a tower at the north west angle, and at the east end a prolongation of the nave which, though too shallow to be called a chancel, serves the purpose of a sacrarium. The style is Perpendicular. The following are the principal dimensions.

Extreme length	96 feet.
Width of nave	30 „
Ditto including aisles . . .	61 „
Depth of sacrarium	20 „
Rise of nave-roof	19 „
Height of apex of ditto from the ground .	55 „
Height of nave-arches	28 „
Span of ditto	20 „

The tower is designed to consist of three stories surmounted by a spire, but at present the first story only is finished. In the west gable is a four-light window, beneath which is a small door (with very poor mouldings) for the use of the soldiers of the neighbouring barracks. The north and south windows are the least praisworthy features of the external architecture. The window at the east end is of five lights divided by a transom.

One of the principal reasons of the satisfactory appearance of the church is the judicious manner in which the architect has used his building materials,—Kentish rag with Bath stone dressings. The ragstone instead of being squared and laid in regular courses (a most expensive and ineffective method) is built in what is technically termed "Random-coursed work." It is a matter of great regret that in many modern churches the ragstones are hewn and laid with the same precision as softer kinds of stone, and that the joints of mortar are moulded so as to give the appearance of projected fillets, in which, as has been observed, the individual stones appear set as in frames. This method is very faulty; it arises from the almost universal ambition of modern architects to make their materials look better than they really are, instead of applying them honestly to the purposes for which they are naturally adapted. The very fact that this coursed ragstone masonry presents the appearance of rustic work is quite sufficient condemnation of it. The practice not only adds to the expense on account of the hardness of the material, but detracts greatly from effect of the masonry. Our old country churches are proofs not only of the beauty of the irregular ragstone masonry, but also of its durability: for a familiar example near London, we may refer to the tower of Lambeth church. Alas, when will modern architects build with the boldness and picturesque simplicity exhibited in that structure?

The interior of the new church, at St. John's Wood is by no means so praiseworthy as the exterior. The internal architecture is in fact as bad as it well could be. The span of the nave arches and the width of the nave are disproportionately great. The north and south windows are treated as mere holes cut in the walls, without any dressings or mouldings to connect them decoratively with the rest of the building. The difference between the forms of the inner vault of the windows and the exterior window opening, which in ancient Perpendicular architecture is a principal source of beauty, is here entirely disregarded. The piers and windows are intersected by galleries supported on paltry cast iron columns. The mouldings throughout are very poor and shallow.

The walls are coated with some kind of plaster on which are drawn black lines to mimic the courses of real masonry: over the heads of the windows and doors these lines converge and suggest imaginary arch-voussoirs. Can any artifice more paltry and palpable be imagined? Were it not so common it would be absolutely laughable. The trick is as shallow and obvious as that of the ostrich which is said to hide its head to escape pursuit. Even if we allowed (which we do not) that deceptions and imitations were at all permissible in building sacred edifices, surely they should be better managed than this is. It is merely a child's make-belief—no one can be deluded for a moment into the idea that a few indentations and black streaks are are the joints of real masonry. The artifice should be reserved exclusively for gin-palaces and the lath and plaster edifices dignified by the appellation of *suburban villas*.

The church is filled with low ugly pews of deal stained and varnished: this staining is another ridiculous deception, an abortive attempt to make deal look like a better kind of wood; whereas in fact it looks much worse than in its natural state, for the varnish renders the coarse grain and misshapen knots of the wood offensively and unnecessarily conspicuous. In village churches where the deal boards are either painted of some uniform colour not imitative of a costlier material, or left in their natural state, the lines of this unornamental wood are little seen, and consequently the appearance is comparatively unobjectionable. But to make an ostentatious display of the "figure" of a wood which has no beauty to recommend it is a piece of vulgar pretence, which we always rejoice to see proved, as in the present instance, a complete failure.

There is a large family pew for the minister screened off from the rest of the church by a curtain; the privileged inhabitants of this pew are therefore enabled to offer up their praises and petitions unseen by their fellow sinners assembled and met together for *public* worship. These invidious distinctions in a church are most unseemly, especially when they who avail themselves of them are those who are set over the congregation, and whose duty it is therefore to afford an example of fervour and attentive demeanour.

We regret to see that it is publicly stated elsewhere that this building is creditable alike to the taste of the architect, and the munificence of those who contributed the funds. These general commendations can answer no beneficial purpose whatever. The great object of architectural criticism should be the advancement of architecture, and therefore eulogiums of bad architecture (except in newspapers, where their value is pretty well understood) can never be innocuous. We have already praised the external design of the new church, but the interior displays the grossest faults. It has however one good feature which we must not omit to notice. Considering the shallowness of the sacrarium, the absence of a chancel-arch is a matter of commendation. In some modern churches with mere recesses for the communion table, the nave terminates with an enormous chancel-arch, which would be in proportion were there a spacious chancel beyond it, but from the absence of that member appears disproportionate and entirely out of place. These cases are instances of the unthinking retention of forms after the use of them has ceased. It also should be stated that the building has not a show-side—it is a church and not a *church-front*. The architect has avoided the vulgar ostentation of making the most conspicuous side of the edifice the most showy: the eastern side of the church is as much ornamented as the western, although the former cannot be viewed from the public road, and is therefore comparatively inconspicuous.

STEAM NAVIGATION.

We are indebted for the annexed Table showing the proportion of British and American built Steam Ships, to the American *Franklin Journal*, it is taken from a Report of Mr. W. C. Redfield, of New York, U. S., to the President of the Board of Navy Commissioners, dated Dec. 31, 1841.

Of the steam vessels comprised in the table, class A is intended to represent the largest class of war steamers which has yet been constructed; together with the most approved and successful class of ocean steamers now employed in transatlantic navigation; but which, in case of war, will also be employed as steam frigates. Of the former, I have selected the Gorgon, steam frigate, belonging to the British navy, the Kamschatka, lately built in this city for the Russian navy, and probably superior to any war steamer in the navies of Europe; together with the Missouri, from our own navy, superior in size to either of the above named vessels. From the mercantile class of steam ships I have selected the Great Western, and also one of the four Halifax or Cunard steamers, each of these being perhaps superior in relative power of engine, and probably in speed, to the war steamers already mentioned. It is known the four Halifax steamers are alike in all respects.

The medium sized war steamers, or class B, are represented in the table only by the United States steamers Fulton, and the two war steamers lately constructed here on the British plan, for the authorities of Cuba. I do not attach much importance to the results shown in this class.

Class C consists of three American steamers which are employed on coasting routes, viz.—the Narragansett, Neptune and New York; together with the South America, one of the steamers employed on the river Hudson. It is to the qualities of this class of steam vessels that I shall more particularly invite the attention of the Board,—believing as I do, that it promises to be more efficient and useful for naval service and coast defence than any other class.

Class D in the table consists of the steamer *Balloon*, a very light vessel, built solely for the navigation of the upper part of the Hudson, but which has been well proved in her sea-going qualities in rough weather, and has been also employed on Narragansett bay, and on James river; together with the steamer *Gladiator*, which was first employed on the coast routes eastward of this city, but now runs regular trips on the southern coast, between Charleston and Wilmington. This class, I shall attempt to show, is also capable of rendering most important services.

It would have been easy to have added other examples of this and the foregoing classes had it consisted with the size of the table, or been necessary to the immediate objects which were had in view in its compilation.

The English methods of computing the tonnage of steam vessels, not being suited to show the full size or capacity of the vessel, and disagreeing also with American rules of computation, I propose to adopt the following as a rule for obtaining the approximate tonnage, viz:—"Multiply the length between the perpendiculars (reckoned from the rabbets of the stem and stern post at the level of the deck) by the full breadth of the hull at midships, and the product by the central depth from the top of the deck beam to the top of the floor timbers, or of the ceiling thereon: divide this product by 100, by separating the two right-hand figures, and the quotient may represent the conventional, or approximate tonnage."

As the estimated working power of marine engines will doubtless continue to be expressed in *horse power*, and as the power actually obtained in practice, even with like engines, must necessarily be variable, it seems desirable to obtain, also, a ready rule for this estimate and expression, founded on the capacity of the cylinder, or of that portion of it through which the piston moves, at each stroke. I have, therefore, in the construction of the table, adopted a rule founded on this principle, "and have estimated fourteen hundred cubic inches of the capacity aforesaid, as being equal, approximately to the power of one horse." This rule affords results which perhaps correspond more nearly with the working power of English marine engines, than with those which are found in the best American steam vessels.

For my estimate of the actual buoyancy of the several vessels in the table, as compared with their entire weight in line 17, I have taken the immersion of the midship cross section, both at the greatest load and at light load, as being the measure of weight; and the floating area of the same section, from the water line to the top of the beam ends, as being the measure of surplus buoyancy. This method of computation is probably sufficient for the purposes of comparison; although the entire weight or displacement of the vessel as compared with the whole floating capacity between the entire water line and the top of the central beam ends, would show the surplus buoyancy more accurately, and would increase somewhat the comparative buoyancy shown in line No. 17 of the table. The want of room has caused the omission of some other comparisons which might be interesting and useful.

On examining the table it will be seen that a strong contrast is presented i the proportions and other qualities of the steam vessels of the classes A and B, as compared with those of the truly American classes C and D. This contrast is mainly founded on the more bulky proportions and greater weight of the two first named classes.

One of the most important elements of proportion in a steam vessel is the ratio of its length to its breadth; as will appear from considerations to which I have already alluded. In the class A, of frigate build, the proportion of length to breadth, line 22 of the table, is found to be as 5·65 to one: while in class C the proportion in nine to one. The proportion also, of *depth* to both length and breadth, lines 23 and 26, afford us a constrast equally remarkable: while the proportion of *breadth* to the *draft of water*, lines 27 and 28, are no less worthy of our attention.

I do not now propose to examine all the various practical results which are exhibited in the table, nor to point out the many important inferences which may be drawn from the facts here presented; but shall confine myself to a passing notice of some of the chief qualities which appear to claim our attention.

It is well known that the finer proportions and lesser weight of the steam vessels of classes C and D ensure for them a higher rate of speed than can be attained by the vessels of the other classes, even if we allow to the latter, in favourable circumstances, the full aid of sails. Nor can it be doubted that superior speed in ships or war steamers must constitute a chief element of success in naval warfare.

Table of Dimensions and Qualities of British and American Steam Vessels.

ON RUSTICATION.

By Candidus.

Taking at his word the writer who has just decried Rustication as being no better than the counterfeit of deformity; and believing, or at least pretending to believe, him sincere when he declares his willingness "to be set right," I purpose to do so—at any rate, to make it apparent to others that he has been setting them wrong,—to expose the futility and one-sidedness of his objections, and to convict him either of great intolerance in some matters, or of great inconsistency in tolerating in others what may have similar objections may be enforced against with equal plausibility. That Rustication is most decidedly expressive of stonework construction, and that it renders the articulation of masonry more *prononcé*, is not to be denied. Buildings are not supposed to be *extructed* or carved out of solid masses, they being known to consist of separate stones put together in courses; wherefore there can be no impropriety—nothing irrational in permitting such compaction and bonding to declare itself* to the eye, and become a mode of decoration for the general surface of the walls, which, accordingly as it is treated, may be expressive chiefly of rude strength and energy, or of finished elegance and elaborate symmetry. While it is so uniform that it does not at all cut up the surface and distract the eye—therefore, is not destructive of simplicity—it gives the surface richness, crispness, and colour, and forms a ground that greatly relieves pilasters and other architectural members, causing them to appear more distinct. So far from deserving to be stigmatized as a deformity or studied counterfeit of it, Rustication appears to me to be perfectly legitimate and æsthetic—at least in itself, for like everything else, it may be made to minister to bad taste as well as to good.

One formidable argument levelled against Rustication, and intended to operate as a complete demolisher, is that it was not practised by the Greeks; at least, not at the best period of their Doric style. Yet what then?—are we at once to condemn, without further inquiry, everything that does not accord with Greek practice? Is it pretended to be affirmed that the Greeks, who contented themselves with just one or two ideas in their temple architecture, so completely exhausted all the modes of beauty, and all the resources of design available for any similar style, as to leave us no other alternative than either doing precisely as they did, or plunging into deformity? Because severe simplicity was the character of the Parthenon, is it to be that of every other structure? Are critics to be allowed to make use of the Parthenon for ever as a bed of Procustes, by which they take measure of every building, lopping off from the unlucky one which has fallen into their clutches, whatever of it exceeds that infallible standard of excellence? The Parthenon was, unquestionably, most exquisite both as to material and execution, as it was constructed of large blocks of white Pentelic marble, so admirably wrought that the jointings of the masonry were imperceptible. But to that kind of beauty our buildings may not aspire—we have neither the marble nor the climate of Greece. Our best ashlar stone-work will not retain perfect uniformity of tint and surface, and even were it to do, and could it be so wrought that the masonry joints would not at all be seen, the effect, it may be presumed, would be no other than that of good stucco,—of course more durable, but no better in appearance than the other, so long as the stucco remains in good condition. It is, therefore, an advantage that we are enabled by means of Rustication to turn the masonry jointings to account, and to produce a different species of regularity and beauty of surface.

If we are to abide by Grecian architecture alone, and to reject all that has been added to or engrafted upon it, only as so many corruptions of it, we ought not only to protest against Roman and Italian architecture, but ought to abandon the study of them, lest we should catch infection from them. The Florentine style more especially must be held in aversion by those who perceive neither grandeur, vigour, nor any other merit in Rustication, but only unqualified deformity, and what the writer whom I am trying "to set right" is pleased to brand by the intended-to-be-ignominious terms of "tatooed masonry" and mere "surface decoration." He will have it that "as soon as chamfered masonry is introduced, all simplicity is lost at once, each stone assuming a separate individuality;" yet, as it appears to me, he might just as well maintain that a striped dress is inconsistent with perfect simplicity of attire; or—to keep to architecture—that a striped—in other words, a fluted—column is contrary to simplicity and is a barbarism, a shaft so decorated being in fact neither more nor less than "tatooed," while each of the fillets "assumes a separate individuality;" and the beautiful rotundity of the shaft itself being greatly impaired by such unlucky "surface decoration." Even the Greeks themselves then, it would seem, were not altogether infallible; and besides being at variance with what appear to be some persons' notions of true simplicity, what meaning is there in the fluting of a column?—what does it express?—most assuredly nothing constructional, whereas Rustication does. It has been supposed by some that the first idea of fluting was derived from fissures in the shafts of wooden columns, or from channels worn by the rain on the surface of stone ones,—an hypothesis, however, that must henceforth be rejected with scorn, because it would make out the Greeks to have been guilty of such very bad taste as to condescend to counterfeit defects and deformities, which would have been an inexcusable enormity, notwithstanding that so counterfeited what were originally defects became beauties. There were very strong æsthetic reasons—too generally known to require to be stated here—which induced the Greeks to adopt the practice of fluting, if such term be not "too dignified" for the scoring produced by "mere streaks," and for the absurdity of covering the shafts of columns "*all over* with mouldings."

May not the deep channels employed for the flutings of Ionic and Corinthian columns be reproachfully described by the terms "gashes" and "incisions," with just as much fairness as the channelled joints of rusticated masonry? Difficult it surely would not be for any one so disposed to get up—upon paper—a pretty strong case against the practice of fluting columns as an unmeaning one at the best, as one at variance with simplicity, and partaking more of disfigurement than of embellishment.

It is contended by the writer who has laboured to prove—and who, no doubt, fancies that he has clearly proved, both the irrationality and bad taste manifested by Rustication—that when employed together with columns, the horizontal channels appear to cut athwart the shafts of the latter and "destroy that idea of verticality which is their essential attribute;" of which injurious effect, he quotes the peristyle of La Madeleine as an instance. Now, had he chosen to say that the columns appear to cut athwart the horizontal lines of the rusticated wall behind them, he might have done so in welcome, and have made out of that circumstance as much as he could for argument against Rustication; but as he did not do so, it is for him now to make out how the columns appear to be cut through by lines which they themselves cut by interrupting and intercepting. It is, therefore, rather the idea of *horizontality* as expressed by the courses of masonry is destroyed, than that of *verticality*, which latter is rendered all the more evident by the direct contrast between horizontal and vertical lines so produced. But of the value of contrast the critic who has detected such equally unlucky and curious appearance in La Madeleine seems to have no idea. Fortunate, therefore, is it for the credit of the Grecian-Doric style itself that it is protected by the ægis of classical precedent and authority, else were it ever to suit his immediate purpose to do so, the same writer would probably not scruple to censure as an absurdity the intermixture of triglyphs and sculpture in the Doric frieze. With far greater plausibility of argument than he has now used, he might urge that if sculpture is to be introduced, the triglyphs ought to be dismissed; or if the latter must be retained, the metopes ought to be left plain, since sculpture and triglyphs together mutually destroy each other's effect, and produce a most unsatisfactory jumble the very reverse of simplicity. Instead of being kept continuous, the sculpture, it might be argued, is cut up into bits and fragments; each piece of it assumes a separate individuality, and really appears to be "set in a frame;" besides which, the sculpture of course seems to cut the triglyphs themselves athwart, precisely in the *same manner* as the rustic joints on a wall *behind* columns cut athwart the columns in front. After being so exercised, criticism might descend—might stoop down to examine the steps of Greek Doric temples, and attack with ridicule the deep moulded channel cut below in the front of each of them, as being a marked defect, and causing the steps to appear undermined and weakened. To be sure, those grooves contribute to æsthetic effect; and if that be sufficient excuse for what, if now done for the first time, would be reprobated as a caprice, excuse may be extended to other cases.

Having pointed out circumstances in pure Greek architecture, upon which the same sort of captious hypercriticism might be brought to bear which protests so peevishly against Rustication, we follow the writer's remarks, and next find him just after observing that the sunk-channels in Rusticated work cannot be received as "mouldings"—and who has ever called them such?—talking of the absurdity of a building "all over mouldings;" so that in one and the same breadth, he denies and admits them to be equivalent to mouldings. As to confusion being produced by so many lines of that kind on a building—that may be left to contradict itself—is,

* The reader will excuse the singular or can substitute the plural number for it.

in fact, strongly contradicted by the exterior of Newgate, which is characterized by breadth of surface, but which, had it not been Rusticated, would have been comparatively an insipid blank; although admirably combined in its general composition, in which respect it fulfils a condition which the writer in question has made a very stringent one, although it is frequently quite impracticable. "It may be safely asserted," he says, that no buildings, whatever may be the style adopted, can be architecturally effective unless some portions of the building throw shadows on the remainder." No doubt, bold relief and chiaroscuro contrasts are highly valuable and impart unwonted spirit and energy to a composition; and the same distribution of projecting and receding parts which produces shadow, produces also great variety of perspective effect. Yet, except in some few cases, how is it possible to plan town buildings so as to obtain the requisite breaks for the purpose in the general line of frontage? Of what can street architecture chiefly consist if not of what so greatly excites the writer's positive indignation, viz., "show fronts" towards the street, and "surface decoration" upon them,—terms which are quite favourite and pet ones with him, and invariably intended to be eminently reproachful? If, without regard to its merits in what it does show, we are to be dissatisfied with every building that does not stand quite insulated, and so as to show itself on every side,—if that is to be made a *sine qua non*, we must be prepared for being very much out of humour for a very long while to come. There is no help for it; so let us console ourselves by fairly damning modern architecture altogether, as our philosophical writer appears disposed to do himself, and, if he can, to prevail on others to do so likewise.

We cannot, however, afford to damn it just yet, because we have not yet quite done with Rustication.—Rough rubble-work, we are told—not that there was much occasion for the information,—would be unfit for the cella of a Greek temple, because "the coarseness of the workmanship would be quite out of character with the rest;" and by this it is intended to be insinuated that every mode of Rustication must be equally unsuitable for the same style. Is there then, I ask, no distinction of character between rubble-work and rusticated masonry?—none between the coarse workmanship and rough surface of the one, and the uniform regularity and elaborate workmanship of the other? This difference—which striking as it seems, the writer does not perceive, or else wilfully shuts his eyes to it,—goes very far towards answering what he says when he calls upon those who would defend Rustication, to point out wherefore, if unexceptionable in itself, such mode of masonry should not be equally proper for buildings in the Pointed as in the Classic style. He affects very innocently to wonder what can possibly be "the characteristic differences between the two styles," that they require, at least admit of, different modes of masonry for them, just after he had himself said that rubble-work would be incongruous in a Grecian edifice. If Rustication is to be held illegitimate, and to be renounced because it does not become all styles alike, the irregular masonry of the stonework in Gothic buildings, together with brickwork, flintwork and rubble, may be all set down as vicious and absurd, unless it can be shown that they are just as appropriate for the Classic as in the Pointed and Old English styles. As well might we be told we ought to be "prepared to adapt" flutings to columns in the Pointed style as well as in the Classic, or else abandon such decoration altogether.

The difference of character between the two styles, or rather the two distinct architectural *races*, is so great that hardly any one except the writer whose opinions and dicta I am controverting, would propose to reject Rustication because though it accords with the idiom and practice of the one style, it is contrary to the practice, and therefore to the idiom of the other. Had rubble-work been used in classic buildings, it would have belonged to the classic idiom of the art; and in like manner had that species of masonry which is distinguished by the term Rustication been practised by the mediæval architects, it would have been incorporated with the rest of their system of design, and would have become idiomatic and characteristic. Separate styles have, like separate languages, their respective idioms and peculiarities; but though peculiarities widely differing from each other, it does not follow that they are therefore contrary to those universal and catholic principles which apply to all styles of the art alike. In architecture a very great deal is purely conventional, and might be applied indifferently were it not that custom has stamped such or such particular mode as belonging to a particular style, as being a part of its *costume*, consequently proper to that, though in any other it might show as a decided impropriety. Possibly, therefore, it will still be pertinaciously maintained, that Rustication is foreign to pure Grecian architecture—a departure from its costume: true; but it is Roman, and so far legitimately antique and classic, quite as much as the Roman, or what we call the Corinthian, order itself. And if the *Romanism* which so decidedly pervades La Madeleine in all other respects be not objected to, wherefore should its Romanism in regard to Rustication and the "surface decoration" of its walls be condemned as nothing less than a barbarism at variance with all classical precedent? If we ought henceforth to abide strictly by pure Greek architecture, just as it was practised by the Greeks themselves in such temples as the Parthenon, without presuming to adopt into it innovations of any kind—not even those which have become to ourselves rather *archaisms* than innovations, let us be told so explicitly; but let those who would enforce such doctrine, keep to their own bond. Let them reject and discard all and every thing that is at variance with Grecian practice and costume—that is, the costume of Greek temples, almost the only class of Greek buildings which we are sufficiently acquainted with to be able to judge of them correctly as a class,—and then perhaps they will discover to what exceedingly limited resources they will have restricted architecture; yet whether even then all of them would actually confess as much. may be questioned, for some of them might feel far more exultation in having gained their own point, than any sort of concern for the consequences to architecture itself. And this seems to be the case with some who not having any real affection for the art, seem to regard it only as a very good subject for them to discourse and debate about, more or less fluently, caring for little else than displaying their own expertness in logomachy. One characteristic of such critics and criticism, is that bigotted intolerance which peremptorily decides every thing to be wrong which differs from their own exclusive standard of what is excellent and right;—nor is it at all difficult to make it appear to those who are content to look merely at one side of a question, and take up with a decisive and seemingly firmly settled opinion without further trouble to themselves,—that whatever deviates from such standard must of course be wrong.

My opponent—at least, the writer to whom I have here presented myself as an opponent, is certainly most intolerant of Rustication, for he insists that it is absolutely intolerable—a gross abuse and absurdity that ought to be no longer tolerated by us at all, nor any longer be recognized as a mode of decoration to which the architect can have recourse on suitable occasions. How greatly I differ from him is sufficiently attested by this vindication of Rusticated masonry,—which, indeed, I could wish to see more frequently and more effectively made use of among us than it now is. I am very far, however, from intending to recommend it as an infallible *nostrum*, or as what ought to be applied in all cases. Rustication may be well or ill-applied; may be either very good of its kind, or very bad; yet the bad is so far from justly discrediting the good, that it rather adds to the merit of the latter. Were not such the case, some of our modern specimens of it would long ere this have brought "*pure* Classic architecture" into utter discredit among us, they being far more deserving of "detestation" than that "*debased* Classic architecture" which had openly revolted from Classic precedent, had thrown off allegiance from it, and had rendered itself independent of it.

FENESTRATION AND WINDOWS.

Audi Alteram Partem.

Although another writer has in the interim taken up the subject of the Decoration of Windows, and given his opinions upon it, especially as regards the employing columns for such purpose, that is so very far from frustrating the intention hinted at by us in a note (page 130), in the article on the Fitzwilliam Museum, by forestalling what we meant to say, as rather to stimulate us to take up our pen without further delay. Having thus apprized the readers of this Journal that the remarks, in the May number, on the building just mentioned, proceeded from ourselves, we may be permitted to confess our surprise at finding, the following month, a second paper on the Fitzwilliam Museum, denying it all those particular merits as a piece of architecture, which had been claimed for it by ourselves. Had that second article distinctly announced itself to be the production of a second writer, and intended to reply to and correct the criticism that had just before appeared, the sort of mystification that must now have been occasioned by it would have been avoided. Strangely enough, it did not even take the slightest notice of what had been previously said,—no more than if nothing had been said at all, at any rate nothing more than a mere account of the building, without any criticism upon it. Admiration was still professed;

only it was made out after all that every thing in it which had been especially admired just before, was naught, and that the design would have been infinitely better, were it almost the reverse of what it is; wherefore we may consider is fortunate for us that what we had said was not formally contradicted and cut up. Tardy as it is, this explanation is due both to ourselves and to the Journal,*—for the latter not undesirable, since it exculpates it from what must have looked like inconsistency.

We are very far from wishing—to say the truth, have more conceit of ourselves than to desire that opinions which militate against our own should be suppressed; and we only claim in return that ours be not suppressed, because they happen not to accord with those of other persons. Differ we most assuredly do very strongly, both from the author of the article "On the Employment of Columns and Pediments as Window Mouldings,"—(*mouldings* seems a term very oddly applied to columns),—and from Dr. Fulton,—who has mistaken a ludicrously droll and whimsical comparison for argument *ad absurdum* against window pediments, and has flourished it about accordingly for the purpose of intimidating those who allow themselves to be scared by words and nicknames. But before we begin to speak of windows themselves, it may be as well to say something on "Fenestration" generally,—its influence on design and composition, and the characteristic physiognomy occasioned by it. Rather strange to say, it is one of those subjects which so far from being taken up are scarcely even approximated to in architectural "treatises," and didactic writings of that kind; and when it has been touched upon elsewhere, it has been only *aslant*, and to fly off from it again in a tangent. While of speaking of columns there has been no end, hardly a word has been uttered as to the essentials and conditions of *Columniation*; and in like manner, instruction with regard to windows is confined to a few ordinary matter-of-fact rules—without anything being said of *Fenestration* as a system. Nevertheless that and Columniation are two such decidedly distinct systems, that buildings now classed together as belonging to one general style might properly enough be further distinguished accordingly as they belong to, or most partake of the one or the other of the two different modes. Neither are the two systems merely different forms, but hostile and repugnant to, and almost incompatible with each other. They conflict so obstinately—what is required by the one is so strongly opposed to what is demanded by the other, that scarcely any treatment, however dexterous, can effectually reconcile them, or effect more than a tolerable compromise.

That windows are totally at variance with the effect attending genuine antique columniation, whose columns are backed by a continuous surface of wall, unbroken by openings for admission of light, is indisputable. If not destructive of beauty, they are destructive of the effect—associated with ideas of classical taste—which results from their absence. Wherefore it generally happens that the more ambitiously and rigorously classical purity of style is aimed at in all other respects, columniation included, the more offensive and incongruous does fenestration show itself. It avails not to say that it is matter of sheer necessity,—that windows there must be, unless the building—however else it may be divided within—has no division of floors, in which case it may be best of all lighted through ceilings and roof. If such unavoidable necessity sufficiently excuses the fenestration, it at the same time condemns the practice of mixing up that and columniation for the nonce, when it is, or to be, known beforehand how greatly the effect of the latter must be impaired by the former. That very necessity which is pleaded by way of apology, ought to be sufficient argument against a style which, however scrupulously copied in regard to matters of mere detail and mechanical execution, must be violated altogether in what constitutes its genuine and peculiar physiognomy. The necessity for numerous apertures in the walls for windows proves that a *pure* Greek style is not the one for us at the present day, it being only in very rare cases, and under peculiar circumstances that it can be adhered to with tolerable fidelity and consistency. Quite idle is it to point out to us the Parthenon as if it were a model expressly fitted for modern purposes. At any rate it ought at the same time to be pointed out also that the *sine qua non* condition of being faithful to its Doric *idiom*, as well as to individual forms of detail, should be observed and attended to.

In such modern structures as the Walhalla near Regensburg, and the Madeleine at Paris, which being lighted within entirely from above, could therefore be made peristylar externally, without any intermixture of windows, the simple dignity of columniation and the repose which ought to accompany it, can easily enough be kept up. So also is it when columniation in the form of portico or colonnade is employed for embellishing that side of a building, where windows can be dispensed with, as is the case with the façade of the Berlin Museum, the Fitzwilliam Museum, and the East or principal front of St. George's Hall, Liverpool.

Fenestration and Columniation are two modes of architectural composition, requiring such very different treatment, and productive of such opposite character, that they mutually neutralize the good effect which each might be made to ensure separately. What would be well proportioned and dignified as an *astylar* front, becomes almost inevitably more or less discordant, and out of character as the background to any colonnade whose pillars are erected in advance of it. Either the colonnade itself has the look of being an afterthought, an addition—whether made for convenience sake, or for mere ostentation,—to what was or ought to have been complete without it. On the other hand, the main structure itself looks as if it had been erected behind a previously existing range of columns, originally belonging to an edifice very differently constituted. While the columns seem as much to encumber as to adorn the front behind them, certainly not to belong to it by evidently growing out of the general organization, the windows—be they ever so unexceptionable in themselves, become blemishes, inasmuch as they cut up the general composition, nay, the graceful simplicity of a colonnade, and contradict the would-be-classical taste which is affected by merely sticking up a few classical columns. Many preposterous instances of the kind are to be met with in the buildings erected some few years ago when we were in the heyday of our *Greekomania*. Of such *examples* we might mention scores, but will content ourselves with one—nor is it by any means the worst, viz., the Law Institution in Chancery Lane, which exhibits the front of a Greek Ionic tetrastyle in antis temple, stuck up before one that is totally different in costume, filled in with windows—it being houselike, and therefore positively undignified, intimately associated as it is with what reproaches it for being homely and dowdy. Well is it, perhaps, therefore that columns cannot kick, or they would frequently be tempted to kick down what stands just behind them.

In fact so far from being at all fit to become yoke-mates, Fenestration and Columniation pull in such contrary directions as to leave only a choice of inconveniences. One of them may be good, or the other may be good, but hardly can both be rendered so or if it be attempted, the result is likely to be that both the one and the other, will prove on a par by being equally unsatisfactory. While good Fenestration requires wide spacing, good Columniation requires just the reverse, otherwise it is attended with a look of meagreness and meanness—the very same defects that are produced by close spacing or *pycnostyle* disposition of the piers between the windows in Fenestration. If there are windows in a wall behind a range of columns, corresponding with the intercolumns, harmony requires that those openings should partake of the proportions of the intercolumns themselves, that is, be very narrow and lofty, and even then such openings will appear crowded together and be destructive of all breadth of surface and repose behind the columns, they being confined to the alternate intercolumns, as is the case in the portico of the Chambre des Deputés at Paris, which consists of twelve columns in front, consequently eleven intercolumns, but has only five apertures (doors) in its background. Therefore in that example—and we are not aware of any similar one, the two different systems are admirably reconciled, and for each the particular mode of spacing which it demands, is duly observed:—a merit which, remarkable as it is, has never before been pointed out by any of those who have spoken of that façade,—not even by Woods himself.

In some cases the Gordian knot has been attempted to be cut by putting the columns in pairs, thereby obtaining great width for the intercolumns, and the breadth of two columns and a half between them. Yet although this obviates the inconvenience of thick set windows and narrow piers, it is objected to as an impropriety—by architectural puritans at least, who will have it to be a downright solecism, because not sanctioned by classical *precedent*; which is surely being over scrupulous and hypercritical, for where can they find precedent for windows at all within a Greek or Roman colonnade? If they can tolerate the one innovation, they have no right to be very much scandalized at the other.

One not unusual mode of getting over the difficulty—at least so it seems to be thought—and obtaining sufficiently narrow intercolumniation, at the

* There was a signature attached to the second article on the Fitzwilliam Museum, which would plainly have distinguished it, as coming from another writer, but it happened, most unfortunately, to be omitted by the printer.—Ed. C. E. and A. Journal.

same time avoiding disagreeable narrow proportions for the piers between the windows, is to adopt a *macrostyle* order for the colonnade, including two floors of the building behind it, and two series of windows. Consequently these latter become small openings, in height at least, as compared with the columns, and by their frequency tend still more than ever to cut up and disturb the surface behind the columns. While greatness is affected by the order, littleness—comparative littleness at least, is expressed by the fenestration, and the inner wall assumes a most unlucky resemblance to an astylar composition, in whose physiognomy Fenestration is intended to predominate, and from which Columniation is intended to be excluded; so that while the windows are a sad drawback upon the pomp and classical style affected by the order, the order itself serves chiefly to put us out of conceit with the Fenestration.

Your Pecksniffs, indeed, get over the difficulty very easily by making no difficulty of it at all. They merely make so many holes for the windows, which being left quite bare of dressings, are not to be considered as belonging or intended to belong to the *architecture* at all: the columns are the things to be looked at; the windows to be overlooked. Yet would it not be far more economic and answer the purpose just as well, to leave it to the imagination to put *in* columns, in the same manner which it is now called up to put *out* windows, by fancying them away?

All things considered, if an order must be employed in conjunction with Fenestration, the best way perhaps, is to make use of it avowedly as decoration, either with pilasters or attached columns, so that the intercolumniation can be regulated according to, or rather accommodates itself without further difficulty to the spacing which is most suitable for the windows; without occasioning that straggling look which would attend a colonnade whose pillars were at the same, or any thing near the same intervals apart. There is at least a certain degree of compactness and solidity attending such intimate combination of columnar architecture and fenestration; whereas columniation is mostly so employed as to appear something quite adscititious—a mere *hors d'œuvre*, and perhaps an inconvenient and encumbering one into the bargain.

Wilkins, who plumed himself so much upon his rigorous observance of classical proportions as to intercolumniation in the portico of the National Gallery, does not seem to have duly considered the consequences of it in regard to the interior of the portico. Had there been within only a single door of loftier proportions, recessed as at present between two columns in antis, there would have been nothing to contradict or disturb the close intercolumniation affected for it; whereas now the interior looks crowded-up even to confusion, and the end doors are of too wide and low proportions, so as to appear crammed into the spaces they occupy, although those spaces correspond to two intercolumns in front.

There is another species of combination of the two systems (columnar and fenestrated) which ought to be noticed, namely, that wherein columniation is employed only for one or more distinct portions of a façade, the rest of it being *astylar* and fenestrated. The Post Office exemplifies such combination the centre portion exhibiting columniation without windows, and the two next fenestration only; while the extreme compartments of the front display, both fenestration and columniation together; the latter however as mere embellishment, because though the columns are insulated, they do not form any sort of practicable colonnade or loggia, therefore seem still more idle and useless than such as by being attached to a wall appear in some degree to perform the office of buttresses to it. Well, what is the effect of the combination alluded to?—does it not partake rather too much of the *sandwich*, the composition being that produced by mere juxtaposition? We behold a portico of temple-like aspect clapped between what look like two distinct buildings, altogether different from it in character and style—constituting a sort of *macaronic* architecture—and by no means very satisfactory in themselves. Of the window dressings we need not speak, they being little more than architectural fig-leaves to screen positive nudity; but the fenestration itself is poor and undignified; the windows are too close together, neither is there sufficient space between the two tiers of them; whence there is nothing of that simplicity which arises from breadth and repose. Notwithstanding however the odd patching together of modern *poly-fenestration* with the windowless system of the Greeks, the Post Office was hailed at first by the Greekomania of the day, as something vastly classical; and so well satisfied with it is the architect himself, that he is now giving us a second edition of it in the façade of the British Museum.—Pity, he is so slow about it, for Greekomania will be all evaporated before that *chef-d'œuvre* of pure classical taste, "neat as imported," be completed.

In the two buildings erected as detached wings to the Museum façade, we have fenestration between a single order of pilasters, carried the height of three floors, which mode certainly preserves due width of spacing as regards the pilasters themselves, but it causes the windows to appear meagre and insignificant, and too much cramped up.

One Greek example of a design for windows there is, namely that afforded by the Triple Temple at Athens, which we could wish had never been made known to us, because then it is most likely that when they wanted windows for buildings in the Grecian Ionic style, architects would have derived ideas for the purpose, from the exquisitely beautiful doorway in the tetrastyle portico of the edifice just mentioned, whose highly finished and delicate ornateness correspond perfectly with that of the order; whereas the window does not partake of, or agree with the order at all; there being no more than a very plain border round the aperture, defined by an external moulding. Yet this unlucky precedent has been taken by us, in our Greekomania, as an authority to be implicitly adhered to on all occasions—no matter how different those occasions may be in themselves. Be the order Doric or Ionic, or if the latter, the plainest or the richest in character, we find that *universal* window perpetrated everywhere alike, as if no modern architect could muster up imagination enough to design a dressing for a window aperture just as easily as for that of a door or a fire-place. Thus instead of being made characteristic features in our modern Greek style, windows are suffered to become quite negative ones,—monotonous, feeble, and inexpressive.

In the Gothic or Pointed style, on the contrary, fenestration is so characteristic, as to be almost indispensable on that account alone; and is besides differently constituted, and accordingly subjected to other conditions,—most certainly is emancipated from most of those restraints and regulations which it has to submit to in Greco-Roman, and Italian architecture. But leaving our readers now to cogitate upon what thus far we have said, we reserve our remarks upon Gothic fenestration till we return to the subject next month,—

"che 'l Canto presente
Non è bastante a dirla degnamente."

—

PRACTICAL PROBLEMS IMPORTANT IN PLANE TRIGONOMETRICAL SURVEYING.

By Oliver Byrne, Professor of Mathematics.

Sir,—In the October Journal of last year, you published a portion of an article of mine, entitled "Problems on Plane Trigonometrical Surveying," as soon as convenient, I hope you will insert the remainder. That spirit of fairness, which has ever been an ascendant property of your valuable publication, will secure also, I feel confident, a corner for the succeeding remarks. The subjects upon which I have written, if they have no other recommendation, have at least the quality of being original; but, in the case of these problems, originality has been questioned by Mr. Turnbull, which, I believe, could not have been done, had the whole of my paper appeared. But, for the following editorial remark, appended to Mr. Turnbull's communication, I would have attended more promptly to the matter: —"We regret to say, that Mr. Turnbull's present letter appears to have been written under most painful circumstances; they are of too private a nature to be made public, but we can assure the reader that they entirely preclude any further strictures on Mr. Turnbull's past productions." Mr. Turnbull says, speaking of me, "The principle from which the Professor deduces the solution was first employed by me for that purpose in 1829, when all the cases of the problem were resolved exactly in the same manner as in your Journal." Why did he not state his principle and compare it with mine? He further adds, "The problems, with their solutions appeared in one of the earliest numbers of Colburn's United Service Journal, but, being without signature, the author's name was unknown to the public." Under the head "Stasimetric Surveying," Colburn's United Service Journal, second part, page 75, 1829, the first four or five problems given by me in your Journal, were solved from the following principle; "The angles of the figure can be ascertained in terms of those observed without involving any of the containing or subtending parts, and hence the distance between two remote objects become known in terms of the observed angles and the measured base. If to all the angles of any plane polygon figure, right lines be drawn from a point within it the product of the sines of the alternate angles will be equal to each other." From what Mr. Turnbull calls an obscure and neglected proposition in Emerson's Trigonometry, *the above principle was very readily drawn.* It will be found that the principles on which Emerson, Gregory, and the writer in Colburn's Journal, proceeded, are but particular cases of the very extensive one, upon which I have based my solutions; this will become very evident when the whole of my paper is published. You will find that I worded my general principle thus:—"If any number of lines A, B, C, D, &c., be drawn, the ratio propounded of the ratios of A : B, B : C, C : D, &c., continued in order to A, is a ratio of equality: or which is the same thing, when each becomes an antecedent and a consequent, taken in the above mentioned order, the continued product of the antecedents is equal to the continued product of the consequents." My application of this proposition I consider entirely original; I have used it in the solution of numerous problems, a few of which I have submitted to you for publication.

When the whole of them appear, I will revert to the subject again.

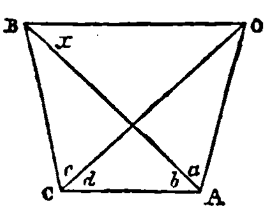
I am, Sir, your's sincerely,

OLIVER BYRNE.

Continued from Part XCVII., Oct., 1845.

(5.) In order to determine the horizontal distance between two remote objects, O, B, a base line A C, of 500 chains was measured, then at each extremity of this base the following angular distances were taken:—At A, OAB $= 75° 50' = a$, BAC $= 45° 05' = b$; at C, OCB $= 75° 30' = c$, and OCA $= 40° 20' = d$. Required the distance between the two objects? From having the angular distance a, b, c, d, all the other angles of the figure may be found, without knowing the lengths of any of the lines; therefore, from having the length of any of the lines, under such circumstances the remaining linear distances can easily be determined. Let angle OBA $= x$, ABC $= 180° - b - c - d = e$. Then OBC $= e + x$. $\therefore$ OA : OB $=$ sin. x : sin. a; OB : OC $=$ sin. c : sin. $(e+x)$; and OC : OA $=$ sin. $(a+b)$: sin. d. Hence, sin. $(a+b)$ sin. c sin. $x =$ sin. a sin. d sin. $(e+x)$; sin. $(a+b)$ sin. $c =$ sin. a sin. d $\frac{\sin.(e+x)}{\sin. x}$. But, $\frac{\sin.(e+x)}{\sin. x} = \frac{\sin. e \cos. x + \cos. e \sin. x}{\sin. x} = \sin. e \cot. x + \cos. e$. $\therefore$ sin. $(a+b)$ sin. $c =$ sin. a sin. d (sin. e cot. x + cos. e); sin. $(a+b)$ sin. c − sin. a sin. d cos. e = sin. a sin. d sin. e cot. x. $\therefore$ cot. $x = \frac{\sin.(a+b)\sin. c}{\sin. a \sin. d \sin. e} - \cot. e$; or, cot. x = cosec. a sin. $(a+b)$ sin. c cosec. d cosec. e − cot. e. RULE.—*Add together, the log. cosec. of a, the log. sin. of the sum of a and b, the log. sin. of c, the log. cosec. of d, and the log. cosec. of e; the natural number corresponding to this sum, rejecting 50 in the index, made less by the natural co-tangent of e, will give the natural co-tangent of x.*

Fig. 1.



a	$= 75°\ 50'$,	log. cosec.	$=$	10·0134127
$(a+b)$	$= 120\ 55$,	log. sin.	$=$	9·9334445
c	$= 75\ 30$,	log. sin.	$=$	9·9859416
d	$= 40\ 20$,	log. cosec.	$=$	10·1889391
e	$= 19\ 05$,	log. cosec.	$=$	10·4855379
				0·6072758
The natural number corresponding			$=$	4·0483290
The natural cot. of 19° 05′ (e)			$=$	2·8905467
Natural cot. of x			$=$	1·1577823

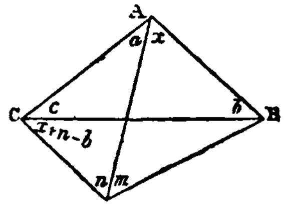
$\therefore x = 40° 49' 04'' =$ ABO; and $e + x = 59° 54' 04'' =$ OBC. Hence, OC $= 1334·49$, and OB $= 1498·34$ chains respectively, which may be found by Plane Trigonometry.

Suppose the angles a, b, c, d, remain as before, but it is found impossible to measure AC with any degree of accuracy, OB being on a plane it is measured and found to be 18609 links. Required the angle x, and the distance AC in feet? In this instance, $x = 40° 49' 04''$; and AC $=$ 4112·227 feet. This could not be solved by the rules of plane trigonometry.

(6.) There are four stations on the same plane, the linear distance between every two of any three of them being given, as well as the angular distance of the fourth from each of the other three; to find the remaining parts.

Let A, B, and C, be the three stations whose distances are known; hence the three angles a, b, and c, of the triangle ABC may be found. [See Problem III, in the Journal for October, 1845.] Having these three angles, and also m, and n, taken at the fourth station, we can find all the angles of the figure without any reference to the lengths of the lines.

Fig. 2.



Let x be the angle made by the diagonal AD and the side AB; then will the angle BCD $= b - n + x$. Hence, AB : BC $=$ sin. c : sin. a; BC : BD $=$ sin. $(m+n)$: sin. $(b-n) + x$; and BD : AB $=$ sin. x : sin. m.

$\therefore$ sin. c sin. $(m+n)$ sin. $x =$ sin. a sin. $\{(b-n)+x\}$ sin. m.

$\frac{\sin. c \sin.(m+n)}{\sin. a \sin. m} = \frac{\sin. \{(b-n)+x\}}{\sin. x} = \sin.(b-n)\cot. x + \cos.(b-n)$. $\therefore \frac{\sin. c \sin.(m+n)}{\sin. a \sin. m} - \cos.(b-n) = \sin.(b-n)\cot. x$. $\therefore$

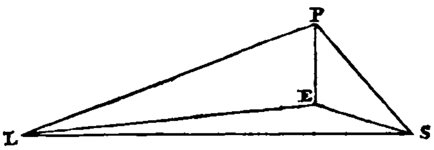
$\frac{\sin. c \sin.(m+n)}{\sin. a \sin. m \sin.(b-n)} - \cot.(b-n) = \cot. x$. $\therefore$ cot x = cosec. a sin. c cosec. m sin. $(m+n)$ cosec. $(b-n)$—cot. $(b-n)$. If $b = n$, the problem will be indeterminate, for cosec. $(b-n)$, or cosec. o, is infinite. It also shows that a circle can be described through the four points A, B, C, D; so that the point D, when such is the case, will have an infinite number of positions all satisfying the question. When A, B, C, are in the same right line, this problem is readily solved by problem 2. Or when any two of the stations A, B, C, and the station D, are in a straight line, the problem falls under the resolution of plane triangles. It may also be remarked, that the angles b and c, are negative when the point A is below the line BC. RULE.—*Add together the log. cosec. of a, the log. sine of c, the log. cosec. of m, the log. sine of (m+n), and the log. cosec. of (b—n); the natural number corresponding to this sum after a proper allowance is made in the index, made less by the natural cotangent of (b — n) will give the natural cotangent of x.*

This problem, of which the three following examples are particular cases, was first proposed by Richard Townley, in the *Philosophical Transactions*, where also is inserted solutions to the different cases by John Collins, No. 69, 1671. The first of these examples is given in the *Lady's Diary* for 1723, by John Richards, and answered the following year by John Topham. Dr. Hutton in his edition of the Diaries gives an additional solution, with a geometrical construction. Professor Leybourn, in his edition of the Diaries, gives a second additional solution, also with a geometrical construction; and in his appendix to the same work, he gives a general one from "Cagnoli's Trigonometry." However, none of these solutions are as simple or as practical as the one here given. Cagnoli makes cot. $x =$ cot. $(B - n) \left\{ \frac{\sin. c \sin.(m+n)}{\sin. BAC \sin. m \sin.(B-n)} - 1 \right\}$. It should be cot. $x =$ cot. $(B - n) \left\{ \frac{\sin. c \sin.(m+n)}{\sin. BAC \sin. m \cos.(B-n)} - 1 \right\}$

This must be a misprint, for it cannot be supposed that either Cagnoli or Leybourn could make such a mistake.

I. It is required to find the distance from the Edystone Lighthouse to Plymouth, Start Point, and the Lizard, respectively, from the following data:—The distance of Plymouth from the Lizard 60 miles, from Lizard to Start Point 70 miles, and from Start Point to Plymouth 20 miles; also Plymouth bears due north from the Edystone Rock, the Lizard W.S.W., and Start Point N. by E. Let E represent the position of the Edystone, L the Lizard, P Plymouth, and S Start Point. When a right line is sup-

Fig. 3.



posed to be drawn from L to S, it is evident that the point E falls within the triangle L P S, the angles of which are found by problem (3) to be as follows:—

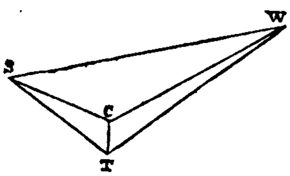
$\angle$SPL = 112° 01′ 27″ = a;
$\angle$PLS = 15 21 32 = b;
$\angle$PSL = 52 37 01 = c; we have also
$\angle$PES = 112 30 00 = m = 10 points, or W.S.W.
$\angle$PEL = 78 45 00 = n = 7 points, or N. by E., and
$\angle$LPE = x. Then by the general rule we have,

log. cosec. a = 10·0329082
log. sin. c = 9·9001454
log. cosec. m = 10·0313847
log. sin. $(m+n)$ = 9·2992357
log. cosec. $(b-n)$ = 10.0486213

Reject 50 and 49·3062953 = $\bar{1}$·3062953 = log. of 0·2024395; from which substract — ·5002568, the natural cotangent of $(b-n)$, and we have, 0·7032063 for the natural cot. of x, ∴ x = 54° 52′ 40″ = L P E. The distances L E, S E, C E, can be found by Plane Trigonometry, and are 53·11906; 17·1334; and 13·91746 miles respectively. John Topham makes them 53·04; 17·36; and 14·333 respectively.

II. Being at a town in Kent I observed three objects on the other side of the river Medway, a castle (C), a windmill (W), and a spire (S), whose distances from one another are known; from the castle, (the nearest object seen,) to the spire, (C S) is 10 furlongs; from the castle to the windmill (W C), 23 furlongs; and from the windmill to the spire (W S), 25 furlongs.

Fig. 4.



I took with a theodolite, the angular distance between the castle and the spire (C T S) and found it to be 28° 34′, and between the castle and the windmill (C T W) 57° 45′; what distance did I stand from each of these objects? From having the three sides of C S W we can find the three angles by problem 3; hence we have,

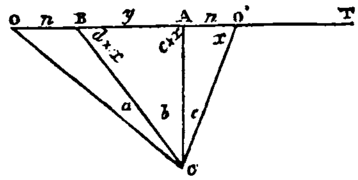
a = 89° 30′ 06
b = 23 34 38
c = 66 55 16 } Being calculated independant of each other, and making 180° affords a proof.
m = 57 45 00
n = 28 34 00

∴ $(m+n)$ = 86 19 00; and instead of $(b-n)$ take $(b+n)$ = 52 08 38 negative. Putting x = $\angle$T C W; and proceeding according to the general rule, we find the sum of the five logarithmic quantities to be 50·1382785, or 0·1382785 which correspond to the natural number 1·374923, which is negative. From — 1·3749236 take the the nat. cot. (52° 08′ 38″) = 0·7773423 and it leaves — 0·5976737:—this nat. cot. corresponds to 59° 08′ 04″; ∴ x = 120° 51′ 56″. Then (59° 08′ 04″) — (57° 45′ 00″) = 1° 23′ 04″ = $\angle$T W C. To find the remaining parts fall under the head of common-place Trigonometrical calculations. T W = 23·3439 furlongs, T C = 9·6570643, and C S = 10·57215.

III. In a garrison there are three remarkable objects, A, B, C, the distance of which from one another are known to be as follows:—B A = 213, B C = 424, and A C = 262 yards. I am desirous of knowing my position and distance when standing at a station A, with respect to the three points A, B, C; at A T observed A to be the nearest object, and the angles B S A = 13° 30′, A S C = 29° 50′. This example was originally proposed in Dr. Hutton's Conic Sections, then reproposed in the Lady's Diary for 1797, where two different solutions are given the following year; but none of the different solutions to any of the cases of this problem are as practical as following the general rule here given. A S will be found = 429·6814; C S = 524·2365; and B S = 605·7122 yards.

(7.) In running a mean line through a country, I arrived at the bank of a river, B; and having booked a station at O, I find by subtraction that O B is 25·36 chains: causing a flagstaff to be plased at O, and another at B, I crossed the river in a boat, and set up a third at A, in a right line with B and O. Proceeding along the line to O′, a distance of 25·36 chains, a fourth flagstaff is set up; then continuing the line to a convenient point T, a theodolite is set up and the point in each staff as O, B, A, O′,

Fig. 5.



which is cut by the same borizontal plane is noted. Now at C any station where the points O, B, A, O′, can be seen, I take the angles a, b, c, and find them to be 12° 05′, 28° 25′, and 17° 23′ respectively; required the breadth of the river A B? Let B A = y; the angle A O′ C = x, then will $\angle$B A C = $c+x$, and A B C = 180° — $b-c-x=d-x$; also d = 180° − $b-c$ = 134° 12′: B O C = 180° − $a-b-c-x$, putting e = 180° − $a-b-c$ = 122° 07′. In this problem we shall compare the ratios round two points O and O′.

First round O, O B : O A = $n : n+y$;
O A : O C = sin. $(a+b)$: sin. $(c+x)$;
O C : O B = sin. $(d-x)$: sin. a.
Second round O′, O′ A · · O′ B = $n : n+y$;
O′ B : O′ C = sin. $(b+c)$: sin. $(d-x)$;
O′ C : O′ A = sin. $(c+x)$: sin. c.

We obtain directly from compounding both the analogies and expunging the common factors,

$$\frac{\sin.(d-x)}{\sin.(c+x)} = \sqrt{\frac{\sin. a \sin.(b+c)}{\sin. c \sin.(b+a)}}.$$

Let the right hand member of this equation for the sake of brevity be called K. But, sin. $(d-x)$ = sin. $(180°-b-c-x)$ = sin. $(b+c+x)$. ∴ $\frac{\sin. \{b+(c+x)\}}{\sin.(c+x)}$ = K.

∴ sin. b cot. $(c+x)$ + cos. b = K.

$$\therefore \cot.(c+x) = \frac{K}{\sin. b} - \cot. b.$$

$$\therefore x = \cot.^{-1}\left\{\left(\frac{\sin. a \sin.(b+c)}{\sin. c \sin.(b+a) \sin.^2 b}\right)^{\frac{1}{2}} - \cot. b\right\} - c.$$

From this equation the rule is deduced. We need scarcely remark, that before finding any of the distances is necessary to find the unknown angle x.

Rule.—*Add into one sum the log. sin. of a, and the log. sin. of $(b+c)$; then add together the log. sin. of c, the log. sin. of $(b+a)$, and twice the log. sin. of b: subtract the latter sum from the former and divide the remainder by 2, the neutral number corresponding to the quotient made less by the nat. cot. of b, will give the nat. cot. of $(c+x)$, and consequently x becomes known.*

Log. sin. 12° 05′ (a) = 9·3208460
log. sin. 45 48 $(b+c)$ = 9·8554654

Reject 20 19·1763050
From $\bar{1}$·1763050
Take $\bar{2}$·6428665

Log. sin. 17° 23′ (c) = 9·4753271
log. sin. 40 30 $(a+b)$ = 9·8125444
2 log. sin. 28 25 (b) = 19·3549950

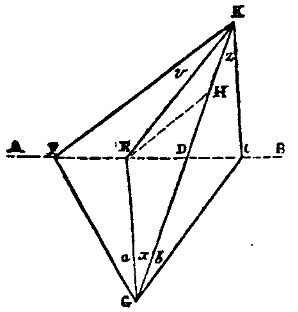
Reject 40 38·6428665
$\bar{2}$·6428665

This divided by 2)0·5334385 = 0·2667192 which correspond to the nat. number 1·8480730, this is to be made less by the nat. cot. of 28° 25′ (b) = 1·8481761, which is greater than 1.8480730 by 0·0001031; ∴ this is the negative nat. cot., and corresponds to 21″; hence, $(c+x)$ = 90° 0′ 21″; but c = 17° 23′, ∴ x = 92° 37′ 21″. The remainder of the calculations are common place. B A = 43·88967; A C = 81·009 chains. Before proposing the next problem, which is rather complicated, we wish to remark, that it is given more to illustrate the properties of the foregoing analogies than for any practical utility.

(8.) In superintending an extensive survey, I gave directions to an assistant who chained one of the base lines, A B, to set up flagstaffs equally distant from each other as he passed over a common which lay in his way; not knowing the comparative length of his proposed line, he was not confined to any particular distances. Now it so happens, that he sets up a staff at each of the four points C, D, E, F, as in the annexed sketch, and continued the measurement of the line. A second assistant who measured a tie line from G to K, before leaving G, took the angular distance between E and F at 16° 16′ 16″; this was the only angle he could take from the point G, he not being able to see C or D, though from the direction C lay, he knew the angle F G C, to be acute:—then measuring from G to K, his line exactly passes through the station D; but when I met him at H, the chain he was using was not correct. Therefore, the only particular we knew of this line was, that G D happened to be the same number of false chains as D H. Leaving this assistant to take the angle E H D, which he makes 34° 34′ 34″, I measured H K, with a correct chain and found it to be 1500 links, and at the station K, I took the angle F K C at 70° 10′ 10″; not being able to see D or E. It is required from this data to find the length of the different lines; not having any information from the first assistant as to the distance he placed the pickets, and on returning to remeasure the distances, the exact place where they stood could not be ascertained.

Now, we have given, the distance CD = DE = EF; and DG = DH; also HK = 1500 links. Likewise, ∠FGE = 16° 16′ 10″ (a); EHD = DGC = 34° 34′ 34″ (b); and FKC = 70° 10′ 10″ (c). Let ∠ DGE = x, DEG = y, CKG = z, and EKF = v. ∴ CDG = $(x+y)$, FKD = $(c-z)$, and EKG = $(c-v)$. Hence, by comparing the ratios round two points C, and E, we have

Fig. 6.



CD : CE = 1 : 2;
CE : CG = sin. $(b+x)$: sin. y;
CG : CD = sin. $(x+y)$: sin. b;
FE : FD = 1 : 2;
FD : FG = sin. $(a+x)$: sin. $(x+y)$;
FG : FE = sin. y : sin. a. By compounding these six ratios and expunging the common factors we have, sin. $(a+x)$ sin. $(b+x)$ = 4 sin. a sin. b. cos. $(b-a)$ — cos. $\{(a+b)+2x\}$ = 2 sin. $(a+x)$ sin. $(b+x)$ = 8 sin. a sin. b. Cos. $(a-b)$ — 8 sin. a sin. b = cos. $\{(a+b)+2x\}$. But, — 8 sin a sin. b = 4 cos. $(a-b)$ + 4 cos. $(a+b)$; ∴ 4 cos. $(a+b)$ 3 cos. $(a-b)$ = cos. $\{(a+b)+2x\}$. An arc whose cos. is 4 cos. $(a+b)$ = 3 cos. $(a-b)$, written thus:—Cos.$^{-1}$ 4 cos. $(a+b)$ = 3 cos. $(a-b)$; made less by $(a+b) = 2x$. ∴ $2x$ = cos.$^{-1}$ $\{4 \cos.(a+b) - 3 \cos.(a-b)\} - a - b$.

Whence the Rule.—*From four times the natural cosine of $(a+b)$, take three times the natural cosine of $(b-a)$; an arc whose natural cosine is the remainder, made less by $(a+b)$, and divided by 2, will give x.*

$(a+b)$ = 50° 50′ 50″, 4 nat. cos. = 2·5255616 } subtract.
$(b-a)$ = 18° 18′ 18″, 3 nat. cos. = 2·8481943 }

Difference = 0·3226327 negative.

The angle which corresponds to this nat. cos. in the table is 71° 10′ 41″; but as the cos. is negative, the angle may be 108° 49′ 19″, or 251° 10′ 41″; but it cannot be the latter, because the angle FGC is known to be acute.

Then from 108° 49′ 19″
take 50 50 50 = $(a+b)$

half of 57 58 29 = 28° 59′ 14″·5 = x = KGE.

In order to determine y, let us compound the ratios of the lines drawn from E, which are compared in the foregoing ratios. Hence we have sin. $(a+x)$ sin. y = 2 sin. $(x+y)$ sin. a. But, sin. a cos. x sin. y + cos. a sin. x sin. y = 2 sin. x cos. y sin. a + 2 cos. x sin. y sin. a. This divided by sin. y, gives sin. a cos. x + cos. a sin. x = 2 sin. x cot. y sin. a + 2 cos. x sin. a. ∴ sin. a cos. x + cos. a sin. x — cos. x sin. a = 2 sin. x sin. a cot y; sin. x cos. a — cos. x sin. a = 2 sin. x sin. a cot. y. ∴ $\frac{\sin.(x-a)}{2 \sin. a \sin. x}$ = cot. y. From this value of cot. y, the following method of calculating y is deduced: Rule.—*Add together the log. sine of $(x-a)$, the sub. log. of 2, the log. cosecant of x, and the log. cosecant of a; the sum will be the log. cotangent of y.* By this rule y is easily found, and x is known,—call their sum m. [Which will be found too by 79° 57 35″·5]. Then to find z, we have

FD : FC = 2 : 3;
FC : FK = sin. c sin. $(m-z)$;
and FK : FD = sin. m sin. $(c-z)$;
∴ 2 sin. c sin m = 3 sin. $(m-z)$ sin. $(c-z$;
cos. $(m-c)$ — cos. $\{(m+c)-2z\}$ = 2 sin. $(m+z)$ sin. $(c-z)$.
= $\frac{4}{3}$ sin. c sin. m;
cos. $(m-c)$ — $\frac{4}{3}$ sin. c sin. m = cos. $\{(m-c)-2z\}$.
But, cos. $(m-c)$ — cos. $(m+c)$ = 2 sin. c sin. m
∴ $\frac{2}{3}$ cos. $(m-c)$ — $\frac{2}{3}$ cos. $(m+c)$ = $\frac{4}{3}$ sin. c sin. m
$\frac{1}{3}$ cos. $(m-c)$ + $\frac{2}{3}$ cos. $(m+c)$ = cos. $\{(m+c)-2z\}$.
∴ $2z = (m+c) - \cos.^{-1} \frac{1}{3}\{\cos.(m-c) + 2\cos.(m+c)\}$.

Rule.—*Add together the natural cosine of $(m-c)$ and twice the natural cosine of $(m+c)$, and divide the sum by 3; the result will be the natural cosine of an angle, which angle taken from $(m+c)$ will leave twice z.*

This gives the angle = 22° 50′ 14″ = v = CKG. To find the angle GKE = v, we have FKG = $(c-z)$ = 47° 19′ 56″ = n; FDK = $(x-y)$ = 79° 57′ 35″·5 = m.

We have also, FE : FD = 1 : 2;
FD : FK = sin. n : sin. m;
and FK : FE = sin. $(m+v)$: sin. $(n-v)$.
∴ sin. n sin. $(m+v)$ = 2 sin. m sin. $(n-v)$;

sin. n (sin. m cos. v + cos. m sin. v) = 2 sin. m (sin. n cos. v — cos. n (sin. v). Sin. n sin. m cos. v + sin. n cos. m sin. v) = 2 sin. m sin. n cos. v — 2 sin. m cos. n sin. v. Dividing by sin. n sin. m sin. v, we have, cot. v + cot. m = 2 cot. v — 2 cot. n;

∴ cot. m + 2 cot. n = cot. v: which affords the Rule.—*To the natural cotangent of m, add twice the natural cotangent of n; the sum will be the natural cotangent of v.* ∴ v = 26° 19′ 55.″ All the other angles of the figure can be found by addition and subtraction; and any of the linear distances calculated at pleasure. EH, ED, and GK, will be 46·4013, 26·7423, and 100·7355 chains, respectively.

THE PRACTICE OF SETTING OUT RAILWAYS AS PRELIMINARY TO THE CONTRACT WORKS.

The duty of an engineer when setting out a line of railway, finally and permanently, has not, so far as I am aware, been described in any publication. It may be serviceable to some of the readers of the Journal to show in what it consists, and to impress the evident fact that its careful and accurate performance is important in every department of the construction of the line, and to the interest of the railway company in relation to the landowners. Can anything be more discreditable than a distorted or irregular alignement;—than a deviation from the gradients established on the permanent section, or than winding slopes? Can anything be more injurious to the character for honesty, which a railway company, through its servants, ought to maintain, than the frequent squabbles with landowners as to the quantity of land purchased from them? Discreditable, however, as these exceptions to propriety are, instances of them all are familiar to the practical engineer. They are in many cases attributed perhaps to the hurry of commencing the contract works, most frequently they can be traced to the want of experience or of care on the part of those entrusted with the duty of permanently setting out the line.

To assist the inexperienced and to direct attention to the points which chiefly require care, is my purpose in offering a contribution to the pages of the Civil Engineer and Architect's Journal, upon this part of an engineer's practice, and it has been my object to avoid all, but the simplest forms of calculation, to reduce them to the fewest in number, and to show how they may be made with the least trouble—in fact, so as to save all the trouble that it is possible, consistently with accuracy.

A line of railway is permanently set out,—First, by tracing upon the ground the *centre line*, which must conform to the final plan, as to curves and tangents.

Secondly, by planting permanent bench marks to indicate the gradients laid down on the final section.

Thirdly, by marking off the widths so as to show the space occupied by the railway at formation level, or balance line, by the slopes, and by fence and ditch, from the dimensions presented by the cross sections.

To the two last operations it is proposed to confine this paper.

Setting out Gradients.

A fixed point to which the gradients are referred is always determined at one end, at least, of a proposed line of railway, and from this point the levels must be carried forward, following the centre line, which, it is assumed, has already been marked by pegs or stumps at distances which ought not to exceed four or five chains. Two levelling staves, a chain of fifty feet in length, and a perfect spirit level in complete and accurate adjustment, are the instruments with which the engineer should be equipped, and which he will require to use with skill and expedition.

The gradients should be laid down in the field,—

1st,—By measuring the length of each from end to end, and fixing ordinary pegs to mark the beginning and termination.

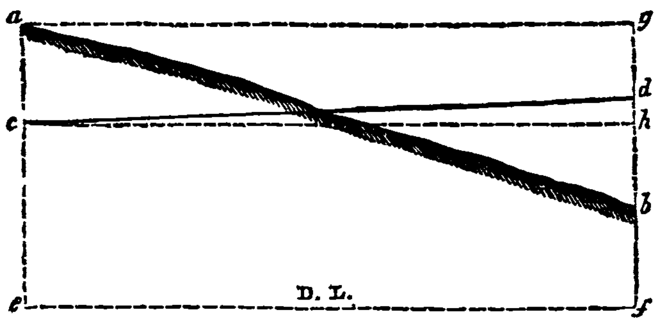
2nd,—By carrying a series of levels over the whole length of the gradient without using the chain, so as to determine the difference of level of the ground surface at each end of the gradient.

3rd,—By planting permanent bench marks within a convenient distance of the line, but secure from being buried or destroyed during the progress of the works.

These bench marks should be formed of posts of squared timber, 6 inches × 6 inches, secured round the head with an iron hoop, and either driven into the ground as a pile, or, being squared at the foot, set upon a slate, tile, or flat stone, in a hole dug to the depth of three feet, or thereabouts; and they should stand 2′ 6″ out of the ground. Upon this post a saw kerf, nick, or other mark, to be described in the level book, must be made as a reference to the height of embankment or depth of cutting at the end of the gradient, already marked by a peg on the centre line.

It is a matter of most essential convenience during the whole progress of the construction of a railway, that these bench marks should be readily accessible and properly protected from injury or derangement, and a little expense incurred to attain this end will save ultimate cost, in the shape of time, to all parties interested, whether contractor or engineer.

Fig. 1.



The only calculation requisite to complete this preliminary operation is readily understood from the figure, in which $a\,b$ is the ground surface, $c\,d$ the gradient line, and $g\,b$ the difference of level at the surface between the limits of the gradient $c\,d$. Then, as we know the position of the point c, with reference to a, at the beginning of the gradient, that is, in the present figure, the depth of cutting $a\,c = g\,h$, then $g\,b - g\,h + h\,d = b\,d$ the height of embankment at b.

Now, to render this process perfectly general and free from any hesitation in applying its result, the following conventionality must be borne in constant remembrance:—

Calling, B the sum of all the back sights.
F the sum of all the fore sights.
G the rate of inclination of the gradient or the height $d\,h$, through which it rises or falls in its whole length.
C the depth of cutting or height of embankment at one end.
C′ the same depth or height at the other end.

Then the general formula is $B - F + C - G = C'$.

In which we must use the positive or negative sign to C and G, as the circumstances may be, thus—

When C is in *cutting* it is always taken with the positive sign; when in *embankment*, with the negative sign.

When G is a falling gradient, it is to be prefixed by the negative sign; when a rising gradient, by the positive sign.

Then the sign which will be the result attached to C′ will indicate whether the end of the gradient is in cutting or embankment.

Suppose a case, in which $B = 200$; $F = 208$; $C = +6$; and $G = +3$; then, $200 - 208 + 6 - 3 = -5$, where we have a cutting of 6 feet at the beginning of the gradient, and an embankment of 5 feet at the other.

Suppose we use the same figures, but work the reverse way; then $208 - 200 - 5 + 3 = +6$.

A little consideration will make this familiar, and the remembrance of the proper signs will be facilitated by connecting them with the fact, that when the ground *falls*, the difference of level is *negative*; or, in other words, the sum of the fore sights is greater than the sum of the back sights. In the same way, when a gradient line *falls*, the expression G is negative. On the other hand, where the ground *rises*, the difference of level is *positive*, for the sum of the back sights will exceed the sum of the foresights; and in like manner, when a gradient line *rises*, the expression G is positive. Also a *negative* sign before C shows that the ground surface is below the gradient line; and when the sign is *positive*, that the ground surface is above the gradient line; the first indicating an embankment, the last a cutting.

The inclination of the gradient must, on no account be taken from the ratio of inclination usually given on the section, but the difference of the heights above datum at the ends of the gradient must alone be employed in all cases.

The ground between the ends of each gradient must be levelled over at least *twice*, and should any difference appear, it must be gone over until all uncertainty as to the truth of the result vanishes; and *then*—and *not until then*—the height of embankment or depth of cutting, above the nick, or saw-kerf, in the bench mark, should be properly painted in figures on the post, say in red paint for cuttings, and in black or white for embankments.

When the length of the gradient is, in the first instance, chained out, pegs should be driven into the ground occasionally where the rise or fall amounts to a whole number; thus suppose a gradient of 1 in 300, a peg at 300 would show that the rise was 1 foot; at 900 feet that it was 3 feet; and so on. The use of these pegs is to serve as a check upon the levels taken for the widths, where an accumulation of small fractional parts of a foot, individually too small for reading on the staff, and therefore neglected in each chain's length, might amount to a serious multiplied error if carried on; and for distinction these pegs should be painted red.

Marking off the Widths.

The first step, at this stage of the work, is to divide the entire length of each gradient into spaces of one chain, or 50 feet each; for these spaces, levels to determine the height of embankment or depth of cutting should be simultaneously carried on with the chaining and measurement of the widths. It is not uncommon that the surface of the ground is covered with soil or grass turf, which is directed in the specification of earthwork to be removed from the site of each embankment, and set aside and reserved from each cutting before the embankments are begun, and to be used subsequently in soiling the slopes, in forming mounds for the quick fences, or to be disposed of to farmers or others. In calculating, therefore, the quantities of earthwork in each chain's length (for it is presumed the contract quantities will be computed from the level books, and not according to the lazy method of scaling heights from a section), we must bear in mind that the removal of this soil increases the quantity in every embankment, and decreases the disposable number of cubic yards in every cutting; and the thickness of soil directed to be removed must be added to the heights of embankment shown, as taken from the surface, in the level books; and must in the same way be subtracted from the depth of cuttings. For the widths, however, the existing surface must be worked from.

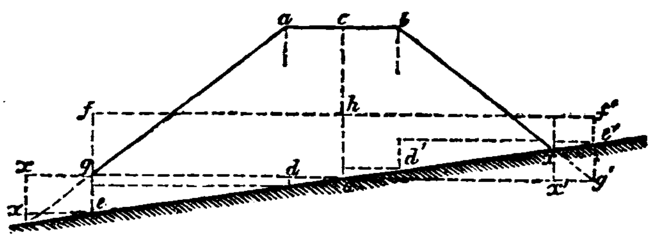
We will now suppose then, that commencing at the beginning of a gradient, a length of 50 feet has been measured along the centre line, the spirit level set up, and a back sight to commencement, as well as a foresight to the end, of the chain's length observed and entered on a level-book, the form of which will be presently given.

The height of embankment, or depth of cutting, must be then calculated, as already explained, for the value of C′, and also entered on the level-books. Half the width of the roadway must be measured off horizontally on each side of the centre line, and at right angles to it, and also a space for each slope corresponding to the value of C′, multiplied by the ratio of the slopes. A reading from the level staff, taken at each of these last points, and entered on the level-book, completes the first part of the field work.

The values of G, or inclination of the gradient, for the several distances of 50 feet, should be very accurately calculated, and entered in the proper column of the level-book in the office;—and it is not sufficient that this calculation be made for one distance and repeated; but the sum of the inclinations for any number of separate lengths should correspond with the inclination for the whole length; so as to correct any multiplication of minute errors from the necessary omission of small decimals.—For example: On a gradient of 1 in 300, the value of G for 50 feet would be 0·16666, &c.; now, if we used 0·17 as the nearest approximation and repeated it, we should obtain a total difference of 17 feet in one hundred lengths of 50 feet; whereas the correct difference for 5000 feet is 16 feet 8 inches. But if we take G, for the first two lengths as 0·17, and for the third 0·16, and pursue the same alternation for the entire length, we shall have a correct result. This will, it is hoped, be sufficient to show one subject deserving of care. All the points laid out should be marked by a nick in the ground; but if such a mark is not very visible, small wooden pegs must be employed.

The cross sections annexed exhibit what has been done so far, and what there still remains to do.

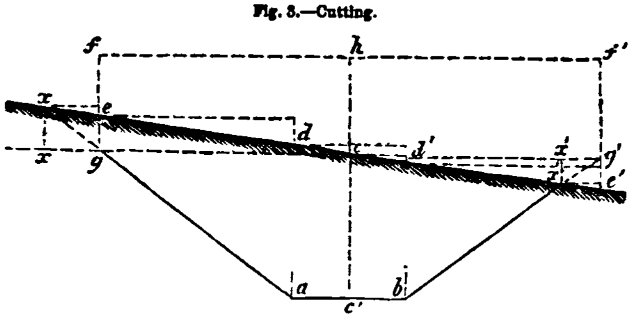
Fig. 2.—Embankment.



There has been determined, the height of embankment or depth of cutting cc'; the width, measured horizontally, of roadway cd, cd', and for slopes de, $d'e'$; and the heights ch, fe, $f'e'$ have been taken. And there remains to calculate, the horizontal addition to the widths for slopes ex on one side, and horizontal deductions on the other side, $e'x'$. The properties of the similar triangles cge, cxx, and of xxg, agd, afford a variety of expressions for the distance xg; and in making a selection from them, I have chosen that which requires the least quantity of field work, without increasing the labour in the office.

The notation employed will be—

Fig. 3.—Cutting.



C′, to represent the height of embankment, or depth of cutting.

r = the ratio of the slopes.

B = half the width of roadway, ac, or cd.

h = the height read off the staff at the centre, ch.

h' = the height read off at the edges of the slopes as first set out, that is fe and $f'e'$.

Take $H = h - h'$. The expression then for the horizontal distance gx in its general form is $\dfrac{(rC' + B)H}{C' + \dfrac{B}{r} - H}$.

In applying this formula we must pay attention to the essential signs of H and $\frac{1}{r}$, as well as of C′.

As already explained, the essential sign of H is *positive* when the ground in cross section is rising, and is *negative* when it is *falling*; and the sign of $\frac{1}{r}$ is to be taken as *negative* in EMBANKMENTS, for the slopes *fall* from the centre towards either side,—and as *positive* in CUTTINGS, because the slopes *rise* in the same manner; the sign by which the result is affected will show whether it is to be added to, or deducted from the width already set out for slopes.

The calculation of this formula is best performed in the office; and the result in each case should be entered in the proper columns of the level-book, to be set out on the ground on the next day devoted to field work, when the marks indicating the spaces for slopes should be removed, and replaced after the corrections.

It is recommended to use the ordinary slide rule in making the calculations—a modification, in the shape of two concentric circles of card board, divided on the edge into a logarithmic scale, of which the circumference of the smaller circle is the logarithm of 10, I have employed with much satisfaction. The outer circle is laid down on a rectangular piece of card-board, and divided from right to left; the inner circle is a separate card, cut exactly round its circumference, is divided from left to right, and is moveable upon the rectangular card on its centre; and all the calculations, involving multiplication and division, are performed by inspection. The smaller circle may conveniently be 3¼ or 3½ inches in diameter.

I need not encumber the Journal with a demonstration of the simple formulæ I have given; the investigation may, however, prove an amusement to the younger members of the Profession, and to them it will be a useful employment for half-an-hour. The only postulate is that the three points, c, e, x, should be in one straight line lying in the plane of the cross sections.

When the corrections to the widths for slopes are made which are due to the inclination of the ground surface, we complete the work by adding the necessary width for hedge and ditch, which should be measured off horizontally; this offers no difficulty.

When all the widths are measured off, the several lines are marked on the ground by nicking it with a spade or grafting tool, or by running a light furrow with a plough over the several marks.

A convenient form of level book for entering the particulars, which ought to remain on record, belonging to the setting out of the widths, has been alluded to in a previous part of this paper. I annex a form of this kind, and have inserted in it, the registry of a short length of railway, sufficient to offer a praxis, to those disposed to pursue the subject.

Form of Level Book to be used for Setting out Widths.

1, *Lancaster Place, August* 1, 1846.

J. H.

WESTMINSTER BRIDGE.

Report of the Select Committee appointed to consider the present state of Westminster Bridge, dated August 5, 1846.

The Committee having taken evidence on the subject of the present state of Westminster Bridge, unanimously agreed to the following resolutions and Report:—

Resolutions. I. That the majority of the witnesses who have been examined on the point concur in the statement, that the foundations of Westminster Bridge having been originally vicious, the bridge can never be permanently sound.

II. That the expense of completing the alterations and repairs new in progress or contemplation, according to contracts and designs under the superintendence of the bridge commissioners, will be very considerable, amounting at the least to £70,000.

III. That this expenditure will still leave the bridge in a state requiring constant attention in respect to repairs, and without any certainty of permanent security; while it will likewise leave the water-way far less adequate to the requirement of the navigation, particularly when the contraction of the stream by the embankment in front of the New Palace is considered, than would be the case under a new bridge.

IV. That, irrespective of the approaches, the expense of a new stone bridge near the site of the present bridge, and retaining the present bridge for temporary use, would not exceed £360,000, according to the highest of the estimates for that object which have been furnished to the committee, either in 1844, or in the present year.

V. That the bridge estates would probably furnish a clear surplus of at least £100,000, in aid of the funds for the erection of a new bridge.

VI. That Parliament having by direct grants from the Exchequer (the remaining expenditure having been provided by money raised in lotteries under Acts of Parliament) furnished a large part of the expense of erecting originally the present bridge, and having constituted the commission under which the said bridge was erected and has since been administered; and having by sec. 20 of the 9 Geo. II. c. 29, declared, that the said bridge shall be extra-parochial, and by sec. 21, that it shall not be a county bridge, maintainable as such bridges are by county rates, has recognized and sanctioned the principle that this bridge, which is thus by law excluded from other support shall be maintained, and when needful, repaired, restored, and rebuilt, at the expense of the State.

VII. That, in these circumstances, a sufficient case has been made out to justify this committee in recommending to the House, that the present bridge be pulled down, and that a new bridge be constructed; and that a bill be brought into Parliament next session to transfer to the Commissioners of Her Majesty's Woods, &c., the estates and property of the bridge commissioners, due consideration being had to the claims of the officers of the bridge estates, if their services should be discontinued.

Report.—The practical question which the committee had to decide, in relation to Westminster bridge, was, whether, under all the circumstances of the case, it were or were not desirable to endeavour to maintain the existing fabric of the bridge, or, on the other hand, to pull it down at once, and to substitute an entirely new bridge.

The result of the inquiry instituted in the session of 1844, and referred to this committee, proved unquestionably, that, without reference to money (*i. e.* assuming that the pecuniary means were forthcoming), every consideration of the convenience of the passage under and over the bridge, and even of economy when the expense of the maintenance of the existing structure is regarded, combined to recommend the removal of the old bridge, and the erection of a new bridge.

It was stated in substance by several witnesses examined in that year, that the foundations of Westminster bridge were originally defective; and therefore that the superstructure could never be made as effectively secure as if the whole were now rebuilt on an improved plan.

Even irrespective of the particular vice of the foundations, the character of the soil on which the bridge is built was sufficiently illustrated by the late Mr. Telford, in the following passage describing one of his own operations on the site: "I then proceeded to ascertain the nature of the matter of which the bed is composed, and on which the piers rest; and I found that an iron rod was easily pressed by hand through sand and gravel, to the depth of six and a half feet below the surface of the bottom of the river, or three and a half feet below the bottom of the platform; how much lower a longer rod might have penetrated I had not an opportunity of trying." And as to the foundations, James Walker, Esq., C.E., who was at the time, and still is, the professional adviser of the bridge commissioners, stated in 1844, "All the defects of the bridge have arisen from the imperfect foundation of the piers." In his original report to the commissioners of Westminster bridge, seven years before, namely, 28th February, 1837, Mr. Walker, after having stated "that for every useful and ornamental purpose a new bridge would be preferable, if the funds will justify the expense," proceeded to state the facts and reasons which led to such conclusion; namely, "that the piers of Westminster bridge were built in caissons, without bearing piles under them; that the bed of the river, for a considerable depth under the caissons, is loose gravel; and that the effect of the removal of the piers and dams of London Bridge is to increase the velocity of the ebbing current, and to deepen the channel between the piers, and thus to endanger the foundations." After the experience of nine more years, Mr. Walker, reviewing the whole case, and being requested to state his opinion as to the perfect stability of the existing fabric of the bridge" says, on the 19th of May, 1846, "After that bridge has sunk and twisted about in the way it has done, from the commencement of its building to the present time, I have seen enough of it not to risk anything like a professional opinion upon it," *i. e.* its perfect stability..... "I feel with reference to Westminster bridge, that it is like a patient whose constitution I did not make, which has been in the hands of doctors from the day it was built to the present time." Mr. Walker added, indeed, on the same day, "I do not think that there is any reasonable expectation of anything like a sudden failure of the bridge that would cause public danger; but when it is considered what an immense stake there is, in the case of any accident happening to the bridge, to be set against the taking of the thing boldly in hand, and making a complete job of it at once, to use an expression common with us, I must say, as I have said from the beginning, that it is nothing but a deference to the Lords of the Treasury which would in my mind make it politic at all to expend a great deal of money upon the repair of the old bridge." Mr. W. Cubitt, C.E., stated in 1837, in his report, "It also appears from the history of this bridge, that the foundations, as at present existing, were designed and calculated for much smaller piers, with a light wooden superstructure for a bridge; which plan was afterwards changed to that for the present stone bridge, and carried into effect upon the original foundations, by casing or lining out the piers, and surmounting them with heavy stone arches." Under these circumstances, it is not surprising, as was stated in a contemporary work, which describes the erection of the bridge,—that, "before the bridge was even finished, viz. in 1747, the third pier from the centre, viz. the fifth from the Westminster shore, began to sink; so that the two arches which rested on it departed from their circular figure, and some of their principal stones fell into the water." (*Gephyralogia*, 1751, p. 111). The remedy applied, in the first instance, according to that authority, was, to lay such a weight on the pier as to sink it gradually to the level where it might find rest. Accordingly, a weight "amounting to 12,000 tons" was laid on the sinking pier, apparently to sink it lower; and it "continued sinking several months after the weight was laid on." Three whole years was the use of this noble structure retarded by this accident," pp. 111-113. It is true, however, as the late Mr. Telford observed, in a memorable report which he addressed to the commissioners of Westminster bridge, on the 12th May, 1823, that "the dangerous instability of the piers of Westminster bridge seems to have passed into oblivion." It is true, also, as Mr. James Walker observed in his evidence, that, "in the course of 90 years the fabric had come to a state of repose, comparatively, until old London bridge was removed, the effect of which was to increase the velocity of the tidal current. This deepened the ground under the bridge; and the piers being thus deprived partly of lateral support, and some of the fine sand also getting from under the caisson bottoms, they began to be restless again."

The cause of the original failure in 1747 was the omission of driving piles under the piers; but the miserable economy of saving five or six thousand pounds, for which Mr. King (whose name ought to be thereupon preserved in honour) offered to execute the work, prevailed; though it was "not one part in 60 or 70 of the whole expense of the bridge." (*Gephyralogia*, pp. 96, 97). Hence, the first failure; and hence all the subsequent weaknesses of the structure, and the enormous expense of makeshift repairs.

When engineers like the late Mr. Telford and the present Mr. Walker suggest a remedy for an evil, occurring in the line of their own profession and in matters daily under their eyes, those who have not the advantage of their science and experience ought to be slow to pronounce an opinion unfavourable *a priori* to any suggestion so made. Mr. Telford recommended, that, as piles had not been originally driven under the piers, "piles should be driven round the piers, using the diving-bell for placing them and cutting them. A number was done in this way; but even those that were done did not seem quite at rest; and the commissioners, from the expense, uncertainty, and delay with which the operation was attended, seemed, before I was called in" (said Mr. Walker in his evidence), "to have resolved, for a time at least, not to enclose any more of the piers in the way I have described." Then came the system of coffer-damming. "My decided opinion is that coffer-damming is the best plan:" and that plan was thereupon adopted; but while Mr. Walker discontinued Mr. Telford's use of the diving-bell, and did not concur in Mr. Cubitt's plan of paving the bed of the river, Mr. Cubitt, on the other hand, equally condemned the use of coffer-dams in the case of Westminster bridge; stating distinctly "That in the case of Westminster bridge, the original construction and present state of the foundations are such as will not admit of the coffer-dam plan being carried into effect with safety to the bridge, or a well-grounded certainty of a successful result." Between these two discordant authorities, the commissioners made their election, and adopted Mr. Walker's plan of coffer-damming, and in the course of the following year entered into contracts for completing it.

It is due, however, to both gentlemen to state that, even in 1837, they each recommended a new bridge, if the pecuniary means could be found, in preference to any attempt to repair the old structure. Mr. Cubitt stated "That there is no doubt but a new bridge would cure all the evils complained of." And Mr. Walker enumerated those considerations, which "would probably turn the balance in favour of the new bridge." At a later period, the committee of 1844 received from that gentleman this further statement: "Without hesitation I say there is no art that can make the piers of this bridge so secure as I could have made a new one." Nevertheless, upon a review of all the case, he added: "I did not doubt as to the security of the whole superstructure. When I say this, I must at the same time allow, that the sinking which has taken place in the 17-feet east pier, after the water was admitted within the coffer-dam, is a drawback," meaning, of course, the only drawback, "which has at all raised a doubt on my mind;" a sinking, be it remembered, which has gone down nine inches, and has left that pier three inches out of the perpendicular: "but ever since last October th at pier has been, as every other part of the bridge has been, perfectly motionless: and therefore I have reason to think that the cause which created that movement in the 16 and 17-feet piers is at an end, and that these also are secure." At this time, the 16-feet pier had gone down two inches, and the 17-ft. pier nine in.: "all the piers," indeed, "sunk a little during the operation of driving the piles."

The confidence, however, or to use Mr. Walker's words in another place, "My faith, which amounted to conviction previously," (*i. e.* to the sinking in October, 1843), "was somewhat shaken" by that sinking; but he adds, "it is proper also to say, that my confidence has revived, by the entire freedom from all movement since that time," viz. up to the date at which he was then speaking, 10th June, 1844. If, however, the confidence revived solely because the piers had ceased to sink, it must, of course, die again when they again begun to sink. And this is the fact. The sinking has begun again; and, though in no one week considerable, or indeed observable except by very nice tests, yet the aggregate sinking in the course of many weeks becomes perceptible to the eye; and above all, as it is pro. gressive, must, at some period, terminate in the destruction of certain portions of the bridge, even if it do not endanger the whole fabric. So early as 1837, Mr. Walker's recommendation to the commissioners, as already seen, had bees to build a new bridge, if the funds could be obtained. On the 7th May, 1845, he stated to the commissioners, still more strongly,—"to the reasons I then gave for recommending the new bridge, there is to be added the bad foundation which has caused the sinking in the two piers; for even half an inch in two years is enough to prove the want of perfect stability, and to weaken that confidence which I ought to feel in order to justify my recommending an outlay of £100,000, in addition to the £90,000 already expended. I have before stated, that all the othe piers, which have been finished, are secure; but two piers on the Surrey side next to the defective piers, remain to be coffer-dammed round and, piled; and if the sand under those two be of as loose a nature as those adjoining, they may cause further trouble and expense. Should they require to be taken down, the difference between the partial plan" (*i. e.* continuing the system of repairs) "and the entire renewal" (*i.e.* the removal of the old bridge and the construction of a new bridge) "will be considerably lessened." The causes which induced Mr. Walker to recommend a new bridge in 1837 and in 1844 and in 1845, have not ceased to operate. The sinking in the 17-feet pier since the 7th May, 1845 to the 19th May, 1846, has been 1¾ inch, and in the 16-feet pier about 1¼ inch; and it continues in both. By the report of Messrs. Walker and Burges to John Clementson, Esq., Secretary to the bridge commissioners, dated 20th July, 1846, those gentlemen state that they have this day taken the levels of the piers of Westminster Bridge, and have to report a further sinking of $\frac{3}{10}$ths of an inch In the 17-feet east pier, and $\frac{1}{10}$th in the 16-feet east pier, since their report of the 6th instant." [6th July, 1846.] They go on to say, "The movement of $\frac{3}{10}$ths of an inch in the 17-feet pier is double what we have had occasion to report for a considerable time. The continued sinking in the two piers has affected the stones of the 72-feet arch which rests upon them, an open joint being perceptible in the soffits between two of the courses near the crown, and one of the south-face stones having dropped down about half an inch." Messrs. Walker and Burges concur, accordingly, in the statement, "that a way or thoroughfare over the river at Westminster, consistently with the safety of the public, can be best secured (or perhaps we ought now to say can be secured *only*) by a temporary bridge; and that no time should be lost in proceeding with it." More than a month earler (11th June, 1846), Mr. George Rennie gave, in substance, the same opinion, namely, that no time should be lost in making arrangements for the construction of a new bridge; and being asked, "Might not the present bridge serve as a temporary accommodation while another bridge is being constructed?" he replies, "It might;" but he adds, "*with all the chance belonging to it.*"

It is true that Mr. William Cubitt, the contractor, whom your committee felt it to be their duty to call as their first witness, inasmuch as the progress of the New Palace was a matter, as has already been observed, of comfort and convenience to the two Houses of Parliament only, whereas the safety of the bridge was of paramount importance to hundreds of thousands of the Queen's subjects, stated in answer to the second question, "I do not apprehend the bridge to be otherwise than safe." * * "I do not mean by that, that it is in a state of perfect stability; that there may not be from time to time slight settlements in it; but I am very strongly of opinion that no settlement will ever take place to a degree that should endanger the public safety."

The same witness, indeed, had stated in 1844, that he thought the bridge may last for two or three centuries:" "that the bridge, with a very moderate repair from time to time, is capable of carrying the public safely for centuries to come;" and he added, accordingly, "I know no reason why it should be pulled down."

On the extent, however, of the knowledge of the witness as to the facts connected with Westminster Bridge, it is due to the other gentlemen who gave a very opposite opinion, to state, that Mr. W. Cubitt, being asked whether he can state the depth of the river at Westminster Bridge now, as compared with its depth before the removal of old London bridge, answered, "I cannot;" and being further asked, "Have you ever understood that it has already (1844) deepened as much as five or six feet?" replied, "I have never hard such a thing: if that has been stated, it can only be in one particular place, where, from some cause or other, there has been a gullying ont by a peculiar current:" and when again asked, "You are not, however, aware of the depth which has been given to the river by the removal of old London bridge?" he replied, "I am not aware of it; but I am pretty sure that it has not given an average of 18 inches." The committee understood, of course, that in this answer Mr. W. Cubitt was speaking at the time of the locality in question, namely Westminster Bridge, and not of the Thames at Staines or Wallingford; and therefore proceeded to put the following question: "You conceive that anything less than an average of five or six feet would not endanger the security of the sheet-piling round the piers, by which they are surrounded?" to which Mr. W. Cubitt answered, "I rather hesitate in giving the precise line: if it came to five or six feet I should begin to feel uneasy, if I was sure it ever came to that." It appears, by sections of the river taken by Mr. George Rennie, and laid before this committee, as furnishing a very curious and interesting view of the changes produced by natural causes in the bed of the river, that between 1823 and 1835, the river, 50 feet below Westminster Bridge, had deepened between six and seven feet; proving the tendency of the river to "engineer for itself," to use Mr. Page's expression, to a greater degree than was previously anticipated; and this measurement near Westminster Bridge proves that the very case had happened which, as Mr. W. Cubitt stated, would have made him "begin to feel uneasy," namely, that the bed of the river had there deepened at least five or six feet: it fact, it has done more, inasmuch as, "by a longitudinal section of Westminster Bridge which appeared in Appendix 15, G. 1, to the Report on the Thames Embankment, and upon which," said Mr. George Rennie in his evidence, "I have coloured by a dark line the existing bed of the river in May 1846, it will be seen that the sixth and seventh piers from the Surrey side have their foundations exposed eight or nine feet."

On the whole subject of the effect which the deepening of the river or any other cause may have had in unsettling the foundations of Westminster bridge, and consequently its superstructure, the committee feel it to be their duty to recal two circumstances to the attention of the House: first, the settlements which did take place in the autumn of 1843, which, as already noticed, caused the bridge to be closed and shut up for carriages during a portion of the winter following; and secondly, that the favourable answers already quoted as to the stability of the whole structure, depend on the assumption that the whole structure is to be subjected to the same process and system of repair which has already been applied to parts. Now, the amount of the contract—remaining so to complete the repairs—was, in 1844, £52,870, together with a further sum of £40,000 to make the bridge of the same width as London bridge. This aggregate of £92,870 was therefore necessary, in 1844, according to the then views of the commissioners, to the repairs of the existing bridge; and might have been saved accordingly, and made applicable to the construction, in part, of a new bridge, if the repairs had been then discontinued, and if a new bridge had then been substituted.

In addition to this, it must never be forgotten, that Mr. W. Cubitt being the contractor for the works commenced in 1838, gave evidence as strong as that of any other witness, on the question of the original vice of the foundation. In 1844, he referred "to the original defect in the surface of the foundation;" adding, "I mean that it never was correct and proper." "There was one pier which had always been called the sunken pier; that was the one they were obliged to unload when the bridge was first built. Then these two other piers in the bridge which were called sinking piers: they had that name given to them because they had been in the habit of sinking more than others." And being asked, in reference to a subsidence of nine inches in one of the piers, whether such subsidence shakes his belief in the future stability of the foundation, he replies, "I always had an impression that the bridge would be liable to sink a little;" and being further asked, whether, "When you say 'a little,' do you consider nine inches a great or a small subsidence?" he replies, "I consider nine inches to be a great deal; but with reference to an arch of that form and with stones of that thickness, it is of very little importance with regard to the safety of the bridge." While, however, Mr. W. Cubitt states, that, so far as the original defectiveness of the foundation is concerned, the bridge is sufficiently stable for all purposes for which it is required, that no disaster ever can accrue by which the public would be damaged from that cause, he does not retract his preceding opinion, "that the bridge always must be an imperfect structure" in reference to the mode in which it was built; and, though he may contradict the opinion of others, he cannot gainsay the fact, that the bed of the river has been gradually deepening, and the foundations of the bridge abraded and laid bare in consequence; and the committee feel, that if this be so, Westminster bridge cannot be "as stable as it ought to be.

The very remedies, indeed, which have been applied to strengthening the foundations of the piers may in fact have loosened them, by loosening the ground on which they rested. Even so early as the 16th of May, 1823, the late Mr. Telford himself admitted, in reference to his own suggestion of sheet-piling, "I believe I did not sufficiently explain that by driving piles through loose sand and gravel, that the matter is always disturbed, and, during the operation of driving, liable to be washed away, and of course produce more risk to the piers than if left undisturbed." And Mr. W. Cubitt being asked, as the contractor engaged on the work, "Can you state to the committee whether it be or be not the fact, that every pier, as has been alleged, with only one exception, sank, more or less, after the sheet-piles round it to secure the bottom of the caissons from being underwashed by the general deepening of the river, were driven?" Mr. W. Cubitt replies, "they have not all sunk;" and being thereupon reminded "The question implies that one was an exception; do you wish the committee to understand, that all the piers, with one exception, have sunk more or less since the piles were driven?" Mr. W. Cubitt answers, "I am not prepared to state positively that they may not all of them have sunk a little. I am not quite sure but that they may have sunk an inch or half an inch, or some very slight thing; but one of them sank nine inches, and another sank two inches." And as to the future, Mr. W. Cubitt had already stated his previously formed opinion, that the bridge was not in any part of it in a state of perfect steadiness; that it might always be liable to subside a little, from the defect of the foundation."

The result of the whole question connected with this species of repair is stated by Mr. Walker in answer the question, "Do you think that the bridge will now be brought to a state of as perfect security and stability as a new bridge, if you were called upon to construct it?"—"Certainly not." And in answer to the next question, "Do you think that by any resources of your professional art, this bridge can be brought into a state of perfect stability and security as compared with a new bridge?" Mr. Walker replies, "Without hesitation, I say, there is no art that can make the piers of this bridge so secure as I could have made a new one." It is right, however to add, that Mr. Walker stated, in his examination this session, "that the measures which had been adopted had been completely successful in preventing any further movement in six of the piers: * * there has been no movement since" (*i. e.* since the 7th of May, 1845,) "in any of the piers, except the two I have already referred to." Nevertheless, in answer to the question, "Are you, or are you not of opinion, that with a due regard to the public convenience, and to avoid danger, arrangements should be made, without loss of time, for building a new bridge?"—Mr. Walker's answer is distinct: "Certainly, without reference to money, I say 'Yes.'"

As to the mere durability of the bridge, by which the committee understand the perfectness of the masonry both in the arches and in the piers, excluding always the question already discussed as to the stability of the foundation, there appears no reason to doubt the accuracy of Mr. Walker's opinion: "There is no part of the work which will not last for ages;" but a qualification to this opinion must here be given on the authority of Mr. Walker himself, who, in 1837, stated as follows:—"From the piers being intended originally to carry a wooden bridge, and being cased round when a stone bridge was resolved to be substituted, and *from the very bad quality of the masonry*, the superstructure never can be made a very secure and solid work;" and even admitting the superior accuracy of his later opinion, when, during the interval, he had had fuller opportunites of examination in relation to the durability of the superstructure of the bridge, it is obvious that this admission does not at all establish the expediency of maintaining the present bridge so long as the first and main question, as to the sufficiency and stability of the foundations on which the structure rests, remains in a state so unsatisfactory as at present.

It was not contended in 1844 that the bridge was then in a "perilous' state: Mr. Walker expressly repudiated the word; and, even before the new system of repairs, he had stated, "that the bridge is not in immediate danger;" and W. Cubitt, Esq., the civil engineer (and not the gentleman of the same name, who is the contractor for the bridge), being asked, in reference to the state of the bridge when the repairs should be completed, "Your conclusion is, that the bridge will be an insecure bridge?" replied, "A very doubtful one." "You will not say it will be an insecure bridge?" —"No." He had been previously asked, "Do you regard it possible, with any talent and any expenditure of money, to make the foundations of Westminster bridge as secure, under existing circumstances, as the foundations of a new bridge could be?" replies, "Certainly not." Mr. Cubitt, C.E., further states, that "from what I have seen, I would rather build a new bridge than spend more money upon this, seeing it has done exactly what I expected it would do when I made my report in 1837. My opinion is, that it is best not to go on spending a great sum of money to repair and widen and beautify this bridge, which never can be good, either in its roadway or in its foundations." Therefore, under all the circumstances, the bridge having proved to be too heavy for the nature of the clay it stands upon, it being very difficult to protect it without piling and paving, I say, as an engineer, that the best thing is to dispense with all further repairs, and make a new bridge. I said so before, and Mr. Walker said so also, and I am confirmed in that by what has subsequently taken place." And when asked in the next question, "You consider the only question to be one of finance?" he replies, "Certainly; the bridge is a mass of rubbish. The piers and the masses of masonry and rubble were first built for a wooden bridge, which was afterwards converted into a stone bridge, and heavy arches were put upon that which was not more than strong enough for a wooden bridge." * * The small piers were then cased round to make them larger; and springings were made for stone arches, and a very heavy bridge was put on those foundations."

Though Westminster bridge so constructed,—without piles and on the imperfectly-levelled natural bed of the river,—did actually fail during its construction, yet, "after it was constructed, and the arches which had failed were rebuilt, it stood for some 60 or 70 years unmoved." * * On the removal of the dam caused by old London bridge, "a wider passage was opened to the Thames, and the foundations of the arches underneath Westminster bridge began to wear away; so much so, that they caused a great apprehension of the bridge falling; and from time to time they were repaired by the diving-bell, and various other modes. Mr. Telford was called on, and advised stones being thrown in; and he advised also to pave underneath the arches between the piers, so that the bottom might not be washed away. After his death, the commissioners did me the honour to call upon me to advise them. I considered the thing, and felt quite aware that disturbing the bottom would not be a good thing; but that if we could continue the bottom exactly as it always was, the bridge would stand the same as it had done; that there would be nothing to prevent it; and to do that, I propose to pave with large stones, two feet thick;" * * * "to pave a perfectly flat floor down as low as the frames which form the foundations, and have been carried into the soil." * * * "I proposed, paving under the whole of the bridge, and 50 feet parallel along it, above and below, so as to make a perfect stone pavement; with such pavement the bottom never could have washed away; and without washing away, the piers would not have fallen down."

A suggestion made by such an authority as Mr. Cubitt, C. E., is of course entitled to just attention; but your committee, after bestowing that attention upon it, feel bound to state two objections to it, which, in their judgment, are insuperable. They relate to the effect of the plan upon the navigation, and to its cost. The one may be conveyed in the admission of Mr. Cubitt himself—"The only disadvantage (if disadvantage it can be called) of this plan is, that it limits the depth of the navigation under the bridge to the level of the stone paving; but as this would be greater, by about three feet, than originally existed, and till after the removal of the old London bridge, I imagine that no complaint could arise on that head." * * The answer to this observation is, that those concerned with the state and probable condition of Westminster bridge have to deal with the river, and its actual depth in 1846, and not with its depth in 1823; and must not forget that if the river has deepened under the arches, say six feet, the proposed plan of raising a pavement of something like three feet, would take away a depth of three feet from the actual navigation. The second objection is, that irrespective of all repairs to the bridge; and leaving that bridge as it is, the probable cost of the paving would, in Mr. Cubitt's own opinion, be about £120,000. It is not necessary, therefore, to pursue this subject.

Another remedy was proposed by another gentleman, Wm. Hosking, Esq., architect and engineer, and professor of the principles and practice of architecture in King's College, London. While he differed from other witnesses on some important points, and specially in his belief that "the present foundations might be rendered sufficiently secure to be entrusted with a new superstructure, especially if the superstructure was not an unnecessarily heavy one," he concurred with almost all in the opinion that the present bridge cannot be made "permanently available," to use his own words, "without the bar or weir I have spoken of, which I consider to be an absolute essential to the security of the existing foundations." Now, inasmuch as the bar or weir in question is, in the judgment of the same witness, a necessary precaution "at the other bridges" also, as otherwise "all the other bridges will be undermined as well as Westminster bridge," it is clear that his remedy must be viewed in relation to the whole of the river as it flows through the metropolis; and irrespective of the objections to which the plan, if ever adopted in any one breadth of the river, would be liable as an obstruction to the navigation at that part (which, even the witness admits, "it certainly would not improve,"), and so on, wherever adopted, the ultimate expense of making successive weirs above each bridge would be obviously immense; and the committee—to confine themselves to the consideration of this project in relation to Westminster bridge alone, the immediate subject referred to them—cannot recommend any further attention to it.

However wonderful as a structure Westminster bridge was regarded at the time of its erection, and there is reason to believe that at that time it was the longest stone bridge which covered water all the year round, not in England only but in Europe, Mr. Hosking expresses an opinion, in which your committee fully concur, "that a bridge, in every respect better, would be produced at the present time by almost any man of moderate ability, who is conversant with the subject."

On the general subject, both of the present state of the bridge and of the expediency of subsistuting a new one, other professional gentlemen, of the first character for skill and for experience, give evidence to the same effect.

Mr. Rendel states, "I should be very indisposed to risk any professional reputation upon giving to the present structure that permanent character which is adverted to."—"The foundations are wholly different from the foundations of any other bridges across the Thames."—"I do not believe that any talent or any skill, or any application of that skill, could, at a cost which I should call justifiable, give to the present bridge that security which its importance demands."

Mr. George Rennie states, "I should decidedly condemn the old one (the bridge), and recommend the expediency of its being taken down, regarding it as an engineering question entirely."—"Setting aside that (*i. e.*

money), I should condemn the present bridge decidedly, and have a new bridge; not only that, but you may be liable to very considerable further repairs besides those at present contemplated." – "I have no other observation to make, but that I consider it a great pity to devote that money to the repairs of an old structure which might and ought to be devoted to a new one, on the ground of the insecurity of the present bridge, and that there is no safe guarantee for the money laid out upon it being properly spent." In his evidence before the present committee, Mr. George Rennie stated that he retained precisely the same opinion: "I think it would be throwing away good money after bad to attempt to repair the bridge so as to make it a permanent structure." The removal of from 20,000 to 30,000 tons, as stated by Mr. James Walker in 1844, in order to lighten the vertical pressure upon the piers, by means of the abstraction of that material, has, in Mr. George Rennie's judgment, not succeeded in preventing the further subsidence. In fact, the further subsidence is stated distinctly in the evidence of Mr. James Walker this session.

The committee could readily extract, for the more easy consideration of the House, numerous other passages in the evidence of 1844; but they have perhaps sufficiently selected some of the most striking answers which have been given to the inquiries made on the subject of Westminster bridge; and they leave the remainder, without further selection, to the attention of the House. But they cannot conclude this collection of extracts from the evidence of 1844 without adverting to the fact, that the witnesses who depose the most explicitly to the propriety of removing the existing bridge are men of the highest engineering talent and experience in the empire; while the only witness, however excellent and respectable in his profession, who gave in that year any testimony in favour of maintaining the present structure, is the contractor employed to repair it.

Mr. Walker, while, as already stated, be repudiated the word "perilous," as applied to the bridge, distinctly stated that the want of money for a new bridge would alone induce him to propose the continuance of the actual structure.

When examined in the present session, Mr. Walker admits that, so far as regards one of the piers, "My opinion of being able to make the bridge perfectly secure, has not been a correct opinion, as far as it is shown at present. There is to be set against that, the expense to which the commissioners have been put, in repairing and strengthening the other piers; but, on the whole, my opinion is now, that, but for the question of expense, the better way is, under all circumstances, referring to the improvement of the situation, the future stability of the work, the giving an easier approach, an easier inclination, a wider bridge, a better water-way, and an improved navigation by a smaller number of piers, the safer and better course is to rebuild the bridge."

This answer well embodies the chief considerations which induced the committee to recommend, by unanimous resolution, the removal of the existing structure, and the substitution of an entirely new bridge.

Other considerations, however, have not been without their weight on the minds of the committee in the resolution which they adopted. The traffic over Westminster bridge has greatly increased within the last few years, "so much that it is difficult at times to get over it." It is obviously immense. Sir James M'Adam stated, in 1844, that he had been directed to cause to be counted the number of horses which passed Charing-cross annually, and that it had been ascertained that it was 6,600,000; and though there was no record of the proportion which passed over the bridge, he added, "I consider that the larger proportion of that thoroughfare, particularly the heavier carriages, passed over the bridge." It is stated further in evidence, that the inclination of Westminster bridge was in 1844 probably greater than that of any bridge over a tidal river in England; that its inclination was, at its commencement, *i. e.* for a distance of 50 yards at each end of the bridge, about 1 in 14½, and about 1 in 33 for the remainder. It is true, that the inclination has been reduced since 1844, but it has been reduced by the sacrifice of a quarter, at least, of the carriage-way of the bridge. As a general principle, it is clear that the wear and tear, both of the animals which draw a carriage on a steep inclination, and of the surface of such inclination itself, must be considerably greater than on a level, or than on any road-way in proportion to its approach to a level. When, in addition to this, it is recollected that, in the course of the system of repairs recently adopted, and for the purpose of lightening the vertical pressure on the bridge, such a mass of stone has been displaced as has reduced the present surface of the road by a depth of five steps below the footpath, on both acclivities, and that the carriage-way has thereby been contracted about the width of a carriage, it is sufficiently evident, that almost in the measure of the increase of the traffic has the accommodation for its passage over the bridge been diminished,

When, further, it is recollected that the headway under the existing Westminster bridge is lower than the headway under any of the bridges in the metropolis, and until reaching Battersea, it is clear that, as favouring the navigation of the river, it has no special claims to consideration.

New Bridge.

The committee of 1844, whose report has been referred to the consideration of the present committee, took evidence on the question, whether, in the event of its being decided to pull down the present structure, and to erect a new bridge, the material should be of iron or of stone; and if of iron, whether in suspension or in the form of arches; and if of stone, whether of granite or what other material. And the committee, in the present session, examined at some length both Mr. George Rennie and Mr. J. Walker, on this general subject. The committee do not feel it necessary either to analyze this evidence, or to come to any formal conclusion on the subject, except to recognise the two following propositions, namely, (1) that a suspension bridge, though affording greater facilities to the navigation than any other form of bridge, is inexpedient; and (2) that irrespective of expense, a granite bridge is expedient. On the first point, Mr. George Rennie compressed into one sentence the whole question:—"The great inconvenience of suspension bridges is, that they are always at work, that they are always in a state of degradation; whereas, bridges by compression are always in a state of equilibrium." The illustrations which he gave will well repay the attention of the House. On the second point, it is clear that, in proportion to the strength of the material, may be its thinness; and a greater waterway can be afforded by an arch of granite than by an arch of Bath stone. From this gentleman, from Mr. Walker, from Mr. Barry, and from Mr. Page, the committee have received designs for a new bridge, and have directed them to be lithographed. All have great merit; and perhaps the one which possesses the least might, if it stood alone, have satisfied every requirement. But the committee do not feel it within their province to give any opinion on the relative value of these productions. They do not, however, consider it to be inconsistent with their duty to recall to the attention of the House a suggestion applicable to the erection of all public works; it was made to the committee of 1844 by a gentleman already cited, who appeared to have given particular attention to the subject. The substance is stated in the next paragraph.

Competition Designs.—On the mode by which competition might best secure the application of the first talents to the production of the best designs, and might thence enable some superior authority to select one from all, or to combine different parts from two or more, Mr. Hosking stated as follows (and the committee concur generally in his opinions):—The essential matters should be defined by the proper authorities, in the first instance, and before attempts are made to obtain designs. A specification of what is required should then be made; and this should be more or less particular, as it may be determined either to fix a sum of money as the limit of expense; or, on the other hand, to receive designs with reference to the object and without limiting the expense. Such a specification should be put into the hands of a reasonable number of competent practitioners, with a request that they would each make a design for the contemplated work in accordance with the stated conditions. All the designs so obtained may be examined and investigated with the advantage of the presence of their authors to explain what they may have intended, and to correct what may be misunderstood. In this manner the best energies of competent men would be applied to the work, and it is probable that the best result would follow. * * * A general competition would end in general disappointment; * * * as none of the persons who would be recognized as most competent, would send designs without being specially applied to for them. * * * At the time London bridge was in contemplation, advertisements were issued for designs, with offers of some three or four premiums. Drawings were sent accordingly by 70 or 80 persons, and the premiums were awarded to the three or four which were said to be the best designs; but not one of them was used; they were immediately thrown away, and a design was taken up which had not been in the competition; but which, indeed, had been in the hands of the bridge committee beforehand, and the author of which was already dead. The late Mr. Rennie's design was executed. In order to avoid this apparent invidiousness and unfairness, and to secure the real benefits of a competition among competent men, the selection of the architects and engineers should be limited; and each should receive a certain remuneration for the work which he might send in. No man can afford to work for nothing. Every design asked for should be paid for; and no one ought to be asked, either directly or indirectly, to make a design, unless it be intended to pay him for it. If this system were adopted, the property in the designs so sent in would belong thereafter to the authority, by the directions of which they had been sent in; so that the good parts of one design might be accommodated to the good parts of other designs, and the combined result of the whole would be something superior to that of any one individual design. This is one of the advantages from requiring designs from persons of known ability, and paying for them, so that all the designs obtained may be turned to account. It is the parties seeking designs, and who desire to derive advantage from the application of many minds to the same subject, that are to be benefited; and they who seek a benefit must be contented to pay for it. It can never happen, but that in several designs for the same thing there will be some points or parts in some of the designs, other than that which may be generally the best, better than the same points in the best design. When all are paid for, all may be used; and the best design in a "concurrence" may be greatly improved by the incorporation of the excellencies of the others.

Site of the New Bridge.

The House will observe that the committee, in their resolutions herein adverted to, have not pronounced any opinion as to the precise site of the new bridge; but it is obvious that, while many considerations might be urged for the removal even to a distant position, other considerations, entitled to the highest attention, might be adduced in favour of the existing line, or one in immediate juxta-position to it. It has been suggested by a high authority that it would be very desirable to remove the bridge to the south of the Victoria Tower, thereby opening a more direct communication from the region of Belgrave-square to the right bank of the river, and generally to Lambeth, Southwark, and London bridge, and the railway termini now established in its neighbourhood, or hereafter to be so established. It has been also suggested, as a consequence of such removal of Westminster bridge, that a new bridge might be thrown over the Thames at the east of Whitehall-yard, with an access from Charing-cross, and another access from the Horse Guards. But independently of the objection, more or less valid, of disturbing the present traffic from Charing-cross to the north, and from George-street, the rest of Westminster, and the parks to the west, the committee think it right to refer to the evidence of Mr. Rendel in 1844: "I do not believe that there is a part of the Thames better suited for a bridge, by which I mean a permanently founded bridge, to stand upon, than the site of Westminster bridge." It is right to add, that the approach to the actual bridge from the left, or Middlesex bank of the river, is carried along Bridge-street, almost the whole of the property on the north side of which is part of the bridge estates; and therefore, that a new bridge, on the existing site, would be erected with little sacrifice of that property; and that a new bridge erected to the north of the present structure, that is, further down the river, and at a better point of view for regarding the New Palace, need involve no other sacrifice of the bridge estates than that of the ten houses forming part of the north side of Bridge-street, and without any considerable outlay in the purchase of the other houses on the same side. In connexion with this consideration, it was at one time assumed, that, though there was no prospect of permanently preserving the present bridge, it might, nevertheless, continue available for the temporary passage over the river, while the new bridge was in the course of erection in juxta-position to it on the north. But Mr. Walker urged, in the spring of 1845, the erection of a temporary bridge as even at that time desirable; and he has urged it with increasing earnestness in the course of the present examination. He estimates the first cost of a temporary bridge, of which he has prepared a plan, at £40,000; and be considers that a certain portion of that expenditure might be recovered by the sale of the timber forming the materials of that temporary bridge, when the new bridge should be opened; and that the remaining portion of the cost of such temporary bridge would be met by the value of the materials of the existing bridge, if used up on the spot.

Estimate of New Bridge.

Your committee will now proceed to consider what means remain in the hands of the commissioners of Westminster bridge, in aid of the expense of a new structure; and what, in the first instance, is the constitution of the commission itself.

The management of Westminster bridge is in the hands of 94 commissioners: 26 sit by virtue of their offices; 57 by virtue of their seats in the House of Commons, as representing the metropolitan counties; and 11 sit as elected by virtue of the Bridge Act, 9 Geo. II. The annual expense of that management, irrespective of the expense of repairs, is in salaries:

	£	s.	d.
Treasurer	300	0	0
Clerk	40	0	0
Clerk of the Works	140	0	0
Sir James M'Adam for "coating the road," including a small sum to himself for superintendence	772	10	0
Police	169	16	0
Gas	65	0	0
	1,487	6	0

The general expenditure in connexion with the bridge from the 5th of April, 1810, to the present time, that is to say, to the quarter ending 5th of July, 1846, has been £190,221 15s. 10½d. There is a further sum remaining due to Mr. W. Cubitt, under his contract; and another sum due to Mr. Walker in respect to his per-centage. Probably, if the account could be closed at the date of this report, the aggregate charged and chargeable upon Westminster bridge would not be less than £200,000 from the 5th April, 1810, to the 5th July, 1846.

The sum actually expended is distributed over three periods: I. From the 5th April, 1810, to 5th April, 1838, when the commissioners began their great system of repairs and alterations in the structure and foundations of the bridge. II. From the 5th April, 1838, when that great system may be held to have commenced, to the 5th April, 1844, which may be taken as the period when the attention of a committee of the House of Commons was called to the question of the expediency or inexpediency of continuing that system. III. From the 5th April, 1844, to the 5th July, 1846, namely, from about the period when the said committee concurred in the expediency of continuing the system of repairs, and thereby encouraged the commissioners to proceed therein, to the period when the present committee, on a review of all the circumstances which had occurred up to the 15th July, 1846, unanimously, on that day, recommended the removal of the existing bridge and the erection of a new bridge.

	£	s.	d.
The sum for the repairs under the old system, and for management, &c. was for the first period	83,097	6	9¼
The sum for the repairs under the new system, and for management, &c. was for the second period	81,341	16	8
And for the third period	25,782	12	5
	190,221	15	10¼

In addition to this sum, in addition to the two items which remain chargeable upon the bridge estates for work already done, and for the percentage upon it, it must always be remembered that, in order to complete the great system of repairs commenced in 1838, two, at least, of the piers remain to be included in that system, at an expense proportionate to that of the others, and the widening of the bridge 12 feet to make it equal in width to London Bridge, that is to say, building a bridge 12 feet broad, in union with the existing bridge, on its south side, at a cost of £40,000, the aggregate of all which was stated by Mr. Walker, the professional adviser of the bridge commissioners, at £100,000, about the time when the works generally were discontinued on the bridge; namely, in the early summer of 1845.

The House will observe that the committee in their resolutions took the sum remaining to complete the repairs, and which might be saved and applied to a new bridge, if those repairs were discontinued, at no more than £70,000; they also took the amount which might be raised on the credit of the bridge estates, in aid of the fund for erecting a new bridge, at no more than £100,000;—in both cases preferring to understate rather than to overstate the facts on which their recommendation has been founded;—but, as they have placed on record the evidence, parole and documentary, which they received on the general subject,—the excess of charge which might remain to be incurred if a new bridge were not built, and the excess of assets, above the amount which they have been willing to take as available for a new bridge, if such new bridge be built, will be open to the judgment of the House.

The commissioners began the works with an amount of £51,124 19s. 6d. in the funds, and a cash balance of £4,299 0s. 10½d., being the accumulations of their income above their expenditure. Since that time, besides the expenditure of their current income, sales have been made, in order to provide for the repairs which they had undertaken. These sales have reduced the capital to £10,000 Consols, giving an income, after deducting the property tax, of £291 5s. The value of their estates was estimated by their architect and surveyor, Philip Hardwicke, Esq., in 1843, at £172,521.

The aggregate of this sum, and of the funded property, might almost have sufficed, according to some of the plans before the committee of 1844, to build a new bridge; or if not, at all events to have required but a comparatively small sum from the public Exchequer in order to complete the whole structure, as well as the approaches, of a new bridge.

It is right to recollect that the case of bridges in the metropolis differs widely from the case of those in the counties of the empire; not only inasmuch as all the Queen's subjects have a common interest in their resort to her capital, and a share in the fame which its aggrandisement reflects on all her dominions; but specially, because, perhaps from this cause, the State did, in fact, erect the only bridge which for centuries existed in London; and in the last century did create, directly and indirectly, by grants from the Treasury and by money raised by lotteries, the very fund from which the present Westminster bridge was actually itself built a hundred years ago. If, therefore, it be said, that the nation does not erect bridges in the county towns of England, or did not erect the other existing bridges in the metropolis, it may be replied, that the case of Westminster bridge, built in a large part by annual votes from the Treasury, stands on different and now exclusive grounds; that the structure has been adopted by the nation; and that when Parliament enacted,—see 9 Geo. II., c. 29, s. 20,—that it should be extra-parochial, and should not be a county bridge, chargeable either to Middlesex or Surrey,—see same Act, s. 21,—it sanctioned its claim to be national, and to be sustained at the expense of the empire.

The expense however of a new bridge, if a new bridge shall be deemed essential, will not, as already shown, necessarily fall on the State exclusively. It was calculated in 1844 that a sum of £172,521 could be raised on the credit of the bridge estates, irrespective of a comparatively small amount of funded property then in the hands of the commissioners: and even deducting from the number of their houses, those which would be required for the completion of a most magnificent approach on the Westminster side, if that site should be adopted, and indeed on the Surrey side also, there will still be left, in addition to the balance of the funded property, enough to raise at least £100,000

Resolution of Committee.—In this state of things, the committee felt themselves justified in coming to the resolution which on the 15th of July they adopted unanimously,—That it is expedient that the present bridge be pulled down, and that a new bridge be constructed; and it is further expedient that a Bill be brought into Parliament next session to transfer to Her Majesty's Commissioners of Woods, &c. the property of the bridge commission; just consideration being had to the claims of those officers of that commission whose services should be discontinued.

Partial Destruction of the New Locks at Bristol.—By the pressure of the high spring tide, on the night of August 9th, at Cumberland basin, the extensive works now in progress by the dock company, with a view to widening the southern entrace lock sufficiently to admit of the ingress to the port of vessels of the capacity of the Great Western and Great Britain, were seriously injured. In order to admit of the necessary excavations and erections, the flow of the tide had to be kept out of the lock in question, and this was sought to be effected in the usual way, by driving double rows of piles and loading the interstices, so as to form powerful dams.

ON THE PROFESSIONAL EDUCATION OF THE ENGINEER AND ARCHITECT, THE BUILDER AND MACHINIST.

The Classes of Architecture and Engineering at University College, under Professors Donaldson and Harman Lewis, closed on the 15th of June. The distribution of prizes, of which we were compelled last month to defer the notice, took place on the 1st July as follows:

In Architecture.—First year's course in Fine Art: Prize and First Certificate to J. Benwell; Second Certificate to F. Lawrence (see below). First year's Class as a science: Prize and First Certificate to G. P. Boyce and F. Lawrence, equal (see below); Second Certificate to B. J. Benwell (see above). Second year's course: Fine Art Prize and First Certificate to John Pollard Seddon; Second Certificate to W. Wood Deane (see below). Second year's course as a science: Prize and First Certificate to J. G. D. Allason; Second Certificate to W. Wood Deane (see above).

In Engineering.— Prize and First Certificate to F. Lawrence (see above); Second Certificate to — Mackenzie.

The advantages of the courses of instruction followed at this Institution must be obvious to every one. It has hitherto been too much the practice for young men in this country, in almost every department of professional knowledge except the medical, to neglect a systematic elementary course of education, and to rely upon the experience of actual practice to carry them through their arduous career. The consequence has been that men of an inferior rank in society, moved by greater energy of purpose, more self-denying habits and activity of mind, have devoted their spare hours to master the elementary branches; and thus having fitted themselves for great undertakings, have stepped forward and acquired reputation and wealth, while their more *genteelly* connected competitors have been thrown in arrear by the weight of the more solid acquirements of the humbler aspirants. Nay, we feel assured, that if, in the inferior ranks of construction and mechanical science, those connected with such pursuits as buildings and machinery would make themselves acquainted with the elementary principles of science, their inventive genius would receive greater development, obstructions would be more readily overcome, and they would find less difficulty in giving reality to their conceptions. In every department of knowledge there is now a great advance, and those, who wish to succeed in the contest for wealth and fame, must prepare themselves for the struggle by their superior attainments. The student, the apprentice, the mechanic, the foreman, the clerk of the works, may, in such courses as these, learn to regard their pursuits in a methodical system of instruction and reasoning. Commencing from first principles and masters of the elements, they proceed to the consideration of their application. The choice of materials, their applicability and adaptatation for economic purposes, are brought before them; a wide and comprehensive view of the world of science is opened; they acquire the habit of reasoning with precision and of a systematic consideration of objects; they have explained to them, in addition, the finest examples; they learn the history and progressive development of invention, with the names and characters of the most illustrious men; they are also made acquainted with the value and importance of the best scientific literary works. They are thus thoroughly grounded with a fund of knowledge, which the hurry of subsequent practical life forbids their ever acquiring, and which they cannot gain in the office of the professional man. It were idle to suppose that this system can supersede the knowledge to be gained under the architect, engineer, or builder; but it completes, at all events, the practical experience acquired on the works of the master: and the education of the young man being perfected by this combination, he is enabled to follow up his pursuit, the matured and well grounded architect, engineer, builder, or mechinist, and not with the raw inexperience of unskilled youth.

Both the Professors accompanied the classes during the session to works in progress, and explained the principles which directed the conception and execution. Professor Donaldson has had to acknowledge the liberal courtesy of the Deans and Chapters of Westminster and St. Paul's, they having granted unrestricted permission to the Professor and his pupils, to visit every part of those edifices, the examination and description of which occupied in each case many hours.

To give an idea of the habits of thought inculcated in the class rooms, we transcribe merely two of the questions out of the series which the students had to answer for the prizes; and we will ask, if the qualification to answer these does not presuppose a course of previous study of incalculable benefit to the future candidate for fame:—

"Take a review of the history of architecture from the third century of the Christian era, and investigate the influences which probably caused the modifications of sentiment perceptible in the edifices of the different epochs of mediæval art in various countries."—"Supposing that the expression of a leading principle in buildings may be distinguished, accordingly as the leading lines of the elevation may be either vertical or horizontal; examine this theory by reference to the edifices of ancient and modern art, and state under what class respectively should be ranged the monuments of Egypt, Greece, Rome, and the Middle Ages."

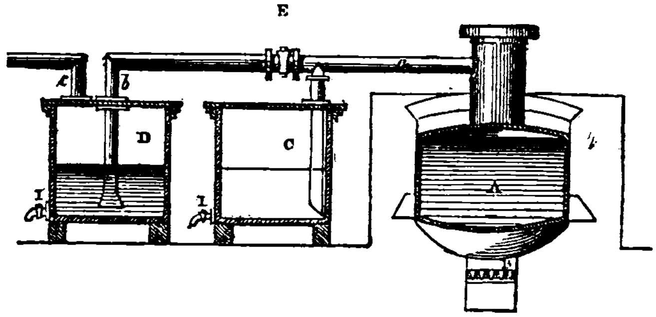
REGISTER OF NEW PATENTS.

If additional information be required respecting any patent, it may be obtained at the office of this Journal.

PURIFYING GAS.

John Robert Johnson, of Nelson-square, Surrey, chemist, for "*Improvements in Purifying Gas, and in the treatment of products of gas-works.*"—Granted December 20, 1845; Enrolled June 20, 1846.

This invention relates, first, to a new mode of purifying gas used for illumination, from those impurities which consist of ammonia and its compounds. The inventor effects the separation of the ammonia, by using the substances possessing the property of absorbing ammonia or its compounds in the dry, or more properly speaking, solid state, instead of in the state of solution, as has hitherto been practised. Among this class of substances are comprised, the solid acids, such as the phosphoric, boracic, and other acids; the salts with excess of acid, as the bisulphates of potash, of soda, and of ammonia, the biphosphates of these bases and other salts of this class; the salts of alumina, and of some other earths. Those substances which absorb the compounds of ammonia entirely, acid as well as base, entering into combination with the components of the substance used. The metallic salts, containing the requisite quantity of water, will serve more or less perfectly for the purpose required; but the salts of iron and manganese, from their cheapness, will be found preferable to others. These salts are reduced to powder, and used precisely as the moistened lime is used in dry lime purifiers.



The second part of the invention consists in a new mode of treating the ammoniacal liquor of the gas-works, for the purpose of preparing the salts of ammonia in a purer state than they have been usually obtained, and without the noxious exhalations which attend the ordinary mode of operating. The liquor is placed in a vessel A, similar to an ordinary steam-boiler, and heat applied through the furnace B. The liquor consists principally of hydrosulphuret and carbonate of ammonia, with small quantities of other salts of that base. As soon as the temperature rises, the hydrosulphuret of ammonia comes over, it being the most volatile product. A slow fire is kept, so as to volatilize this product exclusively, and during its passage is conducted by the pipe *a*, into the vessel C, containing a solution of some substance which has the property of absorbing the sulphuretted hydrogen and the deleterious gas, as the salts of iron and manganese. The product, after sufficient of the vapours have passed to saturate the material employed, is a solution of a salt of ammonia, holding in suspension the sulphuret of iron or manganese. In this plan, one vessel for holding the material through which the vapours are passed is sufficient, but if more be employed they are charged with the same solution. When lime or alkali is used to absorb the sulphuretted hydrogen, the ammonia is liberated and must be conducted into a second vessel D, charged with an acid. At the end of this part of the operation, that is, when all the hydrosulphuret of ammonia has passed over, the products found in the first vessel are sulphuret of lime and some free ammonia, and in the second a solution of a salt of ammonia. If the acid was but slightly diluted, the solution may be obtained saturated and fit to christallize on cooling. The liquid remaining in the boiler, and now consisting principally of carbonate of ammonia, may be treated in the ordinary way for preparing the salts, or the evaporation may be continued in the boiler at a higher temperature, in order to drive over the other volatile salts and the vapours passed through acid to absorb the ammonia. In the latter case the apparatus just described may be used, the cock E being opened. The vapours then pass through the pipe *b*, and through the acid in the vessel D, without entering the vessel C, containing the lime, and are then absorbed. The evaporation is continued until the volatile salts of ammonia are all driven off, when the liquor in the boiler may be rejected, unless it be found that the fixed salts remaining in the liquor are in sufficient quantity to be worth extracting, which may be ascertained approximatively by evaporating a drop of the liquor on a strip of glass, or accurately by evaporating to nearly dryness a known quantity of the liquor, and by weighing the resulting salt. These fixed salts may be obtained by entirely evaporating the liquor in a lead vessel, or by adding to the liquor, while in the boiler A, a certain quantity, more or less, according to the quantity of the fixed salts present, of sulphuret of lime in solution. This substance may be obtained from the first part of the operation when lime is used, or from the liquor of the wet purifiers of the gas-works. The sulphuret of lime decomposes the fixed salts of ammonia, liberating the latter substance in the state of hydrosulphuret, which may be treated in the same manner as that evolved in the first stage of the process.

STEAM ENGINES AND PROPELLERS.

John Seaward, of the Canal Iron Works, engineer, for "*Improvements in the steam engine, and in machinery for propelling.* Granted January 12; Enrolled July 12, 1846.—Reported in the *Patent Journal.* With Engravings, see Plate XIV.

Guide block.—The first part of this invention relates to a guide block (fig. 1) for preserving the parallelism of cross-heads of steam engines, and other machinery. *a a* are two guides, bevelled on both sides, forming angular edges, to which are fitted two sliding pieces, *b b*. *c* is a block fitted between the pieces *b b* and their respective lugs or projections, *d d d d*. Two powerful spiral springs, as shown by the dotted lines, are compressed within the block *c*, forcing the pieces *b b* against the guides, and in order that they shall not cause the friction to be too great it is furnished with two bolts *e e* on each side side, and thus regulated at pleasure; *f* is a hole for the reception of the cross-heads.

Plumber block.—Secondly, this invention relates to a plumber-block, to be used where the force acts longitudinally, or at an angle. It is fitted with two sets or pairs of brasses, one being divided longitudinally, the other vertically; the last-named are closed by keys placed vertically at the back; these are furnished with screws and nuts similar to the key of a connecting rod; the others by bolts, as usual.

Valves.—Thirdly, these improvements consist of an apparatus for working the valves of such engines as are fitted with a double set.

Fig. 2 shows a fore and aft vertical section of a cylinder fitted with a double set of slide valves; and fig. 3 an external side view of the same. *a* is a horizontal slide, which moves in dove-tailed grooves, *b b*, and is connected to the bent lever *c* by a rod, as shown by dotted lines. This lever works on a fixed fulcrum at *d*, the short end being connected in the usual way to the eccentric or other rod by which it may be worked. *e e e e* are four weigh shafts connected in pairs by the levers *f f f f*, and cross-rods *g g*. The levers A A A A on the weigh shafts are connected by links to the valve spindles, as shown in fig. 2.

Now, it will be observed that when the slide *a* is moved to the right by the motion of the engine, the tappet *h* will come in contact with the lever *i*, thereby closing the steam valve *j*, cutting off the steam at any part of the stroke according to where the tappet may be set, and partially closing the escape valve *k*, as shown in fig. 2. On the slide moving still further, the lever *i* will slide along the back of the tappet *h*, till it meets with the tappet *l*; this will entirely close the eduction valve *k*; the lever *m* will be acted on in a similar manner by the corresponding tappets producing the motion of the opposite valves as before described, when the lever *i* is moved by the tappet *l*. The toe *n* (fig. 4) is caught in the step *o*, and held in that position till relieved by the opposite toe *p* coming in contact with the corresponding step, which, it will be remembered, does not take place till the tappet *q* closes the eduction valve *s*, the weight on the weigh shaft bringing it smartly back to its original place; the spiral springs, *r r*, are for keeping the steps more effectually to their work. The tappets are fitted with regulating screws *t t*, for the purpose of altering their position so as to cut off the steam at any required part of the strokes. *u u* are rods by which the weights are hung on the weigh shaft to alter the valves for the return stroke of the engine.

Steam Pipe.—The fourth part of this invention relates to an apparatus for the better separation of the steam from the water in boilers, thereby preventing what is usually called priming; it consists of three circular concentric casings, *a b c* (fig. 5); they are attached to the upper parts of the boiler in the space occupied by the steam. *b* is fitted with a conical bottom, terminating in a pipe *d*, reaching nearly to the bottom of the boiler; the upper part of this casing is perforated with a number of small holes to admit the steam which passes up between it and the outside casing *a*, thence downwards under the inside casing *c*, where the water separates and runs down the pipe *d*; the steam again rising, passes off by the steam pipe *e* to the engine.

Screw Propeller.—Fifthly, this invention has relation to an improved method of shipping and unshipping, or in other words, raising and lowering screw propellers, and the means of fixing them to the shaft.

Fig. 6 is a view of the stern quarters of a ship fitted with these improvements. Figs. 7, 8, and 9, show some of the parts separately. *a a* is a swinging frame furnished with bearings and journals, in which the propeller revolves freely. *b b* are two sliding bearings to support the journals of the swinging frame, and guide it in its ascent or descent. The lever *c* is for swinging the frame on its bearings *d d*, for the purpose of placing or displacing the propeller on or from the shaft, which, it will be observed, is conical at the end, for its more easy entrance and removal. Fig. 8 shows part of the propeller shaft *e e* in section, having an internal shaft, the outer end of which is furnisheed with a screw *f*, the inner with a screw wheel *g*, gearing into a screw spindle by it turned round. The action of this is as follows:—The swinging frame and propeller being placed within the sliding pieces *b b*, it is lowered (by means of the chain and crab placed in the stern, as indicated by dotted lines) till, opposite the end of the shaft, the lever *c* is forced back; this will place the propeller on the shaft, and, by turning the screw wheel, the screw will enter the propeller, thereby firmly securing it. The reverse of this operation will unship the propeller. By another plan the swinging frame is dispensed with, in which case the shaft is supported by two stays, as seen at fig. 9, by dotted lines. The propeller is raised and lowered by means of two round bars, pointed and screwed at the lower ends, and placed in a vertical position immediately over two holes formed in the blades near the centre; these bars slide vertically in guides, and are connected near the lower ends by a yoke, which is attached to a crab by a chain, as shown in the last case; the boss is drawn on and secured to a conical wedge-shaped clutch on the propeller shaft, by the means before described; when it is desired to unship the propeller blades, they are placed in a horizontal position, with the holes before mentioned uppermost; the round bars are lowered and screwed into them; the shaft is then withdrawn from the propeller, and purchase applied to the crab, which will bring it above water under the counter of the ship.

The sixth and last part of this invention has also relation to propelling machinery, and is for the purpose of reducing the friction on the end thrust of the propeller shaft, by introducing a thin film or stratum of oil or water between the rubbing surfaces, which are of hardened steel. The face that receives the pressure from the propeller shaft is secured to some convenient part of the engine, or beam of the ship, and has a channel bored through to the centre of the steel face, which is turned concave about one-third its diameter, as also that on the end of the shaft. A continuous stream of oil or water is forced by three pumps through this channel into the hollow faces, and escaping at the circumference, where it is collected by a casing, is returned through a tube to the tank below the pumps; thus preventing the rubbing surfaces from coming in contact, and thereby reducing the friction.

Claim:—First, the forming of guide blocks of steam engines of three several pieces, having springs and adjusting screws, as before described.

Second, the improved compound plumber block, having two sets of brasses, one pair divided longitudinally, the other vertically, as before described.

Third, the working of steam engines having double slide valves, by means of horizontal slides having double tappets at each end, as before described.

Fourth, the adaptation of an apparatus to steam boilers, for the prevention or lessening of priming, as before described.

Fifth, the methods of connecting and disconnecting the propeller to or from the shaft, in screw-propelled vessels, as before described.

Sixth, the means of reducing the friction consequent on the end thrust of the propeller shaft, in screw-propelled vessels, as hereinbefore described.

PLATE AND SHEET IRON CUTTER.

William Vincent Wennington, of Goscote iron-works, Staffordshire, Esq., for "*Improvements in or improved methods of cutting plate and sheet iron.*"—Granted January 20; Enrolled July 20, 1846. With Engravings, see Plate XIV.

The improvements consist in the combination of a rotary and horizontal continuous movement, by which means plates of iron of any length may be cut without curling or buckling. The rotary movement consists of a circular cutter *a*, set in motion by the gearing hereafter explained and the horizontal movement of another cutter *b*, attached to the traversing table *c*, upon which the iron plate is laid. An alternate rotary motion is produced by the circular cutter *a* being fixed on one end of a shaft *d*, revolving in bearings fixed between the standards *e*, and over the bearings are regulating screws *f f*; on the other end of the shaft is a bevelled wheel *g*, which takes into either of the bevel wheels *h* or *i*, keyed on to the hollow shafts *j j*, and which slide on the main shaft *k*, set in motion by steam or any other known power. For the purpose of giving a horizontal movement to the traversing table, there is a cog wheel keyed on to the shaft *d*, immediately at the back of the cutter *a*; this cog wheel takes into the rack *l* and causes the table *c* to move on the Λ rails *m m*. On the under side of the table are tappets *n*, which act on a lever, *n'*, fixed on the small shaft *o*; and at the other end is a forked lever *p*, which acts on the clutch *g*, for throwing the bevelled wheels *h i* in and out of gear; thus an alternate backward and forward movement is given to both the revolving cutter *a*, the traversing table *c*, and cutter *b*.

The claim is for the combination of a rotary and horizontal motion for cutting plate and sheet iron.

COKE OVEN.

Jabez Church, of Colchester, Essex, gas engineer, for "*Improvements in manufacturing coke.*"—Granted December 20, 1845; Enrolled June 20, 1846. With Engravings, see Plate XIV.

The improvements consist in the construction of coke ovens with regulators, valves, and flues for admitting cold air to the inside of the oven during the manufacturing process and to cool the coke within the oven at the end of the process. Fig. 1 shows one half of the front elevation and one half of the transverse section of a coke oven; fig. 2 the side eleva-

tion; fig. 3 one half of a horizontal plan of the cooling passages under the oven, on a level with the line Y Y, and one half of the plan of the oven on the line Z Z. The other half in each figure is similar in construction to the half shown in the engraving, and similar letters refer to similar parts in each figure.

A is the mouth-piece of the oven (see enlarged view, fig. 4) with a temporary wall of bricks *b*, built up as the coke is put in; *c* cast iron door with oblong apertures *d*, fitted with vertical slides *e*, for regulating the size of the apertures, or entirely closing them; *f f* are two passages on each side of the oven mouth, fitted with regulating valves and inclining upwards towards the top of the interior of the oven; *g* is the floor of the oven; *h* the flue leading from the interior to the chimney *i*. *j j* (fig. 1) are two vertical pipes with hinge caps and covers, opened by the dependent chains, to allow the escape of the air employed for the cooling down process from the interior of the oven to the external air. *k k* (figs. 2 and 4) are two openings with regulating valves, *l l* (fig. 4), through which, after the coal has been converted into coke, the cold air is introduced to the horizontal passages *m*, under and round the oven (but not communicating with the interior), for cooling down the coke: Those parts marked *n* between the brickwork forming the passages are filled in with concrete. The mode of operation is as follows:—The floor of the oven is covered with coal to the thickness of about two feet, the surface inclining a little from the front and sides towards the centre; the brickwork *b* to the oven mouth is built up as the coal is introduced, and the bricks luted with fine clay; a shovelful of burning coal is thrown in at top, and when the coal is fairly ignited the regulators of the door *c* are then closed; the apertures *d*, as well as the passages *f f*, are kept open until the coal is fairly ignited, and at the same time, the passages *k k* are kept entirely closed. At the conclusion of the process, the valves *l l* of the openings *k k* are opened, for admitting cold air to the chambers *m*, to cool down the coke, and at the same time the caps of the exit pipe *j j* are taken off. The coke is not to be removed from the oven until it has been thorougly cooled down.

Another part of the patent is for the application of electricity to purifying of coke from sulphur and other metallic mixtures, which is done in the following manner:—As soon as the flame on the surface of the ignited coal begins to die away, the apertures *s* of the door *c* and *f f* are closed; an iron rod is then introduced through the temporary brickwork of the mouth into the coke near the bottom, and passed through to the back of the oven to the flue *h*. A second rod is passed over the surface of the coke, so that it shall rest and be in contact with it. The former rod is connected with the positive pole of a powerful electric battery, and the second rod with the negative pole by means of copper wire, leaving the body of coke in the oven to complete the electric current. If the mass of coke be equal to six tons, it ought to be subject to the electric action for about two hours.

TANNING.

Robert Warrington, of Apothecaries' Hall, London, for "*Improvements in the operation of Tanning.*"—Granted March 25; Enrolled July 25, 1846.

This invention consists in the application of certain mixtures or compounds to be employed in the process of tanning hides or skins, the several mixtures being divided into three classes, which are as follows:—First, in order to prepare the skins for unhairing, the inventor proposes to employ carbonate of soda or potass, in the proportion of from one to two pounds to ten gallons of water. The second class is also intended to prepare the skins for unhairing and also to swell them, for which purpose the inventor employs various agents, such as baryta, potass, and soda, dilute muriatic, nitric, oxalic, or any other acid, except sulphuric acid. The third class consists of vegetable matters, such as rhubarb, sorrel, apple, mare, vine cuttings, and other similar vegetables, which may be economically employed. In the first class, from half-a-pound to two pounds may be added to ten gallons of water, the same being rendered caustic by the addition of fresh burnt lime; of the second class, the inventor prefers about the same proportions of muriatic acid, of specific gravity 1·17, to the same quantity of water; of the third class, the inventor prefers to employ culinary rhubarb. The following is a summary of the claim:—First, the application of carbonate of soda or potass when soaking the hides or skins, for facilitating the removal of the hair; second, the employment of baryta, soda, potass, and muriatic, nitric, oxalic, or any other acid, except sulphuric, together with the above named and other similar vegetable matters, for facilitating the removal of the hair and also swelling the hides or skins. He also claims the application of vegetable matters and chemical agents for retarding oxydation, which agents are to be used with the tanning liquor; and lastly, he claims the application of bi-carbonate of potass and dilute sulphuric acid for preserving the skins and other animal substances.

RAILWAY SAFETY BUFFER.

Edwin Chesshire, of Birmingham, for "*Improvements in apparatus to be applied to railway carriages to reduce the prejudicial effects of collision to passengers in railway carriages.*"—Granted February 3; Enrolled August 3, 1846.

The apparatus consists simply of a strong straight inflexible rod of either iron or wood, or both combined, placed longitudinally under the centre of the carriages; the ends of the rod are to have enlarged heads, and the length of the rod to be somewhat less than the carriage, to which it is attached, and the buffers when in ordinary contact. This rod, which the inventor calls a "safety buffer," is not intended to have any effect in stopping the motion of the train in the usual manner, but only when a violent collision, either before or behind, occurs,—then the heads of all the bars will be brought in contact, and "form one straight, inflexible, unyielding bar," by which means the effect of the collision will be neutralised.

ELECTRIC LAMP.

William Greener, of Birmingham, gunmaker, and W. E. State, of Peckham, Surrey, Esq., for "*Improved means of ignition and illumination.*"—Granted February 7; Enrolled August 7, 1846.

The invention is for the purpose of effecting illumination of public and private buildings, streets, &c., by means of solid or hollow prisms or cylinders of carbon (purified from impurities), or rods or strips of platinum, or other difficult fusible metal, enclosed in transparent air-tight vessels, and rendered luminous by passing currents of electricity; the carbon or metal is to be divided on the surface into numerous acute points. Hollow cylinders of carbon may be used, partially inserted within, and placed in perfect contact with, hollow cones of platinum, either plain or acuminated, and enclosed as before described.

CEMENT.

John Keating, of North Mews, Fitzroy-square, Middlesex, scagliolist, for "*Improvements in the manufacture of cement,*"—Granted February 11; Enrolled August 11, 1846.

This invention consists in mixing borax with gypsum (sulphate of lime) in the following proportions:—5 lb. of borax and 5 lb. of crude tartar are each to be dissolved in 6 gallons of water, and when dissolved the two solutions to be mixed together. Gypsum in lumps (first deprived of its water of crystallization by heat) is to be put in this solution till it has absorbed as much as it will take up, and then put in an oven and heated red hot; afterwards it is allowed to cool, and ground, and then again mixed with the above solutions and heated in an oven; when taken out, it will be ready for use.

LOCOMOTIVE ENGINES.

George Stephenson, of Tapton House, Chesterfield, engineer, and William Howe, of Newcastle-upon-Tyne, mechanic, for an "*Improvement in locomotive steam engines.*"—Granted February 11; Enrolled August 11, 1846.

The improvement consists in the application of three steam cylinders to locomotive engines, two to be of the same diameter and capacity, and together to be equal in capacity to one large cylinder. The pistons of all the three cylinders are to move simultaneously in the same direction; the large cylinder is to be placed exactly in the longitudinal central line of the engine, and the other two cylinders on each side at equal distances from it. The piston of the centre cylinder is to drive a crank on the axle of the impelling wheels, and the pistons of the two smaller cylinders are to be connected with crank pins fixed on the naves of the driving wheels; the crank to be fixed at right angles to the crank-pins. The intention of this arrangement is to neutralise any tendency that the oblique action of the connecting rods on their crank-pins may have to produce a lateral vibration on the supporting springs of a locomotive when travelling very rapidly.

RAILWAYS AND CARRIAGES.

Conrad Haverkam Greenhow, of North Shields, Esq., for "*Improvements in the construction of railways and railway carriages.*"—Granted January 6; Enrolled July 6, 1846. With Engravings, see Plate XIV.

The improvements relate, first, to forming the tyre of the wheels and rails so that they can be adjusted and adapted to each other. This is effected by using a convex rail and a peculiar formation of a concave wheel tyre, combined with inclined spokes, whereby, in the event of one rail sinking below the level of the other, the tyre of the sunken wheel will bear on the rail with an increased diameter, so as to compensate in surface motion for the depression; and from the peculiar concave shape, the wheel and the rail will maintain a correct adjustment in respect to each other. Notwithstanding any varying elevations and depressions of parts of the length of rails, the wheels on the opposite rails will at all times be running on such diameters as to make the distance moved through (by the common axle) the same, without any drag or friction corresponding with that heretofore consequent on the flanges, when moving against rails similarly circumstanced. And owing to this constant adjustment between the running surfaces of the wheels and the rails, the rails may be laid with the gauge so correct as not to allow of any play, for the adjustment which takes place will prevent, or tend to prevent, any rebound from rail to rail, besides there will be no tendency to run off the rail; and should there be any impediment to the wheels on one of the rails, those wheels may rise over such impediment without injury, owing to the opposite wheels retaining their correct contact with their rail, so long as the raised wheels do not rise off their rail to an extent which will throw the diagonal line on the opposite wheels beyond the perpendicular line.

Figs. 1 and 2 show the section of rails upon the improved form, which may be of wrought or cast iron. The inventor does not confine himself to the section shown, but the rail is such that the surface on which the wheels come is to be a portion of a cylinder, and part of the running surface of the wheels is to be struck to the same radius; hence, the two cylindrical surfaces will correspond. Fig. 3 shows a section of one of the wheels on an axle, and also one of the rails; the spokes are to be set at an angle of 22½°. Fig. 4 is an enlarged view of the rail and tyre.

The second improvement relates to suspending the body of the carriage *a*, as shown in figs. 5 & 6, on axes at each end at *b*, bearing on uprights *c*, fixed on the frame of the carriage *d*; the body is prevented oscillating by means of chains or straps *e*, which allow sufficient movement to the body as may be required. The frame *d* is fixed on the springs mounted on the lower frame *e*. The claim is for combining the suspension, as described, with the use of straps or chains.

The third improvement relates to applying "an uncontrolled locking action to the axles and wheels of railway carriages," as shown at fig. 7. *a* is a strong bar formed into the arc of a circle, sliding in bearings *b*, fixed on the frame; the bearings *c* of the axle of the wheels are made fast to this bar, and can only move within a short space, there being stops at *d d*. By this means, when a carriage is going round curves, the wheel accommodates itself to the curve.

REVIEWS.

Metropolitan Bridges and Westminster Improvements. By Sir Howard Douglas, M.P. Second edition. London: Boone, 1846. pp. 27.

The second edition of Sir Howard Douglas's pamphlet appears opportunely at a time when much public interest has been excited by the report of the dangerous condition of Westminster Bridge, and the proposal to replace it by a new structure. The old bridge was erected about one hundred years ago, and considering that it was built with scarcely sufficient strength to resist the comparatively gentle current of the Thames when its tidal waters were impeded by the huge piers of old London bridge, it would need no prophet to predict that the removal of those obstructions must ultimately involve the destruction of Westminster bridge also. The pamphlet before us describes the defects in the original construction, and the progress of the consequent injuries, but as these subjects are investigated with considerable minuteness in the official report now before the public, it is not necessary to enter into detail respecting them here. We shall prefer giving one or two extracts in which Sir H. Douglas describes his proposition for the improvements between Charing Cross and the river.

"All that can be expected from the expedients which have been tried is, that they may retard the ruin, which nothing, in fact, can avert—so that, with proper precautions, the bridge may serve as a temporary means of communication while a new one is being constructed; but even for this it would be prudent to lighten it as much as possible, by removing the masses of materials which form the foot-path on both sides, down to the level of the carriage-way, and to replace the stone balustrades, with a temporary railing or parapet of wood. Should the piles, which form the present caisson or cofferdam about the pier on the Surrey side, be not removed, they might be cut down; and if that or any other pier should seem to be in danger of settling further by the deepening of the water-ways, the expedient already proposed, of paving the bed of the river in those parts, or depositing there masses of stone, might be adopted as a temporary measure. It is somewhat remarkable, that, notwithstanding the defective mode of construction of Westminster bridge by caissons, and the large sums of public money laid out in vain attempts to rescue this bridge from destruction, it should be seriously proposed to adopt the like expedient on an immense scale in Dover Bay:—to strand caissons containing large portions of ready-made break-waters in 7 or 8 fathoms water for the formation there of a harbour of refuge! A new bridge cannot be constructed on the present site without previously removing the old one; and this would involve an expense of at least 40,000*l.* in erecting a temporary bridge, to avoid stopping altogether, the communication between the Borough and Westminster, whilst the new work is proceeding. There is no room for a new bridge between the Parliamentary Palace and the present bridge, for these are already in contact; and the construction of a bridge any where below the present site, say from Maudslay's premises to Manchester buildings, would occasion a very great outlay in providing new approaches. But, if leaving Westminster bridge, in its present state, as a temporary communication, a new bridge were constructed from Lambeth stairs to the nearest part of the opposite bank, no expense for new approaches would be incurred, a direct communication with Westminster would be established, and a magnificent entrance into the capital formed, at an interesting and venerable part. The river face of the new Parliamentary Palace, would be seen to great advantage; and, no longer disfigured and obscured on the other flank when the distasteful structure which now defaces it shall have been removed, the edifice standing gracefully and boldly out, would form a beautiful object upon the concave sinuosity of the river, extending thence to Blackfriars' bridge, and Somerset House, which, for this purpose, should be reclaimed from its present unwholesome and disgusting state by the proposed embankment and terrace, which it were easy to show is an interference with the state of the river much required at that part,—and thus that pestilential locality would be transformed altogether into a beautiful and highly embellished portion of the metropolis. From the Westminster end of this new Lambeth bridge, a street should be opened to lead directly to Shaftesbury terrace, Eaton and Belgrave squares, or to communicate with some part of that which is now being executed under the provisions of a late act, &c.; and another formed by the river bank, to Victoria Tower and Whitehall, passing between Westminster Abbey and the Parliamentary Palace. Entering the Court end of the town by this magnificent portal—St. Margaret's church removed, in conformity with the unanimous recommendation of a Select Committee, from the immediate vicinity of a splendid and ample place of worship, which requires not the aid of an adjoining church, and the relics which lie around that incongruous building, exhumed—the western face of the quadrangle, by which, according to the present design, it is intended to enclose Westminster Hall, set back, to give greater space between it and Henry the Seventh's Chapel;—Parliament street widened, by removing the block of buildings between it and King-street—Downing-street finished—and the Board of Trade completed, a majestic communication would be formed, between the Regal and Parliamentary Palaces; and if Whitehall-street may not, or cannot be straightened throughout, those buildings at least should be thrown back, which, on approaching Trafalgar-square, obtrude, more immediately on the left, to destroy its symmetry."

The last sentence of this extract pleases us but little. We would much rather see St. Margaret's Church restored than destroyed. It was once one of the most magnificent churches in London, as those who have seen the old prints of it can testify; the work of desecration has, it is true, proceeded very far, but not beyond remedy; and in the hands of a judicious architect St. Margaret's Church might once again raise its head unmarred by the vile barbarisms of the last age. The desire of removing this structure for the purpose of obtaining a clear and uninterrupted view of Westminster Abbey, proceeds from ignorance of the true principles of Pointed Architecture, which always appears most beautiful when it affords picturesque combinations of numerous detached parts. We accordingly see that the mediæval architects loved to group a great many different structures together, and adjacent to a cathedral usually erected its cloister, chapter house, baptistery or collegiate buildings. It is precisely this combination of a crowd of pinnacles and towers, steep roofs and massive buttresses, from which arises the magnificence of a pile of Pointed buildings: and for this reason also (though there are many others) the demolition of an ancient church in the neighbourhood of a cathedral can never be justified except on the plea of unavoidable necessity. St. Margaret's is at present covered over with a thick coating of plaster, the tracery of the windows has been destroyed, the panel-work of the tower concealed by stucco, the finials and crockets churchwardenised; but great as are these injuries, they are not past all surgery, and we unhesitating repeat that a judicious restorer of this ancient church would have the honor of adding one more to the number of beautiful buildings with which this interesting spot is crowded.

For the same reason that we would retain St. Margarets' Church we would resist any project for erecting a continuous pile of buildings concealing Westminster Hall. The irregular outline of the Palace of Westminster on the Abbey side is far more in accordance with the spirit of Pointed architecture than the flat unbroken surface of the river front. It is most desirable that the present pseudo-classic law courts should be removed, and that the magnificent flying buttresses on either side of Westminster Hall should be displayed; but the proposition for enclosing it altogether is unjustifiable. Neither do we see the necessity of throwing down the buildings which "on approaching Trafalgar-square obtrude more immediately on the left to destroy its symmetry." We quite concur with the general opinion that for the sake of the national character for good taste, Trafalgar-square ought to be kept out of sight as much as possible.

To turn to a different subject, we must notice what seems an error of principle in a note (p. 7—14), the object of which is to prove that Hungerford bridge is not built with sufficient strength. It is first shown that the utmost load which can by any chance be put on the bridge at one time is less than one-third of the weight which would impair the chains. This excess of strength is pronounced insufficient; but the opinion is not confirmed by very conclusive reasoning: among other things the curve of the chains is assumed to be a common catenary, which it is not. The note then proceeds

"There is one additional point still to be noticed, namely, the pressures on the piers. It is shown by writers on mechanics, that the horizontal strain at every point of the chain is the same, and equal to the tension at the lowest point of the curve. When a bridge is properly constructed, the catenary on the other side of the pier is a portion of the same curve as the first. The horizontal strains on the two sides of the pier will then be equal, but in opposite directions, and, therefore, they will counteract each other: the two vertical strains will also be equal, and in the same direction: and as it is evident that each of those strains is equal to half the weight of the chain between the piers, the vertical pressure on each pier is equal to the weight of this chain. (See *Military Bridges*, p. 311). In the case of the Hungerford Bridge, however, the catenaries at the two ends when completed, have a considerably less span than the central curve, but they have the same droop or deflection. Hence if $2y$ be the span of the centre arc, $2y'$ the span of the curves at the two extremities when completed; and a, a', the corresponding tensions at the lowest points, we have

$$a = \frac{3y^2 + x^2}{6x} \qquad a' = \frac{3y'^2 + x^2}{6x}.$$

And as y' is considerably less than y, a' will evidently be less than a in a still higher ratio. Hence there will be a constant horizontal strain, equal to $(a - a')$ acting at the top of each pier, (which the ingenious contrivance of the shifting saddles at the summits of the piers cannot remedy,) which will of course tend to pull and shake the piers, and may ultimately overthrow them, founded as they are, without underpiling, on the natural bed of a river, which is continually becoming deeper."

The conclusion here arrived at is erroneous, and the error arises from the application of a formula to a case with which it has no connection. The value given for a' is taken from the expression for the tension in a chain at its lowest point, when the chain is suspended between two piers of the same weight, and *the lowest point is consequently horizontal.* But here the shorter chain at the end where it is attached to the abutment on the banks of the river is inclined to the horizontal at a considerable angle. Moreover if the saddle (which is furnished with friction rollers) were acted upon by an accelerating force $a - a'$, it would be set in motion. And lastly, however, the question may be complicated by mathematical symbols, the general truth remains indisputable, that the pressure of the rollers upon the top of the pier is normal to the surfaces in contact, and is therefore wholly vertical. Consequently the reader, whether acquainted or unacquainted with mathematics, will not have much difficulty in concluding that the danger of the piers of Hungerford Bridge being overthrown by the unequal strain of the suspension chains is purely imaginary.

A Critical Dissertation on Professor WILLIS'S *Architectural History of Canterbury Cathedral.* By CHARLES SANDYS. Smith, Old Compton-street. 1846. pp. 62.

Canterbury Cathedral is in one respect pre-eminent beyond dispute above all other ecclesiastical edifices in England; more has been written about it than about any other. Not only is its library rich in manuscript chronicles and records of the erection of different parts of the building written contemporarily by resident Monks, but the number of Itineraries, County Histories, &c., of comparatively recent date, in which this cathedral is described as unequalled with respect to similar buildings.

The work of description seems to have gone on nearly continuously from the time of the Conqueror to the current year 1846, and probably is not yet finished: for the dissertation by Mr. Sandys, is of too controversial a nature to remain long without an answer. We have no intention of plunging ourselves or readers into the labyrinth of a purely antiquarian discussion; still as the name of Professor Willis of itself carries considerable interest with it, and as his opponent has displayed great learning and accumen in conducting the controversy, a good many architectural readers will be anxious to know what the dispute is about.

Simply this: Professor Willis ascribes the architecture of a large part of the Cathedral to an architect who, Mr. Sandys says, has no claim to the merit. There is something very laudable in this anxiety to commemorate not only the building but the name of the builder, which might be imitated with advantage in more modern instances: still we apprehend that the question whether Archbishop Anselme built merely the choir of the present cathedral, or the external walls of the choir-aisles, the Trinity chapel, and the east transept also, will not attract so large a share of public attention as to render it incumbent upon us to give more than a brief outline of the discussion.

The dispute seems of long standing. We have before us an old and we believe rather scarce copy of Somner's Antiquities of Canterbury,* published in 1640 (the *imprimatur* is dated from Lambeth, October 1639.) Now Somner alludes to the subject of this very dispute—namely, what parts of the cathedral are to be assigned to Anselme and Ernulph—in the following terms.

"*Matthew Paris* Records a dedication of the Church of *Canterbury* in the yeare of Christ 1114. being the yeare of Anselmes death. Haply it was of that new piece or new work, as Edmerus cals it. This doubtlesse is the part meant by *Malmesbury*, ascribed to *Ernulphus* the then Prior of the Church, and of him (erroniously it seemes) said to have beene built in the place of a like part then demolished, whereof he hath these words *Cantiæ* (saith he) *dejectum priorem partem ecclesiæ quam Lanfrancus ædificaverat, adeo splendide erexit, ut nihil tale possit in Anglia videri, in vitrearum fenestraum luce, in marmorei pavimenti nitore, in diversicoloribus picturis quæ mirantes oculos trahunt ad fastigia lacunaris.*"

The above extract proves at least thus much, that there has long been a dispute respecting the architects of the eastern part of the church. Mr. Sandys has not referred to this circumstance; he gives however the Latin sentence from Malmesbury, with his own translation, which commences "Ernulphus having thrown down the *front* (or fore part) of the church which, &c." It may be observed that the assumption that Ernulph was the author of the work of demolition is Mr. Sandys's own. The original Latin simply states that part of the church was thrown down—but does not inform us whether destruction was accidental or intentional, or who was the destroyer. The whole dispute turns on the interpretation of the words "priorem partem," which Mr. Sandys takes to mean the choir and no more; whereas Mr. Willis gives the phrase a much wider signification. The former takes it to mean the choir, the latter the whole eastern part of the church. Might we not translate *priorem* simply "former" or "older"? In that case the meaning of the quotation would be that "Ernulph rebuilt an older part originally erected by Lanfranc, which had been thrown down."

The author in the present dissertation gives several extracts from Edmer, &c., in confirmation of his opinion, but his translations are in one or two cases made more favourable than they ought to be, for his own side of the question. For instance, "*super hæc, ipsum oratorium quantum a majore turri in orientem porrectum est, ipso Patre Anselmo providente disponente, auctum est.*" he translates thus, "Moreover this oratory [choir or chancel] so far as it stretches from the great tower eastward was enlarged, Anselm himself providing for and directing the works." The words *super hæc* are not represented with sufficient force in the translation. *In addition to these things* Anselm enlarged the oratory *itself*—meaning that he had undertaken other works besides that. This interpretation, if it do not specifically assign to Anselm the works which Professor Willis assigns to him, at all events leaves room to suppose that he did more than Mr. Sandys would have us believe. He neglects also the word *ipsum* which adds force to the *super hæc*: and his assumption that *oratorium* means the chancel or choir is at least controvertible. An oratory is a place of prayer in distinction to auditorium, the place for hearing. We may therefore suppose every part of the church set apart for prayer, to be included in the word *oratorium*. Mr. Sandys quotes the expression *finis ecclesiæ ornabatur oratorio beatæ Matris Dei Mariæ*, and this instead of confirming his interpretation seems to show that there were all over the church parts distinguished by the appellation *oratorium*, which therefore is not limited to the choir. The sense of the passage seems therefore—that in addition to other works Anselm's labours extended to that part of the church which is devoted to prayer, and that he enlarged so much of it as was built to the east of the great tower (intimating, it may be surmised, that there were parts to the west also set apart for prayer.)

Mr. Sandys states, page 43, as a conclusive objection to Professor Willis's opinion, respecting the architect of the present Trinity Chapel, that Lanfranc is expressly stated in the Latin history to have been buried in Trinity Chapel, which must therefore have been standing at the time of his death. But this difficulty is entirely got over if we suppose Trinity Chapel to have been one of those parts of Lanfranc's works which were subsequently destroyed and then rebuilt by his successors.

In an architectural point of view it seems difficult to suppose that Anselm could have enlarged the choir without rebuilding the choir aisles and their external walls. There seems nothing unreasonable in Professor Willis's supposition that "the increased space must have affected all the arrangements of the choir of the monks."

We throw out these suggestions merely to show that Mr. Sandys arguments are not of such a nature as to preclude reply. We are tolerably well acquainted with the architecture and history of Canterbury Cathedral, and

* Mr. Sandys quotes from the same book, but from a much later edition: the original work is the more interesting because written before the commencement of the Civil wars, in which the Cathedral greatly suffered.

ave examined the choir with Mr. Sandys's book in our hand, but confess ourselves unable to form a decisive opinion on this question. There is no doubt that Professor Willis's reply will clear up many apparent difficulties: at the same time Mr. Sandys has the merit of arguing his case acutely, and of duly acknowledging the learning and research evinced by his opponent. The following extract from the publication before us is selected rather as a specimen of the general style than as referring to the particular question above alluded to—there is little in it which will gratify the lovers of mongrel architecture.

"*The Dark Ages (16th to 19th Century.)*—England at the commencement of the sixteenth century possessed in its cathedral and parochial churches, abbeys, priories, and other monastic and conventual structures, the most splendid specimens of the Saxon, Norman, early English, decorated, and perpendicular styles of architecture; whilst Henry VII, in his newly erected chapels at Westminster and Cambridge, had carried the florid Tudor style to the utmost perfection. These temples were, however, the abodes of the most abject and degrading superstition, of the most revolting and disgusting idolatry. Hence arose the fierce and bitter contest between truth and error, between the pure and undefiled religion of the gospel, and the legends, lying miracles, and extravagant pretensions of the See of Rome. This struggle terminated in the Reformation. Glorious as was the emancipation of the human mind from the degrading influences of superstition and Papal tyranny, yet we cannot but deplore the iconoclastic zeal of the reformers and puritans, which, not satisfied with removing the idolatrous shrines, altars, and chantries, violated the sacred repositories of the dead, destroyed the tombs and sepulchral monuments which pity had raised to the memory of departed worth, and levelled to the dust some of the most beautiful remains of the architectural skill of our forefathers. Then also arose the Royal Ruffian, at whose name humanity shudders, and religion herself grows pale! This ruthless tyrant having dissolved the monasteries, extorted from his parliament a grant of the possessions which were annexed to them, a large portion of which he afterwards parcelled out amongst his courtiers and flatterers. This led to the rapid decline, and at length, total extinction of English ecclesiastical architecture, and the revival of the classical style, (shortly afterwards introduced from Italy,) completed the downfall of a science which had for many centuries been the pride and glory of our country. In these more enlightened days we are astonished that men of the greatest genius should so long have continued blind and insensible to the sublime beauties of our native architecture. But to show their utter ignorance and contempt, they have even branded it with the approbrious name of 'gothic.' Inigo Jones (the English Palladio) with most inharmonious taste, added a *Corinthian portico* to the west front of the venerable gothic cathedral of St. Paul, London; and Sir Christopher Wren (struck with its want of harmony) afterwards wished to replace the whole of the gothic church by another to accord in style with Inigo Jones's classical portico. This scheme, though opposed at the time, was afterwards rendered inevitable by the great fire of London, which involved both the gothic cathedral and its classical portico in one common ruin. So great indeed was the darkness of this period, that even Addison's cultivated and enlightened mind could not appreciate the exquisite beauties of Gothic architecture. It is at once amusing and instructive to hear his remarks. .... If to the illustrious names of Inigo Jones, Wren, and Addison, we add those of Somner, Battely, and Gostling, (the learned historians of Canterbury Cathedral), no admirer of that venerable and exquisitely beautiful church will censure us for appropriating to the last three centuries the opprobrious appellation of 'the Dark Ages.'"

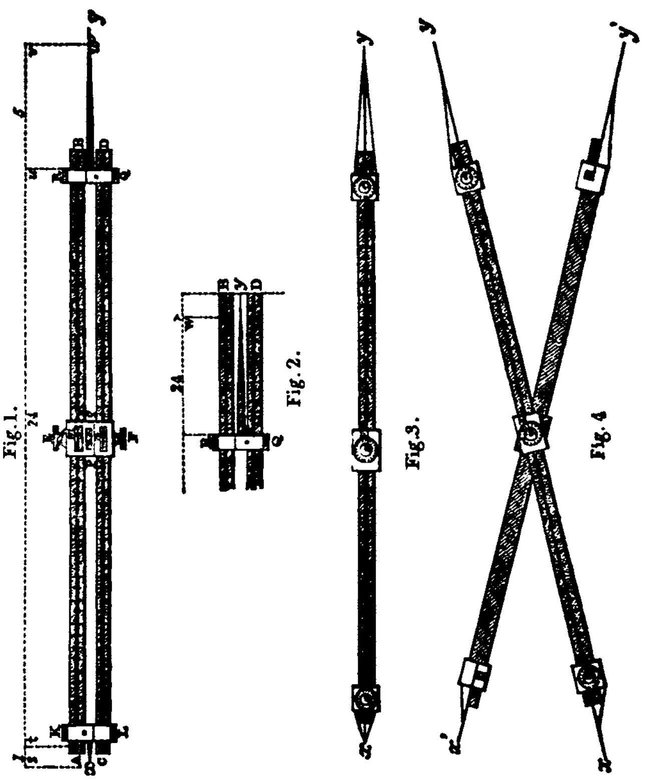
Our author might have added that the ignorance of the true principles of architecture extended to the Classic as well as the mediæval styles. It is not so many years since a great architectural authority expressed his opinion that the Parthenon would be improved if surmounted by a steeple!

Mr. Sandys scolds Professor Willis for not describing the restorations which the present Dean and Chapter have effected in the cathedral, under the supervision of Mr. Austin, their architect. Why did not Mr. Sandys supply the omission? He is an inhabitant of Canterbury, and probably has had ample means for fulfilling the task.

Description and uses of the Byrnegraph, or new proportional compasses, an instrument for multiplying, dividing, and comparing lines, angles, surfaces, and solids: by Oliver Byrne, formerly Professor of Mathematics, College for Civil Engineers. Adlard, 1846; pp. 38.

The purposes of this publication are the explanation and illustration of the uses of an instrument invented by Mr. Byrne, to which the British Association has given the not very descriptive appellation of the "Byrnegraph." The object of this invention is to attain increased accuracy in the use of proportional compasses, or rather, to so extend the use of them, that the improved instrument bears to its prototype much the same relation as a Manton to a matchlock.

With the old proportional compasses, lines could not be reduced with even tolerable accuracy to less than one-ninth their original size; but, by combining with them the vernier scale, the new instrument not only effects much greater reductions with perfect accuracy, but may be made to indicate proportions which extend to several places of decimals. For instance, at page 26 is explained how the compasses may be set to the proportion 1 : 3·1416, the ratio of the diameter of a circle to its circumference. These refined adjustments are perfectly unattainable with the old instrument. Fig. 1 is a side view of Mr. Byrne's invention, of which fig. 3 represents the plan when the instrument is open; fig. 4, when it is shut. Fig. 2 is a separate view of one end of the compass.



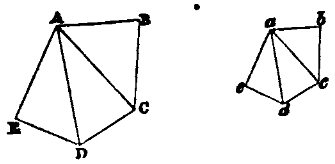
The principal feature of the invention is that the moveable centre E F, about which the two arms turn, is provided with a vernier, and that the points x, y, are moveable and also provided with verniers. Beside this, there are tightening screws to fix all the points when they have been adjusted.

"The framework of this instument may be made to assume different proportions and forms for the sake of ornament, compactness, or convenience, according to the fancy or design of the maker; the first completed was constructed by Cary, 181, Strand, London, and explained at York, before the British Association, in 1844. A view of the instrument, which we shall describe, is given (fig. 1); it differs but little from that constructed, according to the directions of the inventor, by Désiré Lebrun, of Paris. The two boxes E p q, F p q, are so adapted to the beams AB, CD, that they may be moved together by sliding to any part and fixed in that position by tightening the clamp screws E and F. When the moveable centre E p q F, is clamped in any position, the instrument turns on an imaginary line or axis passing through EF, perpendicular to a plane passing through P q, the junction of the boxes E p q, F p q, the friction of the planes meeting at pq renders the motion uniform. Connected with the brass boxes at K and L are two points of the instrument meeting at x: at K and L there are two clamp screws to fix the boxes, which must be moved together. When the points are in their proper places, the proportions of the instrument that we are describing are these:—Suppose $st=1$, then $tu=24$, and $uv=5$. The points at x are represented in proper adjustment, but those at y must be moved till y comes up the line v w, and then made fast by the clamp screws at Q and R."

The faces of the arms are graduated to four scales, which mark the proportions for straight lines, circumferences of circles, surfaces, and solids, respectively. Tables of the numbers corresponding to these graduations are given in the publication before us, and as instances of the application of them, we quote the following problems, taken at random:—

"In the circumference of a circle A B B′ it is required to lay off an arc equal to 3° 39′ 37″·26."—Page 20.

"Let it be required to describe a figure *abcde*, similar to A B C D E, whose area will be $\frac{1}{17}$ of it."—Page 21.



"Let it be required to construct a parallelogram whose area shall be equal to that of a given circle."—Page 26.

"Describe a circle whose circumference will be 11¾ inches."—Page 27.

"Given the diameter of a globe, to find the side of a cube whose solidity will be equal to that of the globe."—Page 28.

"In a certain construction the square root of 33 equal parts is required with great accuracy; at what point must the centre be set to effect this object?"—Page 28.

Mr. Byrne has not spared his labours. The tables which he has given for the purpose of graduating the instrument are very extensive and carried to a greater number of places of decimals than would be generally required in practice. The explanations are so ample and precise that, with this book before him, the draughtsman can never be at a loss respecting the various problems which he is constantly called upon to solve by practical construction. It has been remarked truly that, while the theodolite, sextant, and other instruments of surveying, have been brought to extraordinary perfection by the refinements of modern ingenuity and workmanship, the constructions obtained from these exact instruments are reduced in a very rude manner. While almost everthing that could be done for attaining accuracy in the original trigonometrical operations has been effected, the means by which they are rendered practically available have been comparatively disregarded until the invention of the simple instrument which we have been describing.

Proposal for a general Metropolitan Railway. By J. C. H. Ogier, Esq., Barrister-at-Law. London: Weale, 1846. pp. 14.

This pamphlet is published in the form of a letter addressed to the Commissioners for inquiring into the various railway projects of which the termini are proposed to be established in or near the metropolis; the object of the letter is the discussion of a plan for uniting the various metropolitan railways in such a manner that they may be rendered accessible from every part of London. The impartial opinion of an unprejudiced person, on a subject usually debated with reference to individual interests, is generally worth having: and accordingly in this pamphlet we find the various schemes for perfecting the railway communication with London put in a new light, because for the first time examined by one who has no private interest in the settlement of the question. Mr. Ogier observes truly that with respect to the project for uniting the various great lines which now radiate from London, "the greatest impediments arise from the clashing of the various interests connected with it, rather than from the impracticable nature of the undertaking."

The proposal that a line of railway should be laid down according to a scheme agreed upon by representatives of the interests of each railway company, the city corporation, and the government, appears very practicable, and moreover it is suggested by the wise policy which avoid obstacles instead of overcoming them. There is no doubt that by a little tact all the companies might be enabled to come to an agreement respecting the method of connecting their lines, and the course so agreed would probably be the best that could be devised. In all other great cities but London the traveller is able to pass from one line of railway to another without incurring the wearisome and unnecessary delay of traversing the extreme length of the city through crowded streets; whereas facility of uninterrupted communication with opposite parts of the kingdom is the most important with respect to London, where the traveller is frequently delayed as many hours as would suffice for the rest of the journey. The object is one of national interest, and impartial practical suggestions such as those here offered towards the effecting so important an undertaking, deserve the attention of all who would have the subject fairly discussed.

A Series of Letters on the Improved Mode of the Cultivation and Management of Flax. By James H. Dickson. London: Groombridge, 1846. pp. 248.

This book deserves attention, as the result of the observations of one who has devoted fifteen years assiduously to the examination of the subject. We confess ourselves incompetent to give an opinion as to the merits of the several improvements suggested by Mr. Dickson; still we imagine that his object will be sufficiently answered if we draw the attention of those interested in the cultivation of flax to the fact that they will here find detailed information on every point connected with its agricultural and commercial purposes. The machinery for spinning the yarn, &c., the economic value of the plant, ascertained by a comparison of the cost of cultivating it, and its productiveness, and the methods of cultivation and preparation for manufacture pursued in various countries, are fully and clearly described.

Gothic Ornaments, being a Series of Examples of Enriched Details and Accessories of the Architecture of Great Britain, drawn from existing authorities. By James K. Colling, Architect. Bell, Fleet-street, 1846. Nos. 1 & 2.

Every contribution towards a more accurate knowledge of the beautiful architecture of our ancestors is worthy of commendation; and the work before us is one of the most elaborate which has been published with this object. Each part contains one illuminated, and three uncoloured, lithographic plates. The subjects are the decorative enrichments of Pointed structures, and will comprise "bosses, canopies, capitals, crockets, corbels, dripstone terminations, finials, foliated cusps, gurgoyles, pateræ, poppy-heads, spandrils, subsellœ, string-courses." The subjects of the first illuminated plate are portions of a Perpendicular rood-screen in Langham Church, Norfolk, showing the manner in which it is enriched by painting. The colours are magnificent, and beautifully printed. The other plates contain poppy-heads from Paston Church, Norfolk, wooden spandrils from North Walsham Church, and capitals from the choir of Ely Cathedral. The subject of the illuminated plate in the second part is diaper enamelled on copper gilt, from the tomb of William de Valence, in St. Edmund's Chapel, Westminster Abbey. The other subjects are details from Lincoln and Norwich Cathedrals.

We certainly object to the use of the word "Gothic" as applied to forms so beautiful as those here depicted, but it is difficult to find a substitute for it. We are not favourable to the unnecessary invention of technicalities, but certainly wish the continental term "Ogival" were in more general use in this country; the word is expressive and does not involve an architectural or chronological blunder. The ornaments delineated by Mr. Colling are Ogival—not Gothic. We must not conclude without speaking in commendation of Mr. Jobbins, for the very beautiful manner he has got up the illustrations.

Tables for setting out Curves for Railways, &c. By G. C. Darbyshire, land-surveyor. Weale, 1846. pp. 16; foolscap.

The review of a series of tables can contain little more than an opinion respecting the general method of calculation; an examination of the accuracy of the numerical results cannot be expected. As far, then, as concerns the general method, this little work has our unqualified approbation: there are many grounds of superiority to similar publications; in the first place, instead of mere rules for calculation, which, in practice, would be found tedious and liable to error, the actual figures are here given, and can be referred to at once; in the second place, the curve for which the calculations are made is the arc of a circle, and not a parabola; lastly, alternative methods of calculations are employed, so that where the nature of the ground does not admit one set of tables being used, another may be substituted. The following is the author's preface, which, being brief enough, may be given entire:—

"The author calculated the following tables for his own private use, but at the solicitation of several friends, he has been induced to publish them. He can speak with confidence of their accuracy, great pains having been taken to prove every figure, and the utmost caution observed in correcting the press. When the calculation of these tables was nearly completed, the author's attention was directed to the 'Civil Engineer and Architect's Journal' for January, 1840, containing tables (calculated by Mr. A. A. Mornay) on the same principle, but having only the column headed t for finding the tangent to the curve: and it was satisfactory to find that the principle he had adopted had been approved of by the conductors of that Journal."

A table showing the Contents of Excavations, derived from Mr. G. P. Bidder's formulæ. By C. Creedy. Maynard, Earls Court, 1846. 24 mo. pp. 24.

This is a pocket edition of Mr. Bidder's tables, of which the utility has been greatly increased by Mr. Creedy's additional calculations for much greater depths than those for which the original tables were formed. Mr. Bidder's formula appears quite correct, but has this defect—that the application of it is limited to those cases in which the cross section of the surface of the ground is horizontal. For the admeasurement for side-long ground and excavations of which the vertical depths depend on the inclination of the natural surface of the ground, we must refer the reader to the more comprehensive tables by Mr. Hughes. (See *ante* p. 73.)

COMPETITION DESIGNS.

Sir—It is time for those who regard either the interests or the credit of the architectural profession, to protest in the most unqualified manner against a most scandalous practice that has of late come up, and which if not openly reprobated and stigmatized will become confirmed. The practice I allude to is that of obtaining designs for a mere nominal price, by means of a very plausible artifice, yet at the same time so very transparent that it might be thought no one could possibly be gulled by it; nevertheless that it does succeed is but too certain, since otherwise it would not be continued. Either a builder himself or those who intend to employ one without calling in an architect, wants a design, and accordingly resort to the following clever expedient of getting one as cheaply as possible. They know very well that they cannot apply to an architect only to make them drawings for the purpose without paying him a fair equivalent for his time and trouble. Even their own sense of common decency deters them from going to Mr. A. or Mr. Z., and saying: we do not intend to employ you as our architect, all we require is a set of drawings, and if you will prepare one for us, for Five Pounds or so, you are our man. They have an instinctive suspicion that such an offer would be received not as a kindness, but a personal insult. What therefore they dare not propose to an individual, they do to the profession generally. The additional cost of the advertisement, will they know—at least hope—procure for them, not only one design, but many, from which they can choose. Accordingly the advertisement is *fairly* drawn up, and it very *honestly* stated in it, that the architect whose design is approved will *not* be employed, but that he will be entitled to a SMALL PREMIUM!—so very small it seems that it is not at all adviseable to give it its money name, lest it should operate as a scare-crow instead of a bait. Nevertheless, small as it is, the premium is not to be flung away, but is to purchase for the liberal advertisers the possession of the *fortunate* drawings!

After all, too, what assurance is there that there may not be some dirty trickery at the bottom of this apparent fairness,—though at the best very evident paltriness?—What assurance that the premium is paid to any one? If when the designs are looked at, it is found that there is no occasion to retain any one of them, for expressly making use of it, all that each competitor knows is that he gets back his own, and that he is not the *fortunate* man. After that, nothing further is heard of the matter, till, perhaps some local newspaper informs its readers that: "the new ——— is just completed, and cannot fail to obtain for their talented townsman, Mr. ———, the title of the *Fudgeall* Vitruvius; it is particularly chaste, the windows being quite unencumbered by any mouldings," and so forth.

What is the Institute about—what the profession, and also you Editors, that one and all suffer such iniquitous and shameful transactions to pass unrebuked, instead of exposing them, and branding and cauterizing those who are implicated in them? How much longer do you mean to tolerate such skulking hole-and-corner proceedings,—such a species of systematic swindling—for in reality it is no better, though not of that kind which the law can take notice as *illegal?* But if not illegal it is base and scoundrelry, and if nothing else can be done to check it, it is probable that insulting advertisements would not be hazarded, were public indignation to be most strongly and unequivocally expressed against them. Or are the whole profession so white-livered and pluckless to a man,—each one so entirely for himself alone, that none care for aught beyond self—beyond what concerns self directly and immediately, that they can put up with such abuses without the slightest effort to repress them? The question will be answered one way if not another; for should the matter be let drop, that of itself alone will confirm the opinion of

VINDEX.

THE CATHEDRAL OF COLOGNE.

The following extract from the *Athenæum* will be read with interest, and the concluding suggestion especially is worthy of attention:—

"Before the Germans, incited by the example of the King of Prussia, began to take up the matter so warmly as they have lately done, one of your correspondents wrote with animation and interest on the subject of the works executing at the Cathedral of Cologne—undertaken to redeem what poor Hood so poetically called a "broken promise to God." The nine years which have since elapsed have done wonders; opened many a journal besides yours to the subject,—enlarged progressively the interest of Europe in an undertaking, the accomplishment of which need no longer be considered a chimera,—and added largely to the funds provided. The Colognese gentlemen and Herr Zwirner, the gifted and indefatigable architect, now say with confidence that, in twenty-five years the *Dom* may be completed, even to the spires;—and this, not in bravado, but from calculation, based upon present progress. To the tourist, approaching the building at railway speed, who sees, as yet, no appreciable diminution in the enormous gap betwixt the choir and the crane on the western tower—such promise seems an extravagance; but they who have had the privilege of looking into the details, in company with the architect, may admit the possibility of the feat.

"In two years, as Herr Zwirner *showed* us, the nave, aisles, and transepts of the Cathedral may be thrown open—not, in truth, to the entire height; but complete to a level above the clerestory windows. The vaulting of the side-aisles will be then completed; and a temporary roof will be easily placed over the central portion,—leaving, within, the upper part of the walls, vaults, &c., to be raised:—without, the flying buttresses, pinnacles, and other garnitures, are a more serious business. The raising of the transept walls to their present important height, Herr Zwirner assured us, was a heavier two years' task than what remains to be done in realization of a scheme so attractive to the fancy. Moreover, the casual visitor is little aware of the vast collection of ornamental sculptures, ready to be placed, which the workshops contain. The canopies round the retreating portal of the northern transept are already fixed: the capitals of the pillars of the clerestory gallery are waiting, by the score. Let not my statement mislead any one into imagining a case of *manufacture*. The old capricious variety of fancies in ornament has been as religiously carried out as every other intimation of the nameless architect's intention. The small grotesque figures at the angles of the canopies aforesaid (which are merely shelters for statues of saints, angles, &c.) are as minutely finished and whimsically diversified as if they could be seen without the aid of an opera-glass when they shall be raised to their destined position. The foliage, again, of the capitals has the sharpness of the best period of cutting. No two devices are alike. The stone used for these more delicate portions is of peculiarly fine and close quality, from Rochefort. Nothing seems slighted or overlooked; and the workmen, of course, become more skilful as they proceed, and fuller of spirit and invention. A growing confidence that all this labour is not to be in vain as regards the grand result, probably animates those who have contributed to a scheme so magnificent, but for a long time deemed so visionary. Windows are beginning to drop in. The King of Bavaria's donation of *six* for one of the side aisles will be ready in 1848; and then, it is said, the spell is to be broken—the wall thrown down betwixt nave and choir, with splendid festive ceremonies. This will give an immense impetus to popular feeling. I was shown the corner where our Queen's donation is to be placed. When I saw this, and was told of one window contributed by Herr —— at a cost of thirty *Friedrichs d'or,* and of another promised by some other enthusiast—a wish arose in my mind, to which you will, perhaps, not object to give currency. Would it not be a pleasant thing to the English artists and lovers of art to have *their* memorial in such a building? One of the smaller windows—presuming their zeal unequal to vie with that of Royal donors—might be handsomely compassed for fifty sovereigns: or, let us say—to state the sacrifice more tangibly to those whom I fain would interest—fifty white-bait dinners! Could not so much as this be done, without injustice to any of our own works of art or benificence? It is true that the offering, when completed, would make little more show than the hatchments or votive tokens which cover the walls and pillars of the Catholic churches abroad; but it would be, still, "the Englishmen's window," for the father to show his son—a token of brotherly kindness and sympathy, especially grateful to such lovers of memorials and celebrations as are our German friends;—who, let me add, are more abundantly irritated by the sneers and exactions of our swarm of vulgar summer tourists, than soothed by the courtesies of the refined and intellectual among us. At all events, my hint can do no one harm."

To the above, the following particulars, taken from the report of Zwirner the architect, may be added. The past winter was chiefly occupied in preparing the stones required for the triforium of the nave and the north and south transepts. On examining the foundations of the great north tower, they were found to be so imperfect that it will be necessary to excavate to the depth of thirty feet in order to renew them. This discovery will lead to great delay and labour. Zwirner complains that the employment of workmen on five different portions of the building simultaneously leads to needless trouble and expense. The list of royal donations is as follows:—Emperor of Austria, £833; King of the Netherlands, £84; Grand Duke of Baden, £170; King of Hanover, £86; Prince of Lichtenstein, £96; Queen Victoria, £525. The most favourable signs of progress are the arching of the south aisles and the completion of the north and south portals. The latter are already arched over. Considerable controversy has existed respecting the manner of erecting the south portal; certain traces of foundations which have been discovered, and which are said to indicate the form which this part of the cathedral was intended to assume, have been disregarded in the restoration. The restorers appear, however, to have acted on mature deliberation, and the restoration of the north portal, which is indisputably in accordance with the original plan, furnishes a powerful answer to the objections raised respecting the south portal.

NOTES OF THE MONTH.

The Tubular Bridge.—It appears from the report of the engineer of the Chester and Holyhead railway, that the model tube constructed by Mr. Fairbairn, one sixth of the actual size, has been subjected to such experiments as he considers sufficiently justify the company proceeding with the works. He reports:—"In the former preliminary experiments, I was led to the conclusion that great care would be required to prevent the upper side of the tube from crushing,—that, in short, the main object to be aimed at was to give the top of the tube the requisite stiffness. In this respect, the result obtained from the model has been highly satisfactory; and, being upon so large a scale, may be deemed perfectly conclusive upon several important points. The dimensions of the tube were as follows: length, 75 ft. between the supporters; depth, 4 ft. 6 in.; width, 2 ft. 6 in. The total weight a little above five tons. When progressively loaded, the mean deflection was about one-tenth of an inch per ton; and with a load of thirty-five tons suspended in the middle, it gave way on the under side,—the upper part not having exhibited the least sign of failure up to the moment of fracture. Hence, therefore, we have arrived at a most interesting result; viz., that the liability of the plates on the upper side to crush has been completely removed from the construction in compartments. The experiments having now furnished us with the necessary means of calculating the relative thickness and proportions of the several parts of the tube, we are in a condition to contract at once for their construction." Supposing the strength proportional to the size, the real bridge ought to break with six times the load on the model—that is, with 210 tons, and the deflection would be 21 inches. Mr. Stephenson stated, in his report, that 747 tons on the centre, or double this distributed over the whole bridge, though equal to any weight "that can in practice be placed on the bridge, is not sufficiently in excess for practical purposes." But the supposition which seems to have been acted upon in this experiment that the strength is directly proportional to the dimensions, is founded on false philosophy. The load which can be sustained is a function not of the length, but of the *square of the length* nearly; or at all events, depends on a higher exponent than the first power of that quantity. The deflection would depend not on the breadth and depth simply, but probably on the *cubes* of those quantities.

Buckingham Palace is to be enlarged by the addition of a fourth side, completing the quadrangle: the architect is Mr. Blore. Let us hope that the faults in the present structure will not be repeated—that columns will be used to support the building—not to be supported by it, and that there will be no sham pediments stuck on for show. The destruction of the huge triumphal arch, supporting nothing but a little flag-staff ("a most lame and impotent conclusion"), is happily resolved upon. The proposition to build an altogether new palace of purer architecture seems preferable to that of patching up the old one. The liberality of the people of England must, in the former case, be the more acceptable to the Queen, because forced upon her, as it were, in generous disobedience to her expressed wishes.

Triumphal Arch, Piccadilly.—The statue of the Duke is to be hoisted up after all, and to remain on the arch for three weeks, *to see how it will look.* Sir F. Trench might as well walk through London on stilts, to see how *he* would look. This scheme of putting up the statue on trial appears very much like a *ruse*: the pieces of metal, if soldered together, cannot be disunited without injury. Besides, it would be much easier and cheaper to again raise the great wooden doll which was placed in the same situation as a gazing-stock some time ago.

At the anniversary meeting of the Botanical Society of London the receipts were stated to be £12,641 and the expenditure £9,845.

In the Papal States an Anglo-Indian company has been formed for establishing a complete system of railway communication. The Pope is stated by the *Journal des Debats* to have obtained from the French Government copies of all the statutes relating to railways.

Mont Blanc, this summer, appears for the first time this many years, discrowned. The sun has robbed "the monarch of mountains" of his insignia of royalty; neither "the avalanche is in his hand," nor does the "diadem of snow" remain upon his brow.

Navigation of the Seine.—The French Chambers have voted 26,000,000 francs for the improvement of the Seine navigation. Near the mouth of the river the channel will be narrowed, in order that the current by its increased rapidity may constantly act to scour the passage.

Mr. Hudson's railways.—The following table exhibits the average of fares per hundred miles on the railways under Mr. Hudson's management and eleven other railways:—

	1st. Class.	2nd. Class.	3rd. Class.
Hudsonian lines	24s. 7d.	16s. 6d.	13s. 4d.
Eleven other lines	18s. 9 1/11 d.	13s. 7 1/11 d.	8s. 9 8/11 d.

In one case (the Great North of England), 17s. 9d. per 100 miles is charged for *second* class passengers, while on the London and Birmingham the *first* class fare for the same distance is 16s. 6d!

The Birmingham Town Hall has been decorated in the Polychromatic style.

The Masonic Hall, Cowes.—A long account of the laying the first stone of this building has been given in the newspapers, The *Illustrated London News* publishes the design, which appears to be perfectly disgraceful. It has been observed, among other things, that the Grecian-Doric pilasters are twelve diameters in height!

The Sailor's Home, Liverpool, is to be erected in the Elizabethan style from designs by Mr. Cunningham. It has been calculated that the ceremony of laying the foundation stone by Prince Albert has cost more than will suffice for erecting the building.

St. Michael Heavitree, near Exeter.—This church has been re-erected under the superintendence of Mr. Alexander. The form and details of the former church have been almost exactly repeated.

Trinity Church, Paddington.—The cost of this building is £18,000.

St. John Baptist, Sudbury.—A small church, near the Birmingham railway, has been erected from an excellent design by Messrs. Scott and Moffatt. The style is Decorated; the materials flint, with stone dressings.

All Saints, Harrow-weald.—The first stone of this church has been laid. The design is by Mr. Harrison, in the Early English style.

Frescoes in the House of Lords.—Very favourable reports of the success of Mr. Dyce's labours are in circulation. His mural picture is said to have been recently inspected by the members of the Royal Commission of Fine Arts, and to have given great satisfaction to the distinguished visitors.

Statue of Sir Fowel Buxton.—The competition respecting this statue, which is to be erected in Westminster Abbey, has resulted in favour of Mr. Thrupp. The price is £1,000.

M. Vignon, architect to the Empress Josephine at Malmaison, to Louis Bonaparte when King of Holland, and to Murat, recently died at Paris, at the age of eighty-five.

The Society for building, &c., churches and chapels determined, at their last meeting to grant assistance towards the erection of 11 new churches, the rebuilding with enlargement 7 parish churches, and the enlargement of 19 churches and chapels. The Society, since November last, has contributed £20,360 towards the erection of 69 new churches.

South Devon Railway.—Atmospheric tubes of the increased diameter of 22 inches are said to be in course of formation.

The Midland Counties telegraph, from Leeds to Birmingham, and from Derby to Nottingham and Rugby, has been completed at a cost of £40,000.

Instruction of engine drivers.—The French Minister of Public Works has resolved on instituting a school for this purpose at Paris.

A failure of an embankment on the Sheffield and Manchester railway took place recently, when 3,000 yards of earth fell.

The Richmond line is opened. It cost only £170,000, though the original estimate was £260,000. Mr. Locke is the engineer: the rate of progress was a mile a month.

Foreign competition with English manufactures.—The merchants of Birmingham have been offered Belgian wine-glasses and tumblers 25 to 35 per cent. cheaper than they can be produced in England.

The newspapers announce the death of Dr. Bostock, of Liverpool, an associate of Priestly and Davy in their labours. His principal work was the "Elementary System of Physiology."

Discovery of an ancient forest.—In excavating the new road from Woodside, which has been commenced by the Birkenhead commissioners, the workmen have discovered a forest six or eight feet below the level of the soil. Many of the trees retain their original forms almost perfectly.

The Newfoundland Times asserts, from observations of the sea level, that all the land about Conception Bay, and probably the whole island, is gradually rising above the sea.

Chichester Cathedral.—A rose window has been placed in the east gable. The tomb of Richard, bishop of Chichester (1252), has been restored and placed in the south transept.

London Docks.—A new warehouse is being erected by Mr. W. Cubitt. The length of the new building is 234 feet, the breadth 189 feet, and it is five stories in height.

The *Hotel de Ville* of Aix-la-Chapelle is being restored. In this building took place the congress by which the celebrated treaty of Aix-la-Chapelle was concluded.

Railway Legislation of the Present Session.—3,672 miles of railway have been authorized, with a capital of £90,500,000, and power to borrow £38,700,000 more.

London and North-Western.—In consequence of the grand amalgamation of the London and Birmingham, the Grand Junction, and the Liverpool and Manchester, into one great company, named the London and North-Western, most extensive improvements are contemplated. At Euston-square and Camden-town whole streets will be demolished to gain additional space. The Wolverton and the Crewe stations will be greatly enlarged; but the most important alterations are being carried on at Liverpool: there will be a tunnel right under the town of considerable length.

The Contracts for the Menai Tubular Bridge are distributed as follows: Mr. Walter Williams, 2,000 tons of best iron plate; Bramah and Co. and Foster and Co., each 1,500 tons; Thorneycroft and Co., the Colebrook Dale Company, and the Butterly Company, each 1,000 tons;—in all, 8,000 tons.

The Railway of the United States extend over 10,500 miles.

The late Storm has considerably injured the external masonry of Henry

VIIth's Chapel, which, notwithstanding the comparatively recent restoration, shows signs of general decay. It is of Bath stone.

The Government School of Design.—The annual meeting for distribution of Prizes has recently taken place. This institution has effected little which would induce the public to respond to the tone of gratulation adopted in the annual report.

The Three New Parks at Manchester have been opened.

The Restorations at Ely Cathedral progress rapidly. The tombs of Bishop Alcock and Cardinal de Lidanborough, the Purbeck marble shafts of the triforium and clerestory, the corbels, string courses, &c., have been purged of the coatings of paint and plaster. But the chief works are at the west end, where the towers have been restored and opened to the nave. The Chapel of St. Catherine, which opens into the newly-restored transept, is to be repaired. At the east end of the church, the south pinnacle, which was never finished, is in course of erection at the expense of Mr. Hope. The dean has restored Prior Cranden's Chapel.

MISCELLANEA.

Rocket Making in the Royal Arsenal at Woolwich.—The outside case of the rocket is of thin sheet iron, and the inner case of paper. This case being fixed, a ladlefull of clay is placed at the bottom of the rocket and the composition is then poured in; one ladlefull being put in at a time. Each complement of the composition is then driven down by an instrument called a "monkey," similar to those used in pile-driving, which is allowed to fall on the rammer 60 times. This process is repeated on the addition of each ladlefull of the composition, till the whole tube or case is filled, when it is coated over with clay, which hardens and protects the composition from accident till it is required for use, when the clay is bored through.

Blasting of the White Shell Rocks at Sunderland.—These rocks, which have long been a source of danger to ships entering the port of Sunderland, were examined recently by T. Meek, Esq., engineer. On surveying their form and nature, by means of the diving bell, he satisfied himself of the practicability of their being blasted with gunpowder, and their most dangerous parts removed. The surface was found to consist of rid es of pseudo-magnesian limestone, running in an easterly direction. The highest projecting ridge was not more than two feet six inches below the surface of the water. This being the most dangerous point, it was selected for the commencement of the operations. The first blast loosened and displaced six tons of rock, and by means of two others this portion of the ridge was levelled, and a depth of five feet water at low spring ebbs obtained. Another projecting ridge, not so dangerous, has been lowered and broken up. The operations are still progressing, and much advantage to the port is expected to result from them.

Indian Railways.—The Indian journals, received by the overland mail, are discussing the possibility of constructing the railroads. Mr. Simms, after a fair month's survey, has declined to attempt a regular estimate of the cost of constructing a railway from Calcutta to Delhi. In his general report and guess estimate, however, he sets it down at £15,000 per mile; one bridge alone he estimates at two million rupees. This really appears no extravagant estimate of what it may cost to carry a railway through a country subject to inundations so violent as to sweep the most solid structures away. At this rate, the total expense of a railway from Calcutta to Delhi would be somewhere about twenty million rupees. The Great Indian Peninsular is, at one part of its course, to rise 1718 feet in rather less than six miles and in this portion of it there are two miles of tunnelling and one of cutting through a hard fissured trap. The pass through which these operations are to be conducted leads to a "rugged difficult country."

LIST OF NEW PATENTS.

GRANTED IN ENGLAND FROM JULY 23, 1846, TO AUGUST 25, 1846.

Six Months allowed for Enrolment, unless otherwise expressed.

Charles William Firchild, of Leamington, in the county of Warwick, for "a new engine for obtaining rotary motion."—Sealed July 23.

Peter Claussen, of Leicester-square, Middlesex, gentleman, for "Improvements in methods of, or apparatus for, propelling and exhausting and compressing air and aeriform bodies."—July 23.

John Tulloh Osborn, of Demerara, now residing in London, Esq., for "certain Improvements in power machines, or machinery for tilling, draining, and otherwise cultivating land, and in the mode or modes of working the same."—July 23.

James Henry Dickson, Esq., Capt. Half-pay, of Cheltenham, for "certain Improvements in saddles."—July 23.

Harold Crease, of Brixton-hill, Surrey, paper stainer, for "certain Improvements in the preparation of paints and colours for decorative and other similar purposes."—July 23.

Francois Henry Bickes, of Mayence, on the Rhine, in the Grand Duchy of Hesse, gentlemen, for "Improvements in distillation."—July 23.

George Henry Fourdrinier, of Hanley, in the county of Stafford, paper-maker, for "Improvements in preparing the materials used in manufacturing earthenware and china, and in printing the designs for ornamenting the same."—July 23.

Edward Hammond Bonsall, of Heybride, in the county of Essex, iron-founder, for "Improvements in implements for ploughing land, and clearing land of weeds."—July 23.

Alfred Vincent Newton, of Chancery-lane, draughtsman, for "certain Improvements in the manufacture of sugar." (A communication.)—July 23.

Thomas Bell, of Don Alkali Works, South Shields, for "Improvements in smelting copper ore."—July 28.

Robert Heath, of Manchester, gentleman, for "certain Improvements in wheels to be used upon rail and other roads which improvements are also applicable to mill gearing, and other similar purposes."—July 27.

John Augustin Alexis Sauvage, of Rue Richer, Paris, for "Improvements in condensing the steam in steam-engines, and in supplying water to steam-engine boilers."—July 27.

Thomas Lucas, of No. 113, Aldersgate-street, London, lozenge manufacturer, for "certain Improvements in the manufacture of lozenges or sweetmeats."—July 29.

Henry Bessemer, of Baxter-house, Old St. Pancras-road, Middlesex, engineer, for "certain Improvements in the manufacture of glass, and in machinery and apparatus connected therewith, and also in silvering or coating glass, parts of which improvements are applicable to the manufacture of tin foil and thin sheets of other metal, or alloys of metal."—July 30.

Robert Mallett, of Dublin, civil engineer, and John Somers Dawson, of Dublin, coach builder, for "certain Improvements in railway carriages, and in the machinery for working railways, parts of which are applicable to other carriages, and to the bearings of other machinery."—July 30.

William George Armstrong, of Newcastle-upon-Tyne, for "an Improved lifting, lowering, and hauling apparatus."—July 31.

Theophile Auguste Dreschke, of Rue Therese, Paris, late an officer of Artillery, in the service of Prussia, and late professor of sacred music at the University of Berlin, for "Improvements in the keys of pianofortes and other keyed musical instruments."—July 31.

John Bayley, of Heaton Norris, near Stockport, manager, for "certain Improvements in machinery or apparatus for spinning or twisting cotton and other fibrous substances." August 1.

Thomas Payne, of Handsworth, near Birmingham, gentleman, for "Improvements in the manufacture of rolls for rolling iron and other metals."—August 4.

Charles Vignoles, junior, of Apperby-bridge, near Bradford, Yorkshire, civil engineer, for "Improvements in employing steam as a motive power."—August 4.

Francois Teychenne, of Redcross square, Cripplegate, feather merchant, for "Improvements in treating stone to render it hard and impermeable, and in colouring the same." (Partly a communication.)—August 10.

George Lodge, of Leeds, Yorkshire, engineer, for "certain Improvements in heating water, generating steam, and saving fuel."—August 11.

Frank Hills, of Deptford, Kent, manufacturing chemist, for "a method or methods of treating certain gases, and manufacturing sulphuric acid, muriatic acetic acid, and certain salts of potash, soda, and ammonia."—August 11.

William Kayser, of Bread-street, Cheapside, London, gentleman, for "Improvements in the manufacture of looking glass." (A communication.)—August 11.

Richard Whytoch, of Edinburgh, manufacturer, for "an improved method of manufacture which facilitates the production of regular figures or patterns on different fabrics, particularly velvets, velvet pile, and Brussels, Wilton, and Turkey carpets, being an extension for the term of five years, to be computed from the 8th day of September, 1846, of letters patent granted to the said Richard Whytoch for the said invention, by his late Majesty King William the Fourth."—August 11.

Charles Dowse, of Camden Town, gentleman, for "Improvements in the manufacture and finishing of fabrics capable of being used as substitutes for paper."—August 11.

William Warcup, of Ashton-terrace, Coronation road, Bristol, civil engineer, for "certain Improvements in the manufacture and arrangement of parts and apparatus for the construction and working of atmospheric railways."—August 11.

Henry Constantine Jennings, of Cumberland-terrace, Regent's-park, practical chemist, for "a new method, or apparatus, or machine, for the better or more economic evaporation of fluids or liquids containing crystalline or other matters to be concentrated or crystallised."—August 11.

Jean Michel Borgognon, of New Broad-street, London, gentleman, for "certain Improvements in producing artificial basaltic lavas." (A communication.)—August 11.

Daniel Sydney Hasluck, of Birmingham, merchant, for "certain Improvements in the manufacture of harness for beasts of burden." (A communication.)—August 13.

John Buchanan, of Queen-square, Westminster, gentleman, for "certain Improvements in ships or vessels, and in propelling thereof, and in securing the same from floatal damage, certain parts of which machinery may be used for motion on land."—Aug. 15.

William Aitken, of Aberdeen, in North Britain, gentleman, for "certain Improvements in two and four wheeled carriages."—August 15.

George Phillips, of Park-street, Islington, chemist, for "an Improved construction and arrangement of apparatus for supporting garden-pots, and improving the growth of plants."—August 17.

Moses Poole, of the Patent Bill Office, London, gentleman, for "Improvements in manufacturing terry and cut piled fabrics." (A communication.)—August 17.

Joseph Gray, of Redcross-street, Southwark, machinist, for "Improvements in gas meters."—August 17.

George Remington, of Park-street, Westminster, civil engineer, for "certain Improvements in locomotive engines, part of which improvements are applicable to marine and stationary engines."—August 17.

Joseph Clinton Robertson, of Fleet-street, London, civil engineer, for "an Improved method of constructing boats, ships, and vessels of wood." (A communication.)—Aug. 17.

George Hinton Bovill, of Millwall, Middlesex, engineer, for "Improvements in manufacturing wheat and other grain into meal and flour." (A communication.)—August 18.

Samuel Haven Hamilton, of Paris, gentleman, for "Improvements in machinery or apparatus, for dredging or excavating." (A communication.)—August 19.

William Crofts, of the Park, Nottingham, for "Improvements in the manufacture of lace and other fabrics."—August 20.

Henry Parry, of High-street, Deptford, gentleman, for "certain Improvements in the manufacture of hats."—August 20.

Matthew Gibson, of Wellington-street, Newcastle-upon-Tyne, machine maker, for "a machine for reaping, cutting grass, and other similar purposes."—August 22.

Maximilian François Joseph Delfosse, of Paris, but now of Regent-street, Esq., for "Improvements in preventing and removing incrustation in steam boilers."—August 25.

James Bishop, of Piccadilly, warehouseman, and Thomas Wood, of Upper Barnsbury-street, Islington, gentleman, for "Improvements in passengers' carriages."—August 19.

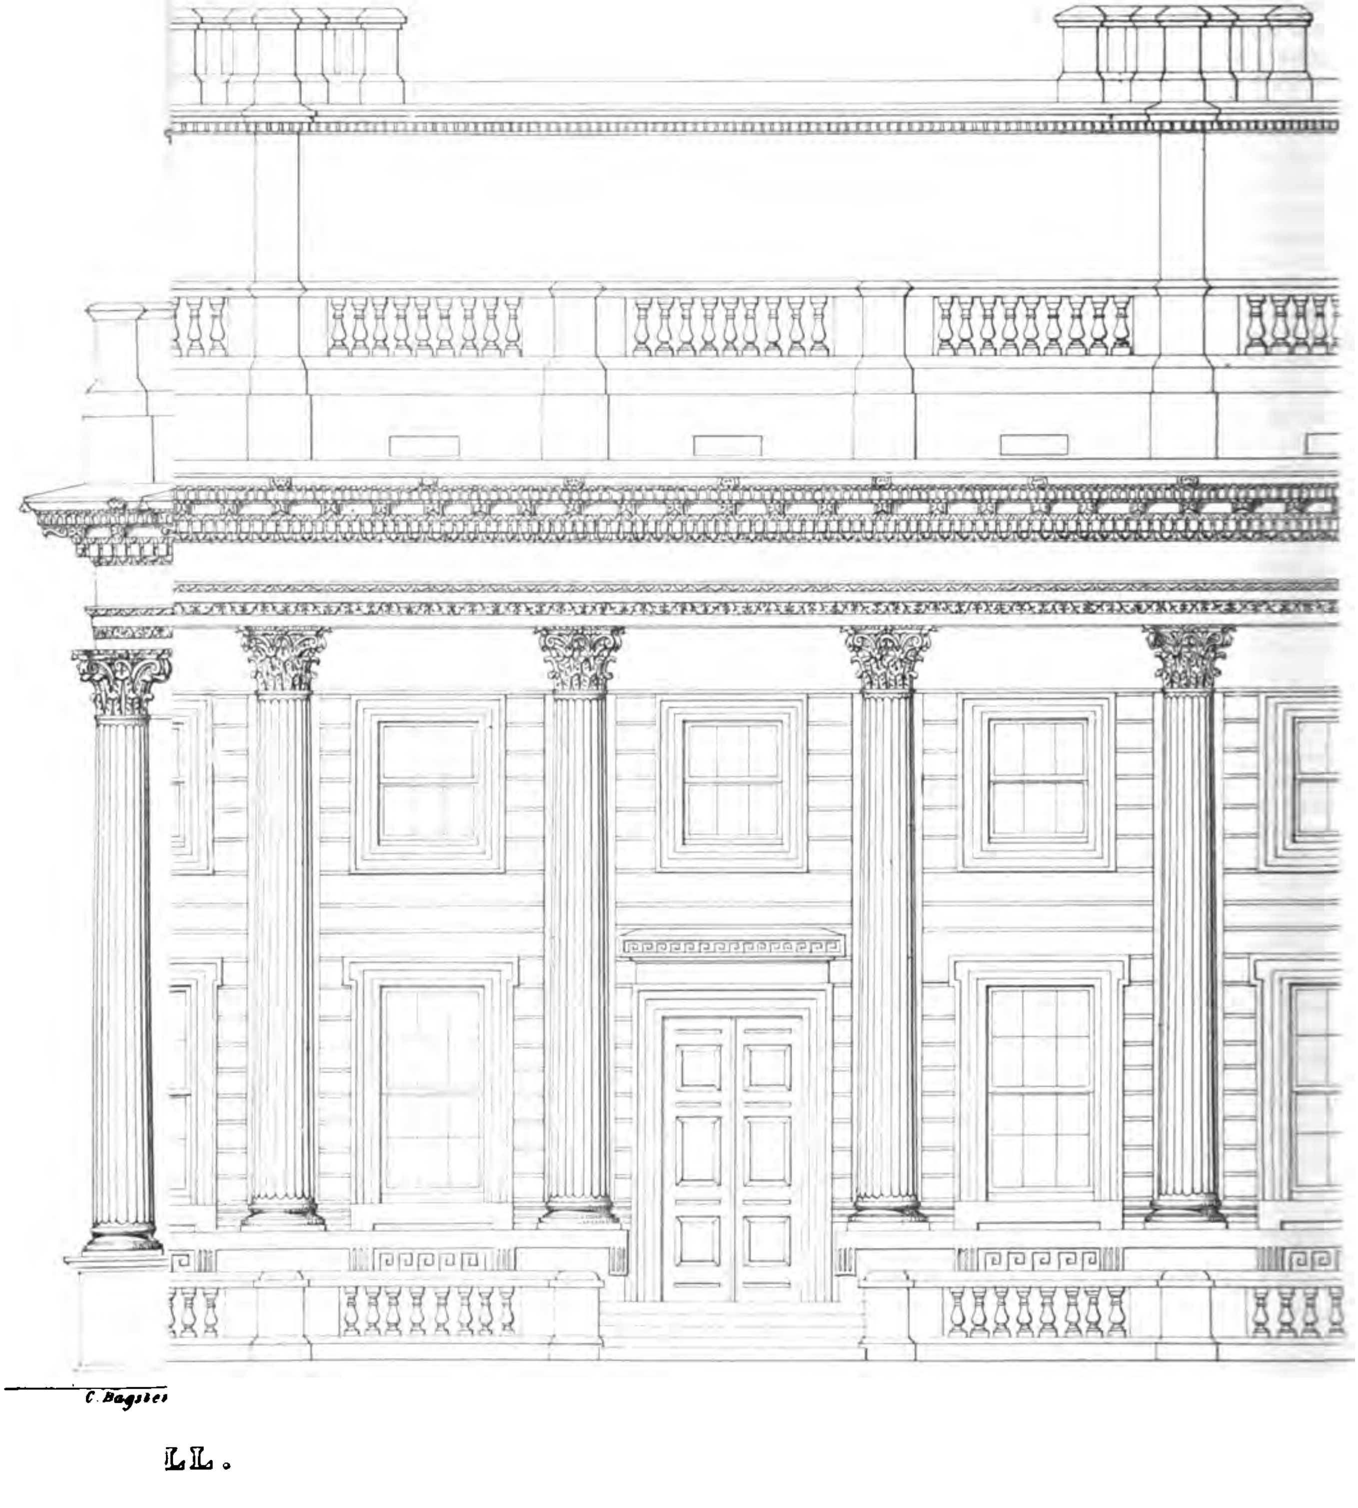
Thomas Russell Crampton, of Adam-street, Adelphi, Middlesex, engineer, for "Improvements in locomotive engines."—August 25.

Alexander Parkes of Birmingham, artist, for "Improvements in the manufacture of candles, and in preparing and combining certain animal, vegetable, and mineral substances, applicable to the manufacture of candles and other uses."—August 25.

James Murdock, of Staple-inn, Middlesex, for a process for "making a composition or artificial stone, applicable to building and other useful purposes."—August 25.

CORRESPONDENTS.

Received "Hodgkinson on the Strength of Cast Iron," "View of Christ Church, Portswood," "Nonnullus." We are again compelled to postpone several papers for want of room. Correspondents who wish to have their communications inserted must send them early in the month.



LL.

THE BOARD OF TRADE, WHITEHALL.

(With an Engraving, Plate XV.)

We have reserved till now, when we exhibit an elevation of it, our remarks on the "Board of Trade," as it was originally designed by Soane, and we may commence them by observing that though he selected a singularly ornate and highly finished example of the Corinthian and adhered to it with that literal exactness which though merely belonging to the province of architectural orthography, is allowed to pass for a positive merit, he deviated widely from—at least did not at all enter into, the spirit of it. Were the rest of the elevation shown before the columns were put in, hardly would it be imagined that the latter were to be of the Corinthian order, least of all that example of it; or *vice versâ*, were it the order that was drawn in first, we should naturally anticipate a corresponding degree of richness for the other features, whereas they are of such marked plainness as to be both inconsistently and affectedly so. It is rather strange that as he did not intend to keep up to tone of the order, he did not adopt the middle course of sobering it down to that of the rest, preserving its proportions and profiles, but retrenching its luxuriance. But like many others, Soane was content to take orders and apply them just as he found them without endeavouring to make them influence the composition. He could copy Corinthian columns—and we are certainly indebted to him for the introduction of the Tivoli example—but he had no clear perception of *Corinthianism*, still less of Ionicism, for his Ionics are intolerable. With all the originality, too, that he possessed, or had the credit of possessing, he does not appear to have ever turned any of it to the composition of a well studied and carefully devised example of his own,—we say example, for we are not so absurd as to expect any one to originate and perfect a new *style* of order—a preposterous idea that has proved a stumbling-block to those who have attempted to do so, and whose extravagant and tasteless conceits have caused those to exult who comfort themselves with that good old orthodoxy which spares them all trouble of invention, and which by making the whole profession mere copyists in regard to the orders, puts all of them so far upon the same level.—But all this may pass for digression, and we therefore break away from it.

In his "Board of Trade," Soane kept up uniformity of intercolumniation, but not to the very great advantage of that portion which had insulated columns, the latter being like the attached ones, four diameters apart; which occasioned in the building what does not show itself in an elevation, more especially an outline one, namely, a certain degree of meagreness as to columniation, at variance with the character of richness aimed at by it, and certainly at variance with the intercolumniation in the original example, where it is only one diameter and a half. Another disadvantage was that the effect of shadow was greatly diminished in consequence of the width of the intercolumns. What is more, those advanced columns were quite as parasitical, and more decidedly for mere embellishment than the others, for instead of the order being a portion of the building, it was merely stuck up against it, the entablature being actually detached from it, and having immediately behind it small windows to a mezzanine floor. It would seem therefore that those columns were brought forward chiefly in order that the entablature might be so also, for the purposing of masking the unsightly apertures required in so ungainly a situation. As an expedient in urgent necessity, such concealment of what would else have blemishes, might have passed for ingenious and legitimate, had not the artifice manifested as much bungling as contrivance by being allowed to show itself; whereas had the soffit of the entablature been closed up, it would not have been even suspected, while at the same time by the entablature being hollowed out, so as to form a mere parapet in front of those windows, the light to them would have been hardly at all obstructed.

In one respect the fenestration of Soane's building was praiseworthy, for the heads of the second tier of windows and their dressings—in builders' phraseology those of the "one-pair"—did not break into the line of the capitals of the columns, owing to which the latter display themselves with more dignity. Nor can we help being of opinion that in this particular point Mr. Barry has not improved upon the original design. We expressed some disapprobation last month of the infraction of linear harmony by the second floor windows being allowed to rise up between the capitals of the order, but we did not mention—in fact had not then considered how the difficulty was to be overcome, the columns being just of the same height as before, and the windows in question considerably taller. As to difficulty, indeed, there was no such word in the case, nothing being more easy of accomplishment, for there was only to raise the columns to the level of the window balustrades, which done, their bases would have ranged with the sills of the first floor windows, and their capitals would have cleared the line of the top of the upper windows. The building would thus have gained an addition of three feet in height, which increase would hardly, we conceive, have been an objection, though decrease of height, to the same extent, might very justly have been so.

Soane's attic looked more like an after thought, and excrescence than as having been designed in conjunction with the order. Instead of contributing any of that play of outline and concomitant piquancy of composition, which so happily mark some portions of the Bank, it produced only monotonous and spiritless heaviness. If that be any great merit, it was certainly free from *Soaneisms*, but unluckily when Soane was not somewhat oddly fanciful he was dull, and sometimes even without a decent idea at command. We have, however, his architectural *autograph* here in some of the chimneys, which have certainly more of Soane than of Corinthianism in them. Pity that with his ambition to be original, he got out of the beaten track only by fits and starts; he jumped out of it only to jump back into it again, or only to jump about the new track he thought he had discovered, but without making any progress in it. He had ideas of his own, but he was apt to put them forth to the public in too raw a state, and he almost invariably left some grating incongruity—some trait of littleness and meanness in every thing he did. His choicest piece of design was the Loggia forming the north-west angle of the Bank—from which, most strange to say, no one has ever taken an artistic lesson in composition.

FENESTRATION AND WINDOWS.

SECOND ARTICLE.

Although there are other characteristics which more or less strongly mark Gothic exteriors, particularly in regard to outline and composition, it is in the apertures alone that the arch, which prevails throughout the entire organization of the interior of the fabric (at least, in ecclesiastical edifices), manifests itself externally, for open arcades corresponding to porticoes, on the outside of buildings are of such exceedingly rare occurrence in the Pointed style, as to be only exceptions. We shall perhaps be reminded of the open arches of porches; but they belong to doorways, and do not form continuous arcades, of which latter, however, or what may else be called a portico of three lofty arches, the front of Peterborough cathedral affords an instance, and is accordingly very remarkable. This comparative absence of the arch from exterior situations has led Schnaase—if we mistake not the writer—to give it as his opinion that the Pointed style seems to have been calculated chiefly for internal effect, inasmuch as it is within buildings that it displays itself in all its completeness and with perfect homogeneousness—not in doors and windows alone, but in a succession of arches, combined with vaulting and its arched surfaces. Externally, therefore, windows are valuable features, because strongly expressive of the style, even should there be, as is sometimes the case, very little besides to indicate it. Nor is it only on account of the presence of the arch in them that they are thus expressive, for in the later Perpendicular the arch is sometimes almost lost, or even entirely so as regards the general form of the aperture, since square-headed windows occur even in ecclesiastical buildings as well as in secular ones; notwithstanding which, the character and constitution peculiar to Gothic windows are strictly kept up. It becomes necessary to consider in what respect Gothic windows are differently constituted from others, and so very much more advantageously, that what renders them both highly characteristic and ornamental externally, renders them also such internally, or *vice versâ*. Perhaps the matter is so exceedingly obvious as to require neither consideration at all, nor explanation,—at least it would seem to be so, for we do not recollect to have seen it adverted to by any one of the numerous writers on the subject; nevertheless, we will, at the risk of putting forth an officious and superfluous observation, lay it down as the distinguishing constitution of Gothic windows, when the style is fully developed, that they consist not of one, but of many apertures united together into a general composition. However large they may be—and they may be extended to any practicable dimensions—they are not mere gaps in the wall; on the contrary, the larger they are the more decorative they become, the increase of size being obtained by an increased number of lights and mullions, and a consequent increase of tracery ribs in the "head" of the window; whereas, unless the general opening were divided in its lower part into lesser apertures, there could be no tracery above.

After the idea of them had been fully developed and brought to maturity, Gothic windows exemplify very strikingly how admirably that disposition of them which originated in convenience if not in actual necessity, was made to conduce to both character and decoration; for the division into separate compartments or "lights," systematically combined into one general whole, resulted in some degree from the exigencies of construction—not indeed as regards the arch which is so filled in, but in order to afford due support, and also the appearance of it, for the glazing and its lead-work. Instead, therefore, of causing mere vacancies and voids in the walls, and of being little better than dull gaps and blanks in the architecture, without any of the bold effect attending unglazed openings, the apertures themselves become positive features in it, they forming so many perforated screens inserted into the arched voids which they occupy. Hence, they differ not only most decidedly but most advantageously from windows in the Greco-Roman and Italian styles, in which ornamental design is entirely confined to the dressings enclosing the aperture, which, however rich they may be in themselves, contribute nothing whatever to internal effect, the aperture itself remaining nothing more than a mere large circular—or square-headed, opening, without any possible variety of design for it; whereas, in Gothic architecture, the actual windows, and not the mere external framing around them, admit of almost inexhaustible diversity; and however plain they may be in their splays and external mouldings, they are both integral and ornamental parts of the structure.

In some instances, however, much external and adscititious decoration is bestowed on Gothic windows,—even such extraneous additions as small crocketed gables enclosing their heads, which therefore seem to offer a direct precedent for the application of pediments to windows in Italian composition, and must accordingly be condemned as gross solecisms,—that is, by those who are intolerant of window-pediments, such gables or Gothic pediments being, like the others, merely "stuck on," and miniature resemblances of constructive forms diverted and perverted from their original intention into mere accessories for the sake of embellishment. Indeed, miniature gables, we may stop to remark, are so exceedingly common in Gothic architecture, that the term *Gablet* has been expressly invented for them; and some of them—*ex. grat.* on the several stages of buttresses—are so diminutive, that they ought to be held very "ludicrous" things indeed by those who adopt the profound dictum that "the lodicrous is inseparable from diminutive resemblances of things noble and dignified in themselves."

To return to windows,—those who denounce the application of pediments and columns to windows in the Italian style, must be equally scandalized at those examples of Gothic windows in which miniature *buttresses* fortify the lower part of the principal mullions, and again, at such enormities as "embattled" transoms. In claiming for Gothic windows the merits and advantages we have done, we must of course be understood to refer to genuine and worthy examples, since we can by no means extend the same praise to that sort of "something like Gothic" that gives us little more than the mere skeletons and rudiments of mullioned windows and tracery,—such as, till very lately, we have been doomed to behold in churches and other modern Gothic buildings, for whose windows, proportions as to the mullions and intervals between them are totally disregarded;—probably, because it has not been even so much as suspected that there are any proportions at all to be attended to. Nevertheless, though it may not have been formally entered among bookish rules, the same principle regulates the spacing of mullions—or, what is the same thing, the breadth of the mullions in proportion to the width of the lights—as regulates intercolumniation. The mullions should not be further apart than 3 or 4 at the most of their diameters, so to call them;—or, in other words, should not be much narrower than from about a third to nearly a fourth of the width of the "lights." It is owing to the non-observance of such proportions that so many modern Gothic windows are very unsatisfactory in character, even when correctly designed in other respects, the mullions being reduced comparatively to mere upright bars, so that the whole window has a wiry and meagre appearance, as offensive to the eye as yawning and straggling intercolumniation, the disagreeableness of which is felt even by those who are unable to account for it. Another point to be attended to, yet frequently disregarded altogether in modern practice, is *systematic uniformity* of division of the windows for all of them alike, both large and small; that is, the width established for the lights in one window should be adhered to for those in all the others, whether the number of lights be more or less; instead of which, modern architects—even those who are very particular and exact indeed in matters that are comparatively quite indifferent and unimportant in compostion—do not scruple to vary the width of lights, just as suits their convenience or their indolence.

f attention to uniformity with regard to the width of the lights seems to be a fettering restriction in Gothic design, there is freedom enough in all other respects as far as windows are concerned, for their dimensions, forms, and position may be varied in the same building, as circumstances require. Nor is it the least recommendation of the Gothic style, that even where exact uniformity, both as to dimensions and general design, is required for windows, they need not be precisely alike in pattern. It is, again, in favour of Gothic windows—at least, for churches and other spacious halls—that even when there is no stained glass in them, the light is considerably moderated by the mullions, transoms, and tracery.

As the value of advantages is generally best appreciated by comparing them with contrary deficiencies, we will now consider how the case stands with windows for churches in other styles of architecture, nor have we long to consider since it is easy to perceive immediately that they have been and continue to be made blemishes in the architecture. Nothing equivalent to tracery has ever been invented or adopted for them, accordingly they are invariably mere vacant though glazed spaces, and as the glass is always of a very ordinary sort and in small panes—in conformity with church etiquette, we presume,—they become actually mean in appearance, and externally present only so many dingy and paltry-looking surfaces, which contrast rather grotesquely with the dressings around them, if these latter are at all noble or elegant in design. The larger too the window the worse does the defect become: the glazing appears insecure and to need support; and no better method, of strengthening it can, it seems, be devised than that of employing sometimes rude metal bars which have an equally mean and clumsy appearance. If Wren's churches in general are not disfigured by their windows, it is—we make bold to say—because there is nothing to be disfigured in them, they being exceedingly uncouth both in composition and style, though there may be a bit of tolerable detail or good feature in their elevations here and there, but the system of design adopted there is radically faulty and tasteless, it being modelled upon the Gothic without possessing any of the qualities or resources of that style: on the contrary, windows which are the source of so much character, beauty and variety in the Gothic style are at the very best only dull, insipid and monotonous features in the other, and to make matters worse, very obtrusive ones. In that otherwise noble edifice, St. Paul's, the windows are sad drawbacks on the architecture generally, both within and without; and within, although there is not that offensive rawness which is occasioned by undue quantity of light scattered in every direction to the destruction of that valuable ingredient—shadow, there is no effect of light—no brilliancy, no relief, for the windows show as so many harsh and cutting spots or holes, in comparison with which the rest looks gloomy. Never do we enter the building without regretting that Wren did not bethink him of getting rid of side windows altogether except those forming the clerestory of the nave; nor would it have cost him much study to do so, the mode of effecting it being obvious enough, for he had only to open the small blind domes in the vaultings over the aisles, and there would have been not only abundance of light but a charming effect of it. In that case the spaces occupied by the present windows would have afforded large compartments for fresco painting, which if such decoration for the edifice was ever contemplated at all, could not have been introduced half so effectively any where else, since the light would diffuse itself upon them from above, and from the nave each picture would have been seen in succession, framed in, as it were, by the arch between the nave and aisle.

At the time St. Paul's was built, *Hypæthral Fenestration*—as we may for distinction's sake call that mode in which the light is admitted from above through the roof of a building, does not seem to have been even so much as thought of, not even for domes, since the light was made to proceed chiefly from windows in the tambour beneath the dome, where they form a circular clerestory. A most noble object externally, the dome of St. Paul's shows itself almost the reverse within, presenting to the eye little more than a mass of sullen gloom, rather increased than the contrary by Thornhill's paintings. It seems therefore to require to be lit up by the most lustrous surfaces and ornaments of the purest white and gilding, which might perhaps sufficiently overcome the obscurity which now prevails in it. As to obtaining a sufficiency of light in a single volume of it by enlarging the eye of the dome, that was and is an impossibility, owing to the great space between the external and internal cupola.

Should the modern Greco-Roman or Italian style be resumed by us for churches—as as it is to be hoped that it will be, at least for those in towns, let us look forward to its being treated in a very different spirit from what it hitherto has been either in the last or present century, and to its being enriched by new elements and combinations. There certainly is abundant opportunity for imparting to it a new and more refined character by correcting it in regard to fenestration, so as to convert what has hitherto been a source of deformity into one of beauty and captivating effect. All the various mode of *hypæthral* fenestration—and they are exceedingly numerous, might be employed according to circumstances, very successfully, although they have hitherto been obstinately rejected for churches,—perhaps with a sort of puritanical horror,—assuredly more for conscience sake than for taste's. We can, however, vouch for the equally novel and happy effect produced in a recently built—in fact not yet finished chapel at the West-end of the town, where the light is admitted entirely from above, and on one side only, and in such manner that the windows themselves are not seen on entering, or afterwards, except by standing on the opposite side to them, and looking directly up at them, when they are discoverable, but even then only partially so. The idea thus thrown out—and to us it is quite new—is a valuable and fertile one. Owing to the beautiful effect of light and half-light—and the breadth of chiaroscuro, the interior we allude to is a complete picture. Possibly, the peculiar mode of lighting was forced upon the architect by circumstances of situation and juxta-position to houses; and if so, he has to bless his stars for the felicitous necessity which compelled him to step out of the hackneyed prosaic track of ordinary church-builders into the picturesque, the artistic, and the poetic. How fortunate would it be for many, were they to be equally favoured by untoward circumstances.—Our subject is not exhausted, but we will here close our present paper on it.

GOETHE'S HOUSE.

As the German Diet have resolved on purchasing Goethe's house, and on having it preserved in its present condition, as a monument of national recognition, the following description, derived from the German, and written by one of Goethe's friends, will, we trust, be acceptable to the reader:—

"On a roomy place (square), enlivened by the murmur of a fountain, stands a two-storied house, painted reddish-grey—the windows surrounded by a black border. Although apparently of spacious dimensions, it in no way exceeds the size of the dwelling of a respectable commoner. We pass the threshold, and enter a hall, whose colouring, resembling yellowish stone, renders it of a light and cheerful appearance. We now ascend the staircase, surrounded by a massive entablature, which leads us, by its broad steps, almost imperceptibly upwards. Its breadth must astonish any one, being disproportionate to the other dimensions of the building—occupying, nay absorbing, the whole lower part of the structure. It is interesting to know how it came to be such. During Goethe's stay at Rome, the house presented to him by the Grand Duke was to be finished, and an appropriate staircase was all ready, when the poet saw one at Rome which enraptured him. Having procured a drawing, he sent it to Weimar, with orders to make a similar one in his house. Vain were all remonstraces sent over the Alps;—there was no help but to obey him. When he returned, he saw, not without surprise, this huge structure, which deprived him of the lower part of his house,—ascended it, shaking his head; and never spoke of it afterwards.

In the upper vestibule, the statues of Sleep, Death, and the colossal head of Juno, gaze at the visitor from their mural niches. Roman landscapes and views, also, remind us of that land, after the leaving of which he said he never more enjoyed perfect happiness.

A small yellowish saloon is now opened. There he dined with his guests. Meyer's drawings of antiques, and Poussin's master-pieces, cover the walls; and behind a green curtain he preserved the Aquarell copy of the Aldobrandini nuptials, also by Meyer, which he considered his greatest treasure. The adjoining localities also exhibit only such objects which appertain to *that* period of art, and to that tendency of Goethe. Here, everywhere the past and its recollections speak to us, and to any one familiar with his works,—"the stones have tongues, and the walls features."

A string of historical associations seizes us,—that sensation which alone can make us thoroughly happy; because nothing is here which had not been touched, as it were, by him during the period of his life-apprenticeship;—and to everything new or different, the access was hereafter rigourously prohibited. It is with a deep feeling that we survey those trifles and minor things, in which this great man found such high edification.

To the right of this saloon we see the so-called ceiling-room; it is not known why Goethe thus called it, as all the rooms have ceilings made of stucco. To the left is his blue receiving-room, and behind it the Urbino-room, thus called after a picture of a Duke of Urbino, which Goethe had brought with him from Italy. On the threshold of his receiving-room greets us his friendly "*Salve!*" When he received strangers, he never came the way which we had passed from the staircase, but went from his study by a passage to the Urbino-room, and from thence he stepped forth, prepared and composed. He did not like—

"That moments, blind-passioned and dark-ruled,
Should have their sway."

These, therefore, were the rooms accessible, in the main, during his lifetime. To his study he admitted no one, with the exception of a few of his most intimate friends—Coudray, Müller, Riemer, Eckermann. When the King of Bavaria paid to Goethe his famous birth-day visit, he asked the poet to allow him also a view of the laboratory of his mind. Goethe looked perplexed, and intimated that his study was not adequately fitted up for the gaze of Majesty. The king seemed resigned, but feigned soon afterwards a bleeding at the nose, declined any one to follow him, and ordered the servant to conduct him to Goethe's washing-basin. The fellow, surprised and perplexed, brought him into Goethe's bed-room, which is behind the study, and left him alone, according to the king's desire. He remained long absent. Goethe, at last, went himself to look after the king—and found him in his study, absorbed in the observation of its contents.

The descriptions which I had found in memoirs and travels, of these rooms had all given me but an incorrect idea. I expected a certain splendour, as it might well be met with now in the houses of those who have talent and means to ornament their *alentours*. It was to that supposition that the flimsy words of visitors had led me. They saw *Zeus*, and therefore the walls surrounding him widened in their eyes to temple-halls, resplendent from *his* lustre. Most probably, I should have found myself in the same position then. Now, as we pass through the widowed rooms, illusion vanishes to give way to modest truth. It is a dwelling, comfortable, cheerful, decent, but thoroughly simple, in the fashion of a time rather passed away—in some places even the worse for wear. It is the dwelling of a patriarch, whose best recollections are attached to some piece of furniture, sashes, or colours, of former days, and which he therefore wishes to be preserved around him, even if they have begun to be unseemly, and are fading away into a duller colouring.

The death of the master has now broken the spell; we pass freely through small closets of communication, right through the house, to his library and study. In one of the rooms, we stopped a moment—it was that in which he dined, when alone, with his children; a blind throws a green shade around. With one step we were in the garden, in which the poet was accustomed, in time of leisure, to enjoy every clear glimpse of the sun. In the corner is a little garden-house, where he used to keep his physical apparatus.

In the fore-room of the museum we saw, in little presses and under glass frames around the walls, minerals, pieces of rocks, shells, fossils—in fact, all which had become a subject of his studies in natural history Everything was kept very clean, and arranged with good taste. A door to the right opened into the library. For such means as were here available, it may appear small; but Goethe purposely did not collect many books, as the libraries of Weimar and Jena were at his disposal — nay, to avoid the accumulation of such sort of treasure, which appeared superfluous to him, he gave away most of what had been presented to him from far and near, after having perused them.

Assistant-librarian Kräuter, clerk to Goethe before he took John as a copyest, now the faithful guardian of this sanctuary, opened the door of the master's study. I recollected from Eckermann's conversations, the occasional allusions of Goethe, which prepared me to find here high simplicity; still, even here, reality was somewhat different. This small, low, unornamented, green cabinet-closet, with the dark blinds of serge, the worn out sills, the nearly decayed frames, was therefore the space whence such an abundance of the most splendid light has poured forth!

Nothing is moved from its place; Kräuter adheres with pious rigour to his charge; every leaf of paper—every worn out pen—remains on the spot where it was when the poet fell asleep. The clock yet shows the death-hour—half past eleven;—it stopped then; an accident almost miraculous! Near it, to the right of the window, stands the small writing-desk, which the grandfather had made for his grand-children, whom, after the death of the father, he took under his care and immediate protection. Wolfgang was his favourite; next to him, Walter; Alma, for the sake of learning to sit still, was obliged to pluck pieces of silk next to her brothers at the little desk. There they are yet, in the envelope of a letter.

Here every spot is holy ground, and a variety of objects, of which the room is full, bespeak the being and actvity of such a mind. Around the walls run rather low presses, in which MSS. and other papers are kept; above are shelves, in which Goethe placed the objects with which he chanced to be occupied. The wood is browned by age, which is much contrasted by a chest of drawers of well polished cherry-wood. It was Goethe's daughter-in-law who gave this piece of furniture to him; but he could not long suffer its insinuating appearance, saying that it "distracted his thoughts." On that account also, there is no object of art in the room, and the visitor seeks in vain for either a looking-glass or a sofa. The latter he was not in need of, on the account that he either stood or moved about the whole day;—he read standing, wrote standing, and even took his breakfast on a high table. A similar conduct he recommended to every one in whose welfare he took any interest, designating it as "life-prolonging,"—as well as the keeping of the hands behind the back, by which, he added, "every narrowing and compressing of the chest is avoided."

Let us look a little more around this reverenced workshop of a great mind! There, at the left of the door, hang a sort of historical testimonials of *character*. Goethe had, at a certain period, written out one column in which was a list of celebrated men and public bodies who, according to his opinion, promised to bear some political fruits; and in the next column was remarked, whether and how far they had yielded, in subsequent years, the result which had been anticipated. Of General Jackson, Goethe had great hopes; his behaviour, however, towards the Indians was subsequently marked in black.

A triangle of pasteboard, which he had himself made, and which occupied the next shelves, is interesting as a sort of physiological *jeu d'esprit*. Goethe wanted to illustrate to himself the action of the powers of soul. The senses (*Sinnlichkeit*) appeared to him the basis of all; to it, therefore, the lower part of the triangle was devoted, and he painted it green. Imagination received a dark red; intellect (*Vernunft*), a yellow; reason (*Verstand*), a blue colour; and occupied each one of the sides. Next to it is a black hemisphere, also of pasteboard, on which, by the aid of a glass ball filled with water, Goethe used to depict all colours of the rainbow, in moments of clear sunshine. With this he could pass his time for hours, especially after the death of his son, and he enjoyed great pleasure when the motley glare was developed right powerfully. And thus he found thorough happiness whenever a phenomenon of nature came within his reach. There stands the small bust of Napoleon, made of opal-flux, which Eckermann brought him from Strasburg, and on which he found confirmed some of the assertions of his doctrine of colours (*Farbenlehre*), which filled him with extacy. A sealed bottle, which we see on one of the tables, he exulted in like a child. There had been some red wine in it, but had long been put aside, and Goethe once holding it towards the light, saw therein the finest crystals of cremor tartari in the shape of leaves and flowers. Like one inspired, he called those around him, ordered a candle, and put, with an air of festivity, his seal of arms on the cork, that no chance should any more destroy this fine phenomenon. The bottle henceforth never came out of his room.

From Napoleon he received revealings in the sphere of light; but he acted also demoniacally upon him from that region, to which, it seems, no ray of an upper world can ever penetrate. On the day of the battle of Leipsig, a medallion of plaster of Paris fell from the wall; a piece of the margin was broken off, without, however, the portrait of the hero being injured. There—in yonder recess—the image is yet to be seen, around which Goethe, parodising Lucan, had placed in red letters: "Scilicet immenso superest ex nomine multum."*

Thus stand's Goethe's house—tasteful, simple, as it behoves the man of mind and letters. A monument of his life and being, it will remain a beacon for others, pointing out the track they have to follow; although there is no person living at present, to whom a similar public recognition could, by any possibility, be ever decreed.

* Of a great name much remains.

ARCHITECTURAL RECOLLECTIONS OF ITALY.

By Frederick Lush.

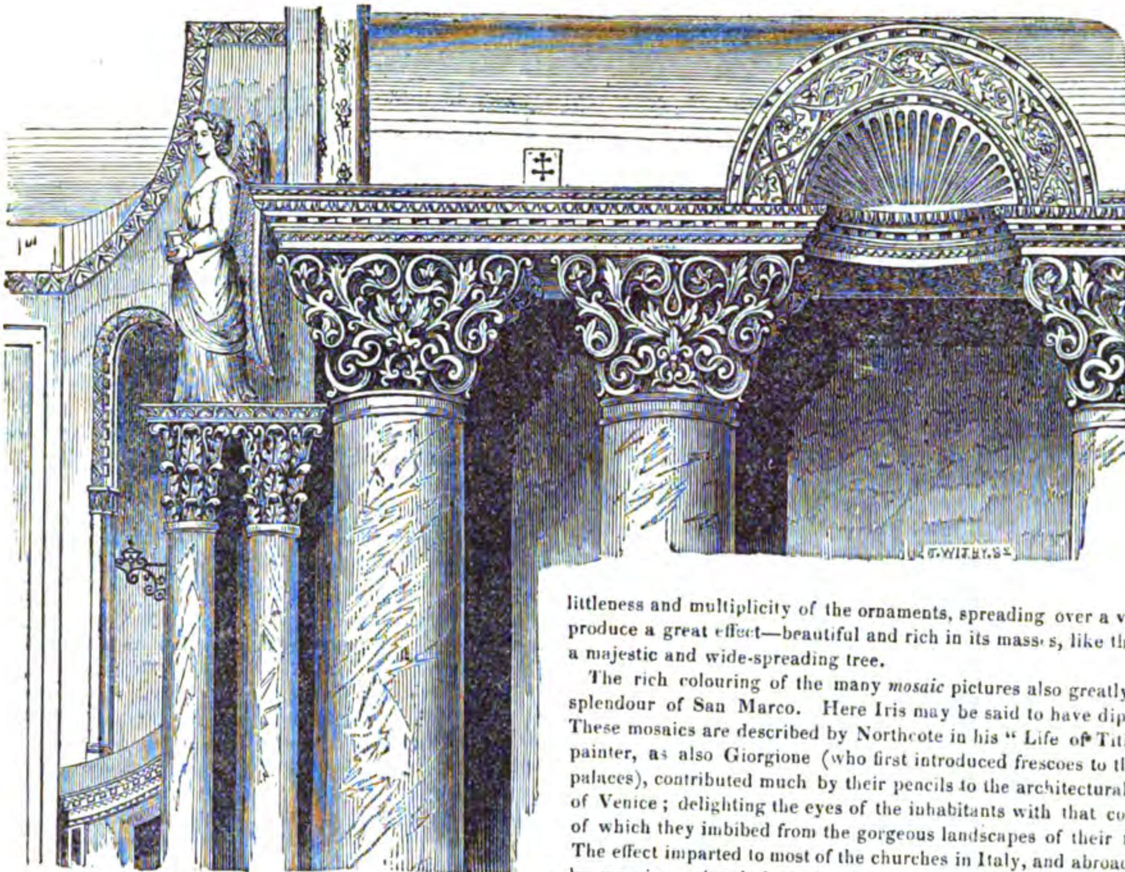
(*Continued from page 264.*)

The dependance of architecture upon painting and the composition of forms, for its most beautiful and majestic effects, and consequently the necessity of studying its principles in the works of eminent painters, was shown merely as an introduction to, or foundation for any remarks which I might subsequently make on the buildings of Italy; for a knowledge of these, forming the judgment to speak accurately upon the effects and combinations of visible objects, seemed the only sound basis for architectural criticism. Writers on art have oftentimes evinced much classic learning, and in some instances much taste; but these are not necessarily connected with each other; in some they are found existing together, though in others not. Wood and Forsyth, to whom the architectural world is indebted for a geat deal of learning, sagacity and research, in some of their critiques, do not appear to have always appreciated those excellencies in Italian buildings which to others were so striking, so obvious, and so often praised. The faculty of looking at them with a painter's eye, seemed to have been deadened, or not called into exercise; the want of perceiving beauty where it existed lying in the temperament or condition of mind under which it was viewed, but sometimes bigotted and pre-conceived notions of what was beautiful, and of a beauty altogether different, perverted their judgment, and they have sentenced a building, as ugly and monstrous, because it was so contrary to their previously imbibed ideas, and exhibited that which was totally at variance with the rules which guided the architects of their own favourite edifices. In these cases, their opinions were produced not upon the feelings or impressions which the objects were capable of making on their minds—or at least on minds not possessed of such antipathies—but from their dissimilarity from other styles to which their thoughts had been restricted.

Now a building which has made a wonderful impression upon myself and many other travellers, is *St. Mark's, Venice*; but this has been severely censured both by Forsyth and Woods. Here it is evident their senses were blind to its magic effects; to those effects at least which other minds differently constituted have experienced. But because they saw beauty in one style of architecture, will they deny it in another? The beauty of one flower differs from that of another—but if we admire the loveliness of the rose, are we to despise that of the lily? Because we have received one kind of emotion in beholding the awful ruins of the Coliseum and have felt the gloomy grandeur of Rome, is the heart incapable of admiring the splendid and magnificent architecture of Venice? The grand simplicity and convenience of the Colisco adapted for the cruel, barbaric daylight spectacles of the Romans cannot be compared with any modern theatre, nor can the massive architecture of the Romans, or the purity and sublimity of the Greeks be placed in juxta-position with the rich fantastic Gothic of Britain, Normandy, and Belgium. But can we infer that one is bad or faulty, because it differs from the other?

It seems that the romance of St. Mark's could in no manner operate on hearts steeled against its influence by a confirmed partiality for the stern, grand, and diametrically opposite features of the Roman school. The dislike to it extended so far with Woods, that in his "Letters," &c.; we find him, after blaming this thing and the other, suggesting such additions and alterations as he thought would improve it. I believe it was the same, or a similar person, who thought it a pity the Parthenon was not surmounted by a steeple! Here the greatest deformity was in the mind, but none whatever in the work, its beauty, along with many another, being that of fitness, whose necessary quality the change proposed would instantly destroy.

The architecture of St. Marks, beautiful in spite of its want of purity and many anomalies, is, as an Italian says, *un grotesco, ma un grotesco magnifico*. Exhibiting a happy mixture of different styles and different materials; making the rules which have limited the conceptions of all other buildings only subservient to its purposes, it can have nothing in common with them, and is put out of the scale of comparison. "There



is no law—says Charles Lamb—to judge of the lawless, or canon by which a dream may be criticised."

Seeing, therefore, by what false criteria St. Marks has been judged, and consequently how the beautiful characteristics of this strange pile, have been misunderstood, I speak in praise of it now, out of pure love and recollection of the feelings which it gave on the spot, and am grateful—as those who have seen and been wrought upon by it must be—for the proud vision which memory frequently brings before the fancy. Its effect on the mind, as well as of the scenery amidst which it is placed, should be pondered over, as a means of raising the taste and increasing our ideas of the beautiful in art.

This Basilica (combining, as it were, the Mosque or Mahommedan house of prayer, with the Christian temple), both in its parts and as a whole, is magical in the extreme. Look for a moment at the profusion and magnificence of its ornaments. The Byzantine-Greeks, unlike their forefathers, avoided the horizontal line as much as possible, and indulged in the curve; the fondness for it resulting from their co-operations with the Saracens; and the communication of the crusaders with the East served to spread it over many parts of Europe.* This love of wavy lines and intricate forms characterises the Venetian architecture, and is most conspicuous in St. Marks. (See the annexed engraving of a portion of the vestibule.) The object of the designers was a great richness of effect—which certainly the nature of the ornaments produced, and often also a grandeur of ensemble,—although, on a close examination into their minutiæ, we find much that is defective: as in the ornate and kindred style of the Alhambra, or that of the Elizabethan. But with all the blemishes in its details, the mind is presented with a view, resulting from the union and consent of so many opposite parts, which is a principal cause of its beauty. The wildness or irregularity in the simplicity of the whole affect the mind with a series of strong impulses, more delightful than that monotonous, though sometimes agreeable, sentiment which is experienced in works built after ordinary rules and common-place precepts. Even the littleness and multiplicity of the ornaments, spreading over a vast surface, produce a great effect—beautiful and rich in its masses, like the foliage of a majestic and wide-spreading tree.

The rich colouring of the many *mosaic* pictures also greatly add to the splendour of San Marco. Here Iris may be said to have dipt the woof. These mosaics are described by Northcote in his "Life of Titian." This painter, as also Giorgione (who first introduced frescoes to the Venetian palaces), contributed much by their pencils to the architectural decoration of Venice; delighting the eyes of the inhabitants with that colour, a love of which they imbibed from the gorgeous landscapes of their native city. The effect imparted to most of the churches in Italy, and abroad generally, by mosaics, painted glass, frescoes, tapestries, carvings, &c., makes one regret that these arts are not more in use amongst us. Or, without referring to the decorated and impressive interiors of the foreign churches, we have eminent examples at home, in the magnificent cathedrals of our Gothic ancestors.

In looking at the rich mosaics in St. Marks, and observing what taste and skill are displayed in shrine, altar, screen, lamps, candelabra, and, in short, every work which the ceremonies and splendour of the church required, we see how every art, that was known at the time, was had recourse to for heightening the effect, both of its exterior and interior. Every object that enriched it, received an additional attraction from, and was in keeping with, the splendid crosses and reliques borne by the processions in the celebration of the festivals;—witness it, for instance, on the festa of *Corpus Domini.* The one absorbing object in its erection and adornment was to render it as splendid and symbolic as possible,—most precious in all materials and workmanship, and to surpass even the Orientals in its magnificence. This was the purport of its inscription: "Istoriis, auro, forma, specie tabularum; hoc templum Marci fore dic decus ecclesiarum." Its interior, though far from "gloomy"—as it has been miscalled—has, it is true, become somewhat dimmed by age and the frequent burning of incense;—but in its palmy days, how bright and glittering must have been its gold! what life and light must it have transfused around, by reflection and refraction!

There is another point for our admiration. Placed in one of the finest piazzas in the world, can anything be conceived more enchanting on such a spot, viewed from the Palazzo Reale, either at noon, when the sun pours its full brilliance upon it; or at night, when the numerous lights below bring out in all their contrast and colours and proportions the wonderful details of its façade;—the moon shedding a bright light on its cupolas and pinnacles, and the dark blue sky around heightening its effect? Can any object be more appropriate than this to Venice? Wealth and gaiety, luxury and romance, make the character of the city,—and the architecture partakes of it. Yet the vesture of mosaics, and gold, and sparkling marbles, in which it is arrayed, seen anywhere else but in Venice, would look like a mountebank in a company of divines.

* An infusion of the Saracenic style is seen in many parts on the continent—from Venice, traces of it along the road to Brescia, and in other directions. The border ornament so common in the Venetian palaces is round the windows of St. Peter's cathedral, Geneva: and the minarets and metal globes on the towers of many churches in Switzerland, give to the towns a rather Eastern appearance. For details, sculpture, &c., of St. Marks, see the works of Cicognara, Zanotto, Kreutser, Canaletti, &c.

NOTES ON ENGINEERING,

VI.

MENAI TUBULAR BRIDGE.

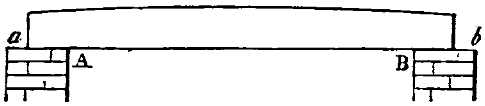
(*Continued from page* 174).

In the last paper on the Menai Tubular Bridge (*ante* p. 174), a formula was given for calculating the *horizontal* strains to which the vertical plates of the tube would be subject, and a truth hitherto entirely overlooked was demonstrated, that these plates ought to be stronger towards their extremities than at the centre.

To complete the investigation of the forces to which these plates are subject, the amount of the *vertical* strains ought also to be determined. But as these papers were already been carried to some length, it is necessary to study brevity; and it will be sufficient to point out the general steps of the calculation.

The vertical plates consist of two different portions discharging two different offices. That part of each vertical plate which lies over the abutments *supports* the upper horizontal plate *upon* the lower: the part between the abutments and clear of them *suspends* the lower plate *from* the upper.

In the following diagram, then, the vertical forces of those parts of the vertical rib which are over A *a*, and B *b*, are thursts, and the vertical forces of the part of A B, tensions. To consider the latter first, let us suppose



sections made at A and B, and that the connection between the upper and lower plates is made not by a continuous rib, but by a number of vertical rods. Then it is clear that we may consider the lower plate and the load on it suspended by means of these rods from the upper plate. We must also take into account the vertical molecular at the sections at A B. But as it is impossible to calculate their amount exactly, it will probably be sufficient for practical purposes to suppose that they sustain half the pressure of the load, and that the other half is communicated by means of the suspending rods to the upper plate. Hence the total tension of these rods will be equal to half the weight of the train + the weight of one of the horizontal plates. If we suppose the rib continuous and not formed of rods, the conclusion will not be widely different. A continuous rib indeed would be *cut* by the section through A and B, but the molecular forces of the rib at the sections would be small compared with the total tension distributed over its whole length.

Hence we conclude that the vertical plates between A and B must together possess sufficient strength that half the load and the weight, one of the horizontal plates may be suspended from them without injuring them.

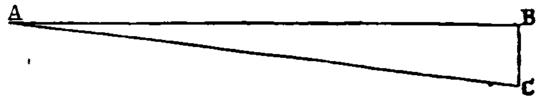
To consider next the vertical thrusts on the portions A *a*, B *b* of the side-plates, it may be easily seen by similar reasoning that these portions support half the load and the weight of one of the horizontal plates resting on them. An important practical conclusion from this is that the portions of the vertical plates over the abutments should be much stronger than the remainder, for they have to resist an equal amount of force distributed over much less surface, and moreover the power of wrought iron to resist thrust is greatly inferior to its power to resist tension.

We cannot conclude this part of the investigation without expressing a conviction that the connection between the upper and lower plates should be maintained, not by continuous plates, but by a lattice of vertical and horizontal rods, firmly clasped together at the points where they cross each other. The necessary strength of them might be calculated with considerable accuracy, they would accommodate themselves far better than continuous plates would to the variations of form produced by changes of temperature, would offer less resistance to the wind, and would admit light and air to the interior of the tube.

7. *Variations of Temperature.*

It may be demonstrated in the simplest manner, that on account of the expansion and construction of the tube from variations of temperature, it would be absolutely necessary that the ends should be left free to move in a horizontal direction.

It is shown by a very common experiment that a plate of metal if fastened in a horizontal direction between two props, and then considerably heated, will, if prevented from expanding laterally, become bowed or deflected. The same thing would happen with the tubular bridge if it were so fastened that it could not expand laterally. In order to ascertain the amount of deflection let A B be half of the length of the bridge before, A C



after, expansion. We will first for sake of simplicity suppose A C a straight line. Then B C is the deflection, and

$$BC^2 = AC^2 - AB^2 = (AC + AB)(AC - AB).$$

It is usual to reckon the limits of expansion of iron at $\frac{1}{1200}$ of the length. Therefore if A B be 225 feet or 2700 inches, the expansion to be allowed for is $2\frac{1}{4}$ inches each way, ∴ $AC = 2700\frac{9}{4}$, $AC + AB = 5400\frac{9}{4}$, $AC - AB = \frac{9}{4}$. Hence $BC^2 = 12150$ inches, and $BC = 110$ inches nearly. Therefore the amount of deflection by expansion would be *rather more than nine feet*.

A C has been here assumed to be a straight line: if however we suppose as a probable approximation to the truth that it is a segment of a circle we shall find that the amount of deflection is not materially diminished. It may be ascertained by a laborious numerical operation which it is not necessary here to repeat that the amount will be about 8 feet. It is clear that a much less distortion than this would suffice to fracture the vertical plates, or wrench them from the horizontal plates.

8. *Effect of Wind.*

A subject of the utmost importance with respect to the permanent stability of the Tubular Bridge is its power of withstanding the lateral pressure of wind. It appears from the experiments of Smeaton, detailed in the Philosophical Transactions for 1757, that the extreme pressure of the wind, when blowing violently, is 49·2 lb. to the square foot. This probably is an amount of pressure which the wind rarely exercises except at sea or when confined between hills. It is said, however, that in March last the force of a gale in Scotland, as registered by an excellent anemometer, was 45 lb. to the square foot. We are also to consider that the situation of the Menai Bridge is one exceedingly subject to the violence of storms, and that the sea-winds confined between the high lands on either side of the straits would exert their force perpendicularly upon the Tubular Bridge, which of course crosses the straits at right angles.

We therefore shall not be exaggerating if we estimate that 45 or 50 lb. per square foot is the amount of lateral pressure which the tube ought to be capable of resisting. In this case we shall find that as the area of one of the vertical sides is 13500 square feet, each span of 450 feet would sustain a pressure of 271 or 301 tons.

Now the utmost vertical pressure which the weight of a train will exert on the same length of the bridge is 200 tons—that is 71 or 101 tons less than the lateral pressure of the wind. It would therefore seem to follow that whatever precautions be necessary for vertical strength are still more necessary for lateral strength, and if it be requisite to strengthen the top and bottom of the tube by a collection of rectangular cells or compartments, the same apparatus (or rather one much stronger) ought to be applied to the sides of the tube. It is quite impossible to assign any solid reason for preferring the consideration of vertical strength to that of lateral, or for endeavouring to obtain the two kinds of strength by dissimilar methods. For it is clear that if the apparatus of cellular compartments be the best possible for ensuring strength vertically, it is also the best for ensuring strength laterally.

It might be answered perhaps that the cellular compartments give to the top and bottom of the tube an excess of strength which will never be required in practice: but then it may be replied that this excess of strength is just as requisite for the sides of the tube; for the effects would be equally disastrous whether the structure broke laterally or vertically. If the tube require an excess of vertical strength, it equally requires an excess of lateral strength: if it do not require an excess of lateral strength, neither does it of vertical. In which latter case the cellular compartments are simply superfluous.

The force of the wind on one span only of 450 feet has been reckoned. If we calculate the force of the two spans of that length, and the force on the two smaller spans of 250 feet each, we shall have the total force tending to overturn the piers or otherwise displace the structure.

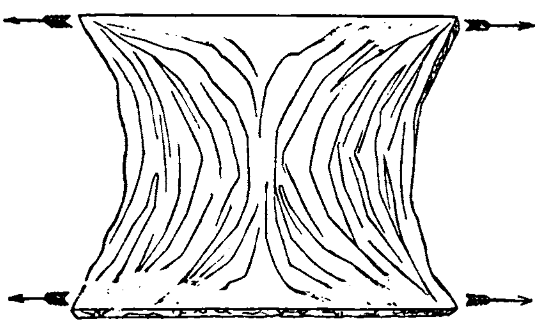
9. *The best form of the upper and lower sides.*

In calculating the strength of the tube, the course taken in the preceding parts of this investigation has been to estimate the sectional area of the metal composing the upper and lower sides of the tube, and to suppose the strain equally divided over the whole area. In order however that the latter assumption may obtain, it is necessary that the top and bottom of the tube should be of a particular form. We shall proceed to show that where the top and bottom consist of continuous plates, extending from one side of the bridge to the other, or where they are formed of cellular compartments such as those described in another part of this Journal, the above requisite is not answered, but that on the contrary, a large proportion of the metal is placed where it is almost entirely inoperative, and that consequently any calculation founded on the supposition that this metal contributes to the strength of the tube must lead to dangerous results.

If the reader will take hold of the page which he is now perusing, at the top and bottom, and pull it, he will see that if the paper were torn the rent would commence somewhere in the neighbourhood of the straight line joining his two thumbs. If, for example, he held the paper by the two right-hand corners the rent would commence on the right side of the page, and the material on the left side would contribute nothing to resist the tearing. Again, if he took the page near the two ends of the black line, separating the two columns of letter-press, the rent would in this case commence in the middle, and the material to the right and left would not under these circumstances contribute anything to the strength of the paper to resist tearing.

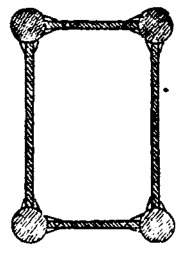
These experiments may appear very simple, and perhaps very puerile. But it is precisely these simple illustrations which give us accurate notions of the action of forces. The case of tearing the paper is exactly analogous to that of tearing the lower plate of the Menai Bridge. It has been shown that owing to the connection of the lower plate with the two side plates, the latter communicate to the former a longitudinal tension which acts all along its two sides. Now this tension is most effective in the immediate neighbourhood of the line in which it acts. If the bridge were overloaded and the bottom plate torn, we are sure that *the rent would commence at the edges, and not in the middle of the plate.*

If a piece of india-rubber, originally square, be stretched by four forces acting in the directions represented by the arrows, it will be found to assume the form here represented; that is, the extension will be greatest in the neighbourhood of the lines joining each pair of opposite forces, and least midway between those lines. In fact if the forces be not too great it is possible to extend the sides of the india-rubber without extending the middle portion at all; so that a small slit made near the centre will remain closed. There is probably some law for the decrease of tension from the sides towards the centre, but there seems no way of ascertaining it except by experiment.

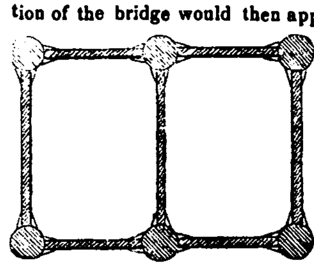


In the recent discussion respecting the Tubular Bridge, in the Mechanical Section of the British Association, it was asserted by Mr. Lamb that provided the top and bottom plates of the tube were of a given sectional area, it was immaterial what proportion the thickness of the plates bore to their width. If this theory be true, it must be true in the limit; and consequently if the top and bottom plates were rolled out till they were no thicker than the finest gold leaf, or the film of a soap-bubble, they should retain their original strength. The mere statement of this notion might be considered a sufficient proof of its absurdity, had not something very similar been sanctioned by high authority. Professor Moseley states in a passage already quoted, that the strongest form of a beam would theoretically be that in which the material of the extended and compressed sides is "collected into two geometrical lines parallel to the neutral axis." Now this would be perfectly true were we dealing with mathematically rigid bodies, but with extensible and compressible substances it seems obvious that the extension or compression could not be uniformly distributed over two indefinitely thin flanges, but would be greatest in the neighbourhood of the vertical rib. Professor Moseley has throughout his investigation assumed that in the vertical section of a deflected beam the extension or compression is proportional to the distance from the neutral axis, and it seems curious that he should have overlooked the fact that in a girder with wide flanges the extension and compression of the flanges also would be, not uniform, but greatest in the neighbourhood of the rib.

We come then with the utmost security to this conclusion, that the strongest form of a beam is one in which the material of the flanges is collected as closely as possible to the upper and lower edges of the vertical rib. This form is very nearly approached in the rails in most general use on our railways, and may be easily imitated in the case of the Tubular Bridge. The accompanying diagram shows a section of the bridge with the principal portion of the material collected at the four angles. If we suppose these four masses to have circular sections, it is easy to calculate what diameter they must have in order to satisfy the conditions of the preceding investigation. It will be remembered that the sectional areas of the upper and lower plates were each taken at 180 square inches, and if the half of this area be assigned to each side of the tube, the area of each of the circles represented in the diagram must be 90 square inches, and the diameter will consequently be about $10\frac{3}{4}$ inches. Let us take the diameter at one foot. Then the thickness of the solid masses at the angles will be equal to one-thirtieth of the height of the bridge. These masses should not be united by continuous plates but braced together by a lattice of iron rods. There are many reasons for preferring open lattice—they are chiefly these—superior strength for equal weight of material, diminished resistance to the wind, admission of light and air to the interior of the bridge, equalisation of temperature by which the danger of distortion by unequal expansion is avoided, and lastly facility of construction.



The bridge is to consist of two parts, containing two parallel roadways. These two parts should be united so as to afford mutual support: the section of the bridge would then appear as in the accompanying illustration. The upper and lower sides of the bridge would be braced together by lattice work similarly to the vertical sides. By these means it will be seen from a mere inspection of the section that the lateral strength would even exceed the vertical. This may be considered another most important advantage arising from the disposition of the material in masses at the angles. If the bridge be covered above and below by cellular compartments extending across it, the same apparatus ought to be applied to the vertical sides, as has been clearly proved; whereas by disposing the material in compact masses it is made to answer both purposes at once—it resists the lateral pressure of wind and the vertical pressure of a train with equal efficiency.



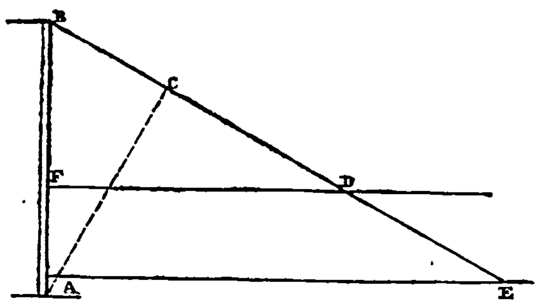
There is one reason more to be assigned for the employment of the upper and lower lattice work. It was observed during one of the recent experiments that the top or compressed side of the tube bulged out transversely; and it may be seen that with a bridge of the construction here suggested, the masses at the upper angles would, when in a state of compression, tend to be similarly bent. They would be likely to be bowed outwards or inwards, and this tendency is restrained by the horizontal bracing. These considerations confirm, to a certain extent, the views of Mr. Byrne, recently propounded in this Journal. The particular mode of calculation adopted by him may fairly be subjected to discussion; but it cannot be doubted that his general views respecting the horizontal transversal strains to which deflected beams are subject, when they tend to break rather by the distortion of the material than the disruption of it, form a valuable addition to the theory of the strength of beams.

10. *The employment of Suspension Rods.*

The reader who has followed the course of the present argument will have no difficulty in understanding that the strength of the bridge depends on the moments of the molecular forces about the abutment—that is, the molecular forces multiplied into their perpendicular distance from the abutment. And it will follow as a necessary consequence of this consideration, that by a proper disposition of suspension rods, an enormous saving of material may be effected.

In some of the published views of the Tubular Bridge, there are represented curved chains, similar to those of common suspension bridges, meeting the tube at a very acute angle. The only points where these suspension-chains are attacked are their extremities, and as they are unprovided with vertical rods, their action is extremely indirect, the greater part of the tension being revolved horizontally instead of vertically. A more inefficient contrivance could scarcely be suggested.

If however *rectilineal* rods be applied according to the plan explained by Mr. Bashforth, in a former number of this Journal, the result is very different. Let the diagram represent a section of part of the bridge and



one abutment-tower. B D E one of the straight suspending rods joining the points D and E of the bridge directly with the top of the tower. Then the perpendicular distance of B E from the abutment is equal to A C, and the moment of the forces about A is the tension of the rod multiplied by the length of A C. This length may be termed popularly the leverage of the rod. But the leverage of the horizontal forces in F D will never exceed A F, the height of the bridge, and consequently the efficiency of the material in B D, over the material in F D is the proportion A C : A F. If we suppose the height of the towers to be 80 feet, (the height of the towers of the Hungerford Bridge), and E to be at the centre of the bridge, we shall find by simple trigonometry the proportion A C : A F equivalent to 2·985 to 1. In other words by putting the material in the form of a straight rod the efficiency is in this particular case nearly trebled.

The enormous increase of strength for a given quantity of material which this reasoning demonstrates ought scarcely to be neglected. Even if we look at the question practically without regard to definite mechanical principles, it seems clear from a mere inspection of the diagram, that the rod B D exerts an upward pull or strain applied directly to sustain the bridge and that the action of F D is comparatively indirect and inefficient.

But there is another great advantage in the use of suspending rods—that they act by tension only. Where the metal is applied to exert a thrust it will give way far sooner by bending than by actual disruption, as the recent experiments abundantly prove: but where it exerts a tension it can only fail by being torn asunder. If it were accidently bent, a thrust would tend to bend it still more,—a tension to straighten it again.

It will be seen by reference to Mr. Bashforth's paper that the effect of the expansion of the rods in summer would be so small that it might safely be neglected, and small as it is, it would be almost entirely compensated for by the expansion of the masonry of the towers. The sinking of the bridge from this cause would not be nearly equal to that due to a heavy load. The rods could never become loose and cease to exert a tension. Even if we suppose they could do so, their value as means of security would still remain the same: for this is certain—the bridge could never actually give way under the effect of a heavy load *until* the rods were broken.

The experiment of the application of rods to the tube has not yet been tried. If this were done, it may be safely predicted that the amount of the breaking weight would be very greatly increased. It would be difficult to calculate beforehand the exact increase of strength, but if the comparison be fairly instituted by experiment between a bridge with cellular compartments and without suspending rods, and one with suspending rods and the material collected in masses at the angles of the bridge, it may be confidently anticipated that the strength would be increased to three times—probably many more times—its former value.

The suspension chain should be relied upon as the principal means of security, the masses at the angles of the bridge as the principal means of rigidity. By thus assigning to each part its separate appropriate office, the efficiency of the whole is most likely to be ascertained.

The preceding investigation has been carried to so great a length that many things are necessarily omitted which are important with respect both to the theory and to the practical construction of the bridge. The circumstance of the experiments being confided into such hands as those of Messrs. Fairbairn and Hodgkinson has prevented the appearance of many suggestions which otherwise might not have been superfluous. If however the remarks here offered conduce to any improvements in the particular structure which has been here considered, or should facilitate the application of simple statical principles to the general theory of the strength of materials, the labour of the writer will not go unrewarded.

H. C.

SETTING OUT RAILWAY CURVES.

Sir,—In reference to Mr. George Heald's communication to you on the subject of laying out railway curves, I beg to say that I have occasionally used a method which is, I think, more simple and accurate, which is as follows:—

Take any given curve, and fix the two extremities of it by two poles and flags. Then run a right line between these two points, which will, of course, be a chord to the curve. Divide this chord line by two, which point of division will be its centre, and each half will = sine of ½ the whole arc, and its versed sine will be the perpendicular to set off at this point; and this *v. s.* is found by multiplying the tubular *v. s.* by radius of curve.

Then proceed to ascertain, in a similar manner, the centre points of each of the two halves of the curves, by running chords, dividing them in two parts, and setting off the perpendicular from the centre by means of its versed line.

When the curve has been divided into a few parts in this way, the small divisions, being now equal and close at hand, may be ascertained by striking one of them on a large size, and, by a scale of equal parts, ascertain the ordinates of one part, which serves for all the other parts.

I am your obedient servant,

An Engineer out of Employment.

Oswestry, July 18, 1846.

[The suggestion above is well worth recording. The method described by our correspondent appears to be very practicable, and is geometrically accurate. Whether, however, this method, or that requiring tables of railway curves, similar to those reviewed by us last month, require the least labour, can only be determined by actual experience.]—Ed.

THE PROBLEMS IN "PLANE SURVEYING."

Sir—Such communications as those of your correspondents, Messrs. Byrne and Turnbull, are little calculated to support the high credit to which your work aspires, and to which by the general ability of your articles it has attained. In common, therefore, with other of your readers with whom I have conversed on the subject, I could not but feel indignant at the unwarrantable pretensions to originality which characterise both; and still more, at the accusation brought by one of them of *bad faith* on the part of the late Dr. Olynthus Gregory. At the same time, it was a source of real regret to see your pages made the medium for claims, which, to say the least, are preposterous; but much as I should dislike any personal dispute, or other intercourse, with either of those writers, I consider that the importance of any otherwise unworthy statement which may appear in your pages, is so far enhanced by that circumstance, that it ought not to be allowed to pass into currency without a caveat from those who set an estimate upon truth, and are themselves cultivators of science.

In the first place, Mr. Byrne's "fundamental principle," upon which he sets such extraordinary value, was given by Carnot, nearly half a century ago, in his *Géométrie de Position*, and in his *Essai sur la Théorie des Transversales*. The application of it to the problems in question have been given over and over by Dr. Gregory in successive editions of *Hutton's Mathematics*, and there they still remain in the last edition of that work, published in 1842, in a form only differing so far from that in your pages as would follow from a wish to conceal their origin. So much for Mr. Byrne's boasted "quality of being original."

With respect to your other correspondent, Mr. Turnbull, I have in the second place to admit, that against his opponent his claim is conclusive for as much as it is worth. That worth is however, inconsiderable, in a practical point of view, at least; and beyond being useful exercises in trigonometrical reduction, they have no scientific value whatever. Under either aspect, no person whose inventive powers in mathematics is of the average order, would consider the discovery worth a moment's dispute. It is to the grave charge made against Dr. Gregory by Mr. Turnbull, (who should have been the last man to make that charge against him) that I take the most decided objection, and to which I will wholly confine my remarks.

It was in your number for October 1845 that I believe this strange charge was first made, and on the same page you refuse to allow any animadversions on Mr. Turnbull's writings—merely from private reasons affecting that person. It must have escaped your notice, at the time of writing that interdict, that you had just marked for press a communication from him which casts a serious imputation upon the memory of a distinguished geometer and truly good man, whose name is justly endeared to the engineering profession.

Now it appears to me that notwithstanding any private considerations affecting Mr. Turnbull, you and the public are entitled to demand of him his *evidences* of the truth of the statement which he makes respecting Dr. Gregory. Mere allegation in such a case is not enough from any man—from Mr. Turnbull certainly not. The question is one between Dr. Gregory's honesty and Mr. Turnbull's veracity: it is a question of *character*, and must not be slurred over as one of no moment. Originality is in this case a question of such minor importance as not to deserve a single thought, except so far as regards its decision upon a question of personal character. I at once apprize Mr. Turnbull that his explanation will be submitted to a scrutiny so rigid, that it will be desirable that he attend more closely to strict accuracy than usual: for the character of public men, and especially of such men as Dr. Gregory, is public property, and will be guarded with corresponding vigilance.

Pending Mr. Turnbull's proofs that Dr. Gregory appropriated his discoveries "without acknowledgment of the source from which they were derived," I only claim that *due weight shall be given to the admitted characters and known talents of the accuser and the accused*:—and that with this shall be coupled a recollection of the triviality of the scientific part of the question at issue.

I am, Sir, your obedient servant,

VINDEX.

September 15, 1846.

PROCEEDINGS OF THE BRITISH ASSOCIATION.

The British Associaton for the Advancement of Science held its annual meeting at Southampton during the past month. The President's address appears on another page. The following report contains merely a selection of those parts of the sectional proceedings most interesting to the engineer. The proceedings of the mechanical section are the most fully noticed, and are followed by some editorial notes. The report will be concluded next month.

On Thursday, Sept. 10, the General Committee met in the Town Hall over the Bargate, Sir John Herschel in the chair. After the minutes of the committee meetings, Cambridge, were confirmed, Colonel Sabine read the following Report of the Council, being the account of their proceedings since June, 1845:

Report of the Council to the General Committee.

1. The Council have the very satisfactory duty to perform of reporting to the General Committee that the Resolutions of the Magnetical and Meteorological Conference, adopted by the General Committee at Cambridge on the 22th June, 1845, were submitted to the Right Hon. Sir Robert Peel, Bart., by the president, Sir John Herschel, Bart., accompanied by a communication from the Marquis of Northampton, president of the Royal Society, conveying the concurrence of that body in the recommendations contained therein; that they received a very favourable consideration from her Majesty's Government, and that the recommendations connected with the British observations both at home and in the colonies are in progress of being carried out. The resolutions relating to the East Indian observations and surveys have met with an equally favourable reception from the Hon. Court of Directors of the East India Company, and the recommendations which they contained have been approved and sanctioned. In accordance with the resolutions passed at Cambridge, therefore, the Magnetic Observatory at Greenwich is permanently continued upon the most extensive and efficient scale, The magnetical and meteorological observations are constituted a permanent branch of the duties of the Astronomical Observatories at the Cape of Good Hope, Bombay, and Madras, and arrangements are in progress for making them also a permanent branch of the observations to be made at the Observatory at Paramatta. The detachment of the Royal Artillery, by whom the duties at the Cape of Good Hope have been hitherto performed, has been relieved by a permanent increase in the civil strength of the Astronomical Observatory; and in like manner the officers of the Royal Navy and the marines who now form the establishment of the Observatory at Van Dieman's Island, will be relieved as soon as the establishment at Paramatta is completed. The Ordnance observatories at Toronto and St Helena are to be continued until the close of 1848.

With reference to the recommendations relating to magnetic surveys, a magnetic survey of the Indian Seas, by Lieut. Elliot of the Bengal Engineers, has received the sanction of the Hon. Court of Directors of the East India Company, and arrangements are in progress for its commencement. Also, early in the present summer Lieut. Moore, of the Royal Navy, proceeded under the direction of the Lords of the Admiralty to Hudson's Bay, in one of the vessels belonging to the Hudson's Bay Company, for the purpose of connecting the observations of the Canadian Survey with those which the expedition under Sir John Franklin is making in the seas to the north of the American Continent.

In accordance with the recommendation concerning the co-operation of foreign magnetical and meteorological observatories, communications were made, on the application of the president, by the Earl of Aberdeen, her Majesty's principal Secretary of State for Foreign Affairs, to the governments of Russia, Austria, Prussia, and Belgium, from all of whom very favourable replies have been received.

2. The resolution passed by the General Committee to the effect "That it is highly desirable to encourage by specific pecuniary reward the improvement of self-according magnetical and meteorological apparatus, and that the Presidents of the Royal Society and of the British Association be requested to solicit the favourable consideration of her Majesty's government to this subject," has been brought under the notice of government, and favourably received, and arrangements have been made to carry the recommendation into effect. Whilst on this subject, the Council has also much pleasure in noticing that the President and Council of the Royal Society have granted £50 from the Wollaston Donation Fund, to assist in the construction of apparatus devised by Mr. Ronalds for the self-registry of magnetical and meteorological instruments, and which apparatus is in progress of completion at the observatory of the British Association at Kew. The Council are persuaded that the General Committee will view with satisfaction this co-operation of the Royal Society and British Association for objects common to both, and for which the observatory at Kew furnishes a very convenient locality.

3. The General Committee at Cambridge having passed a resolution, "That it be referred to the Council to take into consideration, before the next meeting of the Association, the expediency of discontinuing the Kew Observatory," the Council appointed a committee, consisting of the President (Sir John Herschel), the Dean of Ely, the Astronomer Royal, Professors Graham and Wheatstone, and Lieut.-Col. Sabine, to collect information on the scientific purposes which the Kew Observatory has served, and on its general usefulness to science and to the Association. The report of the committee was as follows:—

"*Kew Observatory*, May 7, 1846.—Present: Sir J. F. W. Herschel, Bart., the Astronomer Royal, Professors Graham and Wheatstone, and Lieut.-Col. Sabine. After an attentive examination of the present state of the establishment, and of other matters connected therewith, the following resolutions were unanimously adopted, viz.:

"That it be recommended to the General Committee that the establishment at Kew, the occupancy of which has been granted by her Majesty to the British Association, be maintained in its present state of efficiency. 1. Because it affords, at a very inconsiderable expense, a local habitation to the Association, and a convenient depository for its books, manuscripts, and apparatus. 2. Because it has afforded to members of the Association the means of prosecuting many physical inquiries which otherwise would not have been entered upon. 3. Because the establishment has already become a point of interest to scientific foreigners, several of whom have visited it. 4. Because the grant of the occupancy of the building by her Majesty, at the earnest request of the British Association, is an instance of her Majesty's interest in, and approval of, the objects of the Association. 5. Because, if the Association at the present time relinquish the establishment, it will probably never again be available for the purposes of science. 6. Because it appears, both from the publications of the British Association, and from the records in progress at the establishment, that a great amount of electrical and meteorological observation has been and continues to be made, and that a systematic inquiry into the intricate subject of atmospheric electricity has been carried out by Mr. Ronalds, which has been productive of very material improvements in that subject, and has in effect furnished the model of the processes conducted at the Royal Observatory: and because these inquiries are still in progress under local circumstances extremely favourable. 7. Because other inquiries into the working of self-registering apparatus, both meteorological and magnetical, are in actual progress at the establishment, and that there is a distinct prospect of the facilities it affords being speedily much more largely profited by. 8. Because the access to the observatory from London to members of the Association will shortly be greatly improved by railroads, and because the local facilities and conveniences of the establishment have been very greatly enhanced by alterations in its relations to the Commissioners of Woods and Forests."

"J. F. W. HERSCHEL, *Chairman*."

In laying before the General Committee the report received from this committee, the Council desires to add the expression of its own opinion in conformity with its resolutions.

4. The Council has received a letter from the honorary secretary of the Literary and Philosophical Institution at Cheltenham, expressing on the part of the members of that Institution deep regret that circumstances have arisen which render uncertain their being able to give the British Association that welcome and generous reception which it would be their desire to do, and which they last year felt they could have done had the Association been so circumstanced as to have accepted the invitation for the summer of 1846.

5. The Council has been informed by a letter from W. R. Grove, Esq., F.R.S., that a deputation has been appointed by the Mayor and Corpora-

tion of Swansea, the principal inhabitants, magistracy, and the country gentlemen of the neighbourhood, and by the members of the Royal Institution of South Wales, to attend the meeting at Southampton for the purpose of inviting the British Association to hold their annual meeting at Swansea at as early a period as may suit their convenience. The General Committee will therefore have before them at this meeting invitations from Oxford, Norwich, and Swansea.

Southampton, Sept. 9, 1846.

Proceedings of Sections.

SECTION A.—MATHEMATICAL AND PHYSICAL SCIENCE.

President: Sir J. F. W. Herschel.—*Vice-Presidents:* Sir D. Brewster, Prof. Wheatstone, Col. Colby, Dr. Whewell.—*Secretaries:* Dr. Stevelly, Messrs. G. G. Stokes, J. Drew.—*Committee:* Prof. Oersted, M. Svanberg, Prof. Wortmann, Messrs. Allen, W. R. Birt, Hon. and Rev. C. Harris, Messrs. W. S. Harris, R. Aunt, Dr. Lee, Mr. J. Phillips, Rev. Dr. Robinson, Mr. F. Ronaldo, Capt. Sir J. C. Ross, R.N. Mr. J. Scott Russell, Col. Sabine, Rev. Dr. Scoresby, Rev. Dr. Wilson, Rev. R. Walker, Mr. J. A. Dale, Dr. Green, Col. Evorest, Mr. R. W. Fox, Prof. Eicenlohr.

Sir J. F. W. HERSCHEL, President, on taking the chair, explained the objects of the Association.

The first paper read was a Report, "*On Gauss's Magnetic Constants,*" from Professor ERMAN.—The author, after pointing out, by several examples, the uselessness of accumulating, beyond certain bounds, mere observations, without subjecting them to scientific reduction, and the importance now attached on all hands to such reductions—as exemplified in the case of the reduction of all the Greenwich Observations, lately executed by the Admiralty, at the solicitation of the British Association—a work which M. Bessel welcomed in the last moments of his life as the beginning of a new period in astronomy; and, after instancing the fact that the Association had been compelled to discontinue many valuable and systematized courses of meteorological observations, in consequence of the stores of unreduced observations outstripping their power to have them reduced, stated, that the determination of the Gaussian magnetic constants had appeared to them at the meeting at Cambridge last year, of such importance, that a sum of 59*l.* was entrusted to him, for the purpose of reducing certain observations made by him on terrestrial magnetism during the year 1829, at several stations round the earth; and applying them to the purpose of determining those constants for that year. The present report was a statement of the results already obtained from this arrangement. The observations to be reduced had been made by M. Erman, from the year 1828 to 1830, at 650 nearly equidistant stations, along a line encircling the globe between the latitudes 62° N. and 60° S.:—at each station the dip, the horizontal direction, and the intensity had been observed. The labour of reducing these had not only far exceeded that which he (M. Erman) could afford to bestow on it, but even the leisure of an industrious and intelligent young mathematical friend, M. Petersen, to prosecute the task; and the report now detailed the extent to which he had gone in his labours.

"*On the Bands formed by the Partial Interception of the Prismatic Spectrum.*" By Professor POWELL.

"*On the Constitution and Forces of the Molecules of Matter.*" By Dr. LAMING.—This was an elaborate theory of the molecular constitution of matter; applied in forty-two distinct propositions to the explanation of gravitation, temperature, and specific heats of gases, cohesion, affinities, latent heat, volume, disturbances of electrical equilibrium, and other electrical phenomena, with electro motion and electro-chemical decomposition. One remarkable consequence of this theory is, that gravitation depends on the electrical atoms alone; and that hence a positively electrified body must be heavier, and a negatively electrified body, lighter than the same body with its electricity in the ordinarily undisturbed state. This the author proposed to prove experimentally to the Section by an experiment to which he was conducted by the theory, as soon as he could procure a cylinder electrical machine with an insulated rubber. The president proposed that discussion on the communication should be suspended until Mr. Laming had exhibited this experiment.

"*Report on Recent researches in Hydrodynamics.*" By G. B. STOKES.—This report was divided into the following heads:—1. General theories connected with the ordinary equations of fluid motion. 2. Theory of waves, including tides. 3. The discharge of gases through small orifices. 4. Theory of sound. 5. Simultaneous oscillations of fluids and solids. 6. Formation of the equations of motion, when the pressure is not supposed equal in all directions. The first head referred to investigations of a rather abstract nature. Under the second, the researches of Mr. Green, Professor Kelland and Mr. Airy. on the subject of waves, were particularly alluded to, and the accurate agreement of theory with the experiments of Mr. Scott Russell pointed out. The important investigattons of Mr. Airy on the the theory of the tides, were also mentioned. Under the next head were mentioned some experiments of MM. Barré de Saint-Tenant and Wantzel, by which an empirical formula was obtained for the velocity of discharge of air through a small orifice, when the discharge is produced by a considerable difference of pressure. The common formula does not apply to extreme cases. A memoir, by Mr. Green, on the reflection and refraction of sound was then alluded to—a memoir which is remarkable from its bearing on the physical theory of light. The investigations mentioned under the fifth head related principally to the motion of pendulums in resisting media. Mr. Green has solved the problem in the case of an oscillating ellipsoid. The last head contained a notice of the theories of MM. Navier, Poisson, and others on the irregularity of pressure in different directions about the same point. This theory may be considered to be that of the internal friction of fluids.

Dr. WHEWELL thought be had ample reason to congratulate himself and the Section on the success of the advice which he had given when, in the year 1830, his friends Mr. Harcourt and the Dean of Ely, had consulted regarding the proper objects which such an association as the then contemplated British Association should propose to itself. He had then advised that one very prominent object should be the preparation of reports on the actual state of human knowledge in the several departments of science.—and one of the fruits of that advice had been the very able report which had just been presented by his friend Mr. Stokes. When he contracted the present scientific position of British philosophers with what it had been only sixteen years ago, when Britain was vastly behind the continental philosophers, not only in scientific attainments, but even in the knowledge of what had been achieved by others, he could not but congratulate all concerned that that stigma had been so completely wiped away. Dr. Whewell then proceeded to comment on several parts of the report and pointed out the importance of keeping distinctly before the mind the essential difference between two kinds of waves, in one of which the motions of the particles of the fluid were the same from the top to the bottom, in the other, the motions of the particles, while all circular, or rather elliptical, diminished rapidly until at the bottom it became nothing. Of this latter kind a familiar illustration could be had by watching the waves which the wind produced as it swept over fields of standing corn or long grass. He then adverted to the formation of the double wave—an example of which was afforded by the tides at Southampton; and which had been investigated by Mr. Scott Russell in the Forth, and by others at Ipswich. He then briefly reviewed the theoretical researches of Weber, Kelland, and Airy, on the subject of waves; and concluded by saying, that as waves of sound were reflected echoes, so he conceived they must suffer refraction, though the observing of this was attended with experimental difficulties; but that these waves were diffracted, he conceived no one could doubt who would attend to the varying sound of a cascade as you approached it round a bending course, it being at first hidden from sight by interposed rocks, banks, or other obstacles. The President agreed with Dr. Whewell, and not only did he conceive that sound could be reflected, refracted and diffracted, but pointed out several cases, as in some of the phenomena of the tuning fork, where something closely analogous, at all events, to polarization must take place.

"*Notice of a New Property of Light exhibited in the Action of Chrysammate of Potash upon Common and Polarized Light.*" By Sir D. BREWSTER.—The chrysammate of potash, which chrystallizes in very small, flat rhombic plates, has the metallic lustre of gold, whence it derives its name of golden fluid. When the sun's light is transmitted through the rhombic plates it has a reddish yellow colour, and is wholly polarized in one plane. When the crystals are pressed with the blade of a knife on a piece of glass, they can be spread out like an amalgam. The light transmitted through the thinnest films thus produced, consists of two oppositely polarized pencils—the one of a bright carmine red and the other of a pale yellow colour. With thicker films, the two pencils approach to two equally bright carmine red pencils. It is to the reflected light, however, and its new properties, that I wish to direct the attention of the Section. Common light, reflected at a perpendicular incidence from the surfaces of the crystals, or of the films, has the colour of virgin gold. It grows less and less yellow as the incidence increases, till it becomes of a pale bluish white colour at very great incidences. The compound pencil, thus reflected and coloured, consists of two oppositely polarized pencils—one polarized in the plane of reflection, and of a pale bluish white colour at all incidences, and the other polarized perpendicular to the plane of reflection, and of a golden yellow colour at small incidences, passing successively into a deeper yellow, greenish yellow, green, greenish blue, blue, and light pink, as the angle of incidence increases. This very remarkable property, which I have discovered also in some other crystals, is not caused by any film of oxide formed upon the natural surface of the crystal, nor is it the result of any change produced upon the surface by external causes. It is exhibited, under the usual modifications, if the surface of the chrysammate is in optical contact with fluids and with glass: and when the crystal is in the act of being dissolved, or when a fresh surface is exposed by mechanical means, the superficial action of the crystal upon light is in both cases the same. When the chrysammate is re-crystallized from an aqueous solution, it appears in tufts of prisms of a bright red colour, the golden reflection being overpowered by the transmitted light; but when these tufts are spread into a film by pressure, the golden yellow colour re-appears. When the crystals of chrysammate are heated with a spirit lamp, or above a gas burner, they *explode* with a flame and smoke like gunpowder; and, by continuing the heat, the residue melts and a cross of colourless amorphous crystals is left. I have found the same explosive property in the aloetinate of potash.

Dr. WHEWELL conceived this was rather a curious action of the chrysammate and aleotinate of potash on light than any new property of light. The President, Sir J. HERSCHEL, was inclined to agree in that opinion, since nothing was more clearly established than that the colours ultimately exploded by light reflected from the surfaces of bodies depended on the number of superficial particles which the light penetrated in the first instance, and their power of absorbing or extinguishing a portion of that light during that penetration. This had been experimentally decided by thin plates of gold, through all the various shades of that metal, down to the red of copper. Whether the title of the paper, however, exactly agreed with the observed facts or not, all must admit that these facts were most important, and deserving of serious attention. He was not acquainted with the substance—chrysammate of potash—but its properties, both optical and mechanical, seemed to be interesting. The plasticity which it seemed to exhibit in particular occurred to him as curious; and this reminded him of a somewhat analogous property lately discovered in the substance plumbago, or the black lead which pencils are made of. It is well known that that substance can only be obtained in any purity at Borrowdale, in Cumberland, and is lately becoming very scarce. Now, although the powder of plumbago is one of the best materials for preventing friction, or the partial adhesion of other things, yet it has been lately found that the particles of the powder themselves are capable of being made to adhere into a mass—indeed, more compact and uniform in its texture than the best mineral plumbago, by simply inclosing it in a case, extracting the air from among the particles, and subjecting the mass to violent compression.

Professor Powell said that the young gentleman who sat near him was the discoverer of the chrysammic acid, and would, perhaps, be kind enough to describe its mode of production. Mr. Schunck (of Rochdale) said that he had discovered the acid, which was part of the composition of the salt of which Sir D. Brewster's paper treated. It was formed by the action of boiling nitric acid upon aloes, and was one of the last products of that action. The chrysammate of potash was a beautiful and curious salt; and although so plastic as to be readily moulded into thin plates, was yet so sparingly soluble as to require above 1,500 times its weight of water to dissolve it.

"*On Elliptic Polarization.*" By Mr. Dale.

"*On certain Cases of Elliptic Polarization of Light by Reflection.*" By Professor Powell.

"*On some of the Results of the Magnetic Observations made at* General Sir T. M. Brisbane's Observatory, Makerstoun." By J. A. Broun.—1st. *Magnetic Declination.*—The annual diminution of westerly declination at Makerstoun is 5′ 8″. When proportional parts of this have been added to the monthly means, from January 1844, till August 1846, their whole range is only 2′ 1″; that is to say, the mean position of the magnetic needle for any month, freed from secular change, has not been about 2′ 1″ farther west than the mean position for any other month. Mr. Broun conceives that he has found the *annual period* of westerly declination to consist of a minimum at the vernal, and of a maximum at the autumnal, equinox: the mean range being under 1′ 2″. From the observations for 1843, Mr. Broun has concluded that there is a maximum of westerly declination when the sun and moon are in opposition, and a minimum when they are in conjunction; that there is a maximum of westerly declination when the moon has its greatest north, and also when it has its greatest south declination, minima occurring when it crosses the equator. In the *diurnal period*, the double maximum and minimum have been found to exist in each month of the year. In the "Transactions of the Royal Society of Edinburgh," Mr. Broun has given certain results relating to the horizontal and vertical components of the earth's magnetic force; but these results were obtained in scale divisions corrected for temperature by his method. In order to deduce the variations of magnetic dip and of the total magnetic force, from the variations of these components, it was necessary to determine the values of the scale divisions in known units. Mr. Broun had previously shown* the inapplicability of the method given by the Committee of Physics of the Royal Society of London for the balance magnetometer. He now described a method by which the value of the micrometer divisions may be satisfactorily determined. This method will be found in the Introduction to the Makerstoun Observations for 1843. He has applied the same method to the bifilar magnetometer, and has found that the value of the scale divisions, obtained in the way recommended by the Committee of Physics, is also inaccurate for this instrument. With the aid of the values obtained by the new method, the following results have been deduced 2nd. *Magnetic Dip.*—The dip is a minimum when the sun and moon are in opposition. In the mean diurnal period for the year,

The principal	maximum	occurs at	10h.	10m.	a.m.
,,	minimum	,,	5	40	p.m.
A secondary	maximum	,,	2	0	a.m.
,,	minimum	,,	5	40	p.m.

Makerstoun mean time being always used. These periods vary to some extent throughout the year, the principal minimum occurring at 6 a.m. in winter; the two minima being nearly equal to the equinoxes, and the diurnal curve being single in summer. Mr. Broun has found that there is a maximum of dip about four hours and a half before the moon's passage of the superior meridian; a minimum about half an hour after the passage; a secondary minimum about three hours after it; and a secondary maximum about eight hours after it. 3rd. *Total Force of the Earth's Magnetism.*—A minimum occurs when the sun and moon are in opposition, equal maxima near the quadratures, and a secondary minimum at the time of conjunction. In the mean diurnal period for the year,

The principal	maximum	occurs at	5h.	40m.	p.m.
,,	minimum	,,	2	10	a.m.
A secondary	maximum	,,	7	10	a.m.
,,	minimum	,,	10	10	a.m.

The periods of maxima and minima shift about two hours in the course of the year, and in summer the principal minimum occurs at 10h. 30m. a.m. The variations of force with reference to the moon's hour angle were found by Mr. Broun as follows:—The principal maximum occurs about two hours after the moon's passage of the inferior meridian; a secondary minimum about four hours before the passage of the superior meridian: a secondary maximum about one hour after the superior passage; and the principal minimum about six hours and a half after that passage. Curves were exhibited illustrating these results, and also the diurnal motion of a magnetic needle freely suspended in the direction of the magnetic force. From the latter some curious results have been deduced, which will be found elsewhere. It will be enough to mention, at present, that in the mean for the year, the motion from 6 a.m. till 6 p.m. is very trifling; between midnight and 6 a.m. the needle is almost stationary, nearly the whole motion occurring between 6 a.m., noon, and 6 p.m. The end of the needle describes an ellipse whose major axis is at right angles to the magnetic meridian; but the direction of this axis varies throughout the year.

Mr. Hopkins, "*On the relations of the Semi-Diurnal Movements of the Barometer to Land and Sea Breezes.*"—Mr. Hopkins exhibited diagrams, drawn up from Col. Sabine's paper "On the Meteorology of Bombay," of the diurnal temperature curve, total pressure curve, and gaseous pressure curve; with a diagram representing the swelling and sinking of the land and sea breezes; and endeavoured to show that these were inconsistent with the explanation given by Col. Sabine, but harmonised with alternations of pressure caused by the alternate extrication of heat and absorption of it during the alternate evaporations and depositions of water, in the state of clouds and dew.

Capt. Shortrede asked Mr. Hopkins several questions; and, from his own observations in India, extending over many years, must dissent from Mr. Hopkins, as to the manner in which he supposed clouds to form and disperse. The effects he ascribed were disproved by the fact, that several miles inland, where there were no land and sea breezes, the clouds were formed and dispersed in precisely the same manner.

"*On the Presence of Atmospheric Air and Uncombined Chlorine and Carbonic Acid found in the Water of some of the Wells in the Suburbs of Southampton, and their Action on Lead.*" By H. Osborn.—The principal object of this paper was to caution persons residing in the neighbourhood of Southampton, against the use of leaden pipes for conveying water, and to induce them to avoid the use of lead in any form for that purpose, without having the water previously examined in order to ascertain whether it possessed the property of acting upon the metal and holding it in solution. The author brought forward several instances of the serious consequences which had resulted from the use of water impregnated with lead, and pointed out the different solvent principles found in the water; one of which was uncombined chlorine discovered in a spring in the New Forest. The water possessed the property of bleaching brazil paper, and reddening litmus paper by evaporation. The amount of uncombined chlorine was estimated as chloride of silver,—by deducting the amount of the latter contained in 20 ounces of water from that of the chlorine contained in the solid contents, the former weighing 1·2 more than the latter—thus indicating 0·296 of uncombined chlorine, which is capable of uniting with 0·864 of lead, forming 1·16 of chloride of lead in the imperial pint. The lead held in solution by carbonic acid, and the oxygen of atmospheric air, was converted into chromate of lead, and estimated as chloride of lead, which indicated 0·25 or 0·2 of the oxide in twenty ounces of water. The solid contents in an imperial pint were found to vary from one grain to three grains, and to be composed of the chlorides of sodium, calcium, and magnesium, sulphate of lime, silica, and vegetable matter. Notwithstanding the preservative property, which the salts contained in spring water are said to possess, by forming an insoluble crust in the interior of the pipes, it was found that the leaden pipes had been in use for some years, and the action of the water on the lead still continued with as much energy as when they were first laid down, thus showing the presence of the above solvents, and that they met with no resistance from the presence of the saline matter.

Dr. Daubeny made some remarks pointing out the importance of the inquiry of Mr. Osborn, and the necessity of paying attention to the condition of the water supplied to towns through leaden pipes, or received in leaden cisterns.—Mr. Pearsall stated that he found that the presence of lead may be constantly removed from the water by the action of carbon, and that lead may be always separated by well agitating the water in con-

* Trans. Roy. Soc. Edin. vol. xvi.

tact with the air, and mixing up the sedimentary deposits.—The subject excited considerable attention, and many gentlemen joined in the conversation, all of them adducing additional evidence of the importance of investigating the condition of water supplied to large towns.

"*On the Artesian Well on the Southampton Common.*" By R. Keele, Esq.—The town of Southampton has hitherto depended for a supply of fresh water to private wells, which are attached to almost every house. They are sunk through a bed of gravel, and vary in depth from 10 to 20 or 25 feet,—at which depth the London clay is reached. An uncertain quantity has also been obtained from the public water-works, supplied by land springs. These sources being insufficient for a growing town, with 30,000 inhabitants, other modes of supply have long been contemplated. The river Test was considered too distant; and the commissioners could not accede to the terms proposed by the proprietor of the most convenient part of the river Itchen. In November, 1835, Mr. Clarke, of London, made an experimental boring on the Southampton Common, through 80 feet of alluvial strata, 300 feet of London clay, and about 100 feet of plastic clay; and afterwards the boring was extended 50 feet into the chalk. The supply was ample; and an Act of Parliament was obtained for providing the means necessary to construct a well which should supply 40,000 cubic feet of water daily. Mr. Clarke estimated the expense at £7,000. In 1837, a contract was made with Mr. Collyer, who proposed to sink an iron cylinder, having a diameter of thirteen feet, to the depth of 160 feet, and from that point to bore to the further depth of 400 feet, commencing with a bore of 30 inches, and gradually diminishing to one of 20. The estimate amounted to £9,980. The cylinder was found inefficient; and a brick shaft, of 14 feet diameter, was continued to the intended depth of 160 feet. Two pumps were employed to raise the water, which amounted to 4,000 cubic feet per diem. Here, instead of commencing the boring, the brick shaft was carried on, by advice of the consulting engineer. At the depth of 164 feet, the diameter of the shaft was reduced to 11 ft. 6 in. At this period, the candles could scarcely be kept lighted; and an air-tube of zinc, with a pair of bellows worked by the steam-engine, was attached, for the purpose of ventilation. Masses of limestone, five or six tons in weight, had frequently to be raised. There was a considerable escape of gas from the sides and bottom of the well, which, together with the vapour that filled the shaft and the impure air caused by so many men at work, occasioned some alarm. At the depth of 214 feet, the shaft was reduced to 10 feet in diameter; and at the depth of 270 feet, to 8 feet 6 inches. The work was then suspended till more powerful pumps could be obtained. On emptying the shaft, and deepening it 23 feet, the influx of water became so great that iron cylinders, 7 feet in diameter, were again resorted to, instead of brickwork. At 322 feet the brick shaft was resumed; the quantity of water raised by the engine amounted to 30,240 gallons in twenty-four hours. At 380 feet from the top of the well, the plastic clay was reached, and the brick shaft continued through it to the chalk. Little or no sand or water was found in the plastic clay. The work was continued day and night till December 4, 1841, when the shaft was 520 feet deep; about three gallons of water flowed into it per minute, its temperature at the bottom ranging from 61° to 62° Fah. The atmosphere of the well at 50 feet was 54°; at 160 feet, 60°; at 543 feet, 65°. The temperature of water at the surface was 44°. In March, 1842, the shaft measured 562 feet; and the pumping having having been suspended for a week, the water rose 400 feet, amounting in quantity to 21,578 cubic feet. This supply being insufficient, the contractors commenced boring with a 7½-inch augur, attached to a rod, conducted to the bottom of the shaft by an iron tube, fixed in the centre of the well. The total depth of the shaft and boring amounts to 1260 feet; and at the time the boring was suspended the water rose to within 40 feet of the surface. In 1845, during upwards of four months' daily pumping, the delivery of water was at the rate of upwards of 1,500,000 gallons per month; and afterwards, in eight days, the quantity raised exceeded 725,000 gallons. When the pumping was discontinued in November, 1845, the water rose, as before, to within 40 feet of the surface.

Mr. Hopkins, in reply to questions as to the advantage of continuing the operations, and the probable supply, stated that the example of the artesian well at Grenelle was calculated to give confidence in similar undertakings where a general analogy existed. The comparison, however, between Paris and Southampton was not complete. Paris was in the very centre of a tertiary, and probably over the deepest part; the water flowed to it in all directions; the inclination of the beds, too, was gentle; and there were no dislocations. Here, however, the chalk of North Hampshire inclined gradually towards the sea, and, passing under it, rose again, with a much greater inclination, in the Isle of Wight. There was no reason for supposing that Southampton was situated over the lowest part of this basin; and since, in the Isle of Wight, there was an enormous dislocation, there might be other dislocations or fissures in the intermediate space, which might afford an outlet for the water below. The height to which water would rise in an artesian well would be affected by the construction of other wells in its neighbourhood. The first artesian well at Cambridge rose 15 feet above the surface, but other wells had reduced its height to 4 feet below the surface. The borings in these instances were only 4 or 5 inches in diameter; but the supply was large, and independent of the existence of any large caverns or fissures. The water came from the iron sands below the gault clay; it had a slightly ferruginous taste, but was quite good. No water was obtained in the chalk, nor could an artesian well be expected in that formation, which is too permeable to hold water. In conclusion, Mr. Hopkins said that he should himself recommend the continuation of the boring, as the trial was not complete till the beds below the chalk were reached.

Mr. Greenhough remarked on the extent of the dislocation which extends through the centre of the Isle of Wight. He believed geologists had done more good by discouraging hopeless speculations than by encouraging useful experiments; and they would not give a positive recommendation, except from experience. He alluded to the artesian wells of Lincolnshire, in a district before scarcely habitable, on account of the scarcity of fresh water, and the thickness of clay impervious to water. Porous beds, resting upon others which were not porous, could alone afford a supply of water.

"*On the Origin of the Coal of Silesia.*" By Prof. Goeppert, of Breslau. This paper was an abstract of an essay which received the prize offered by the Society of Sciences of Holland, at Haerlem, in 1844. Prof. Goeppert remarks, that hitherto few well-preserved plants had been obtained from the coal itself, but its composition had been inferred from the plants which lie in the associated shales. In the coal-fields of Upper and Lower Silesia, which yield four millions of tons a year, he had met with extensive layers, in which the plants were so well preserved, that he could distinguish coal formed from Sigillariæ from that formed by Araucariæ or Lepidodrendra. In most instances the bark alone was preserved—the specimens being flattened; but the Araucariæ, being much harder than the rest, often retained their woody tissue and medullary rays. The species, 80 in number, were found to be differently grouped in the various coal strata, and also under different conditions; and this, with the delicate preservation of the ferns, the multitude of upright stems, of which 200 have already been observed, and the uniform thickness of the strata over a space of many miles, are considered by the author a proof of tranquil deposition on the present localities. The Silesian coal strata are from 30 to 60 feet thick; a larger portion of which M. Goeppert supposes to have accumulated after the manner of *peat*, during the lapse of time. He has ascertained that, by keeping vegetables in boiling water for three months or a year, they are converted into brown coal (*lignite*), and, by the addition of a small quantity of sulphate of iron, a salt which occurs commonly in coal, acquire, at last, a totally black, coal-like condition.

Sir R. I. Murchison expressed his readiness to receive this explanation for the origin of many extensive coal strato. There were other large coal-fields to which the explanation would not apply at all, the materials having certainly been drifted to a distance by currents of water.

Mr. J. Phillips remarked, that although even fragments of coal-plants were uncommon in the coal of England, yet, with the aid of the microscope, *coniferous tissue* might be detected in much of the fibrous coal, which differed only in being less bituminous than the rest. In the ashes of coal, siliceous casts of vegetable tissue were always to be found; and Mr. Bowerbank had detected traces of structure on the fractured surfaces of ordinary solid coal.

President: Mr. G. R. Porter.—*Vice-Presidents:* Sir C. Lemon, Colonel Sykes, Messrs. Heywood, R. Nightingale.—*Secretaries:* Messrs. W. Cooke Taylor, J. Fletcher, F. G. P. Neilson, Rev. T. L. Shapcott.—*Committee:* The Mayor of Southampton, Messrs. W. Duckworth, H. Hallam, M. Phillips, M.P., M. Ricardo, J. C. Sharpe, J. Shuttleworth, T. Tooke, G. S. Kenrick, Dr. King, Mr. M. Milnes, M.P., Capt. Allen, Rev. Prof. Elton.

Among the papers read was "*A Review of the Mines and Mining Industry of Belgium.*" By R. Valpy, Esq., of the Board of Trade. It stated that, as a coal-producing country, Belgium ranked the second in Europe. The ratio of the coal district to the total area is

		Acres.		Tons annually.
Great Britain	$\frac{1}{20}$, or	2,930,000	producing	34,000,000
Belgium	$\frac{1}{22}$, or	335000	„	4,500,000
France	$\frac{1}{210}$, or	630,000	„	3,783,000
Germanic Union..........................				3,000,000

In 1838 the total number of coal-mines in Belgium was 307, with 470 pits in work, and 172 in process of construction, employing 37,171 persons; being an increase of 8,454, or 28 per cent. on the number employed in 1829. The increase of the quantity of coal raised was not accurately ascertained, but it appeared to be about 37 per cent. The average cost of production is 10s. 8d. per ton, and the average price 23s. 1d. for first quality, and 16s 6½d.

for the second quality of coal; the average rate of wages is 1s. 6$\frac{5}{10}$d. per day. The establishments for preparing other mineral productions for market in 1838 were, for iron 221, copper 8, zinc 7, lead 2; the total number of furnaces was 132, of which 47 used coke and 22 charcoal. The total number of accidents from 1821 to 1840 was 1,352, which occasioned severe hurts to 882, and deaths to 1,710, making a total of 2,592 sufferers.

A paper was read "*On Plate Glass-making in England in* 1846, *contrasted with what it was in* 1827." By Mr. H. Howard.—The writer furnished carefully all the materials for establishing this comparison. Amongst other results he stated, that in 1827 plate glass was sold for about 12s. average per foot, to the extent of about 5,000 feet per week; in 1835, for from 8s. to 9s. per foot, to the extent of about 7,000 feet; in 1844, for from 6s. to 7s. per foot, reaching about 23,000 feet; and in 1846, for from 5s. to 6s,—about 40,000 feet per week. The sale is now about 45,000 feet weekly. He mentioned that, in 1829, a plate glass manufactory ceased operations because of the small profit realized when selling at 12s.; while, in 1846, a company, with a paid-up capital of 130,000*l.*, realized a net profit of 30,000*l.* selling at from 5s. to 6s. Looking at this extraordinary increase, in spite of the severity of excise restrictions, the author asks, what would be the probable demand if the price were reduced to 4s. or 3s. 6d. per foot, which, free as the trade now is from excise interference, would yield an ample profit?

Section G—Mechanics. Professor Willis in the Chair.

Vice-Presidents: Rev. Dr. Robinson, Messrs. G. Rennie, J. Scott Russell, W. Snow Harris.—*Secretaries:* Messr. C. Manby, W. Betts, jun.—*Committee:* Messrs. J. Taylor, J. Walker, R. Stephenson, J. Locke, I. K. Brunel, C. Vignolles, W. Fairbairn, E. Hodgkinson, E. W. Dent, W. Chatfield, J. Whitworth, J. Nasmyth. J. G. Bodmer, J. Fincham, R. C. Grantham, T. Hoblyn, Dr. Phipps, M. Ricardo, Mr. R. Roberts, Sir J. Guest, Messrs. Grant, Brockedon, C. H. Gregory, W. Harding.

Dr. Robinson gave an account of a "*Modification of Dr. Whewell's Anemometer*," for measuring the velocity of the wind. He explained to the section verbally the nature of the various anemometers hitherto employed to measure the *force* of the wind, and distinguished Whewell's from them, as a measure merely of comparative *rate*. The fault of it was, that the instrument gave no absolute measure of velocity in miles per hour, and that it reduced the rates to no standard, and therefore the observations made at one observatory were not capable of comparison with those at another. He had applied an observation of Mr. Edgeworth, who was a family connexion of his own, to the construction of such an addition as would render Whewell's anemometer more perfect in this respect. He mounted on a vertical axis three or four arms, carrying hemispherical cups at their extremities. These cups opposed much less resistance to air acting on the concave sides than on their convexities, and in such ratio that uniform revolution was produced, at the rate of *one-third* of the velocity of the wind. From this measure, which would be the same for all sizes of the instrument, and at all places the mean velocity of the wind during a given period could always be obtained in miles per hour. He concluded by reading some of the determinations of his own instrument at the observatory at Armagh.

The Chairman, in giving the thanks of the Section to Dr. Robinson, expressed their sense of the scientific elegance and great practical value of an invention applicable generally to the measurement of velocity of fluids; and he called their attention to the dexterous logical process by which the one definite desired term had been eliminated from a multitude of unknown quantities. as exhibiting an admirable example of the combination of sound mathematical reasoning with sagacious experiment.

Mr. Vignolles read a paper furnished by M. Arago, for the express purpose of being communicated to the Association, at which M. Arago was prevented by illness from attending, "*On a new method of boring for artesian springs*," *by* M. Fauvelle, *of Perpignan, in France*. The paper, which was an abridged translation of M. Fauvelle's own account, stated that—

"In 1833, I was present at the boring of an artesian well at Rivesaltes; the water was found, and spouted up abundantly. They proceeded to the tubing, and for that purpose enlarged the borehole from the top downwards. I was struck by observing that it was no longer necessary to draw the boring tools to get rid of the material, and that the water, rising from the bottom, brought up with it, in a state of solution, all the soil which the enlarging tools detached from the sides.

I immediately observed to my friend, M. Bassal, who was with me—"This is a remarkable fact, and one very easy to imitate; if, through a hollow boring rod, water be sent down into the bore-hole as it is sunk, the water, in coming up again, must bring with it all the drilled particles." On this principle I started to establish a new method of boring. The apparatus is composed of a hollow boring rod, formed of wrought iron tubes screwed end to end: the lower end of the hollow rod is armed with a perforating tool, suited to the character of the strata which have to be encountered. The diameter of the tool is larger than the diameter of the tubular rod, in order to form around it an annular space through which the water and the excavated material may rise up. The upper end of the hollow rod is connected with a force-pump by jointed or flexible tubes, which will follow the descending movement of the boring tube for an extent of some yards. This boring tube may be either worked by a rotatory movement or by percussion with a jumper. The frame and tackle for lifting, lowering, and sustaining the boring tube, offer nothing particular. When the boring tube is to be worked the pump must be first put in motion.

Through the interior of the tube a column of water is sent down to the bottom of the bore holes, which water, rising in the annular space between the exterior of the hollow boring rod, and the sides of the bore-hole, creates an ascending current which carries up the triturated soil; the boring tube is then worked like an ordinary boring rod, and as the material is acted upon by the tool at the lower end, it is immediately carried up to the top of the borehole by the ascending current of air. It is a consequence of this operation that the cuttings being constantly carried up by the water, there is no longer any occasion to draw up the boring tube to clear them away, making a very great saving of time. Another important and certainly no less advantage, is, that the boring tools never get clogged by the soil; they work constantly (without meeting obstructions) through the strata to be penerated, thus getting rid at once of nine tenths of the difficulties of boring. In addition, it should be mentioned, that experience has shown there are no slips in any ground which ordinary boring-rods can penetrate; that the boring tube works at 100 yards in depth with as much facility as when only ten yards down, and that from the very circumstances of its being a hollow rod, it presents more resistance to torsion than a solid rod of equal thickness and quite as much resistance to traction: these are the principal advantages of the new system of boring. Indeed these advantages have been fully confirmed by the borings which I have just completed at Perpignan, in St. Dominico's-square. This boring was commenced on the 1st July, and was completed on the 23rd, by finding the artesian water at a depth of 560 feet. If from these twenty-three days, each of ten hours' work, are deducted three Sundays and six lost days, there remain fourteen days or 140 hours of actual work; which is upwards of one yard per hour, that is, ten times the work of an ordinary boring rod.

In the method I have described, it will be perceived that the water is injected through the interior of the boring-rod. Experience has taught me that when gravel, or stones of some size are likely to be met with, it is better to inject the water by the bore-hole, and let it rise through the boring tube. The additional velocity which may be thereby given to the water, and the greater accuracy of calibre of the tube, allow the free ascent of all substances which may be found at the bottom of the bore hole, and which the former mode of working may not so readily accomplish. I have brought up by this latter way stones of 2½ by 1¼ inches.

The idea of making the water remount through the interior of the boring tube suggests an easy mode of boring below a film (sheet) of flowing water: it would be sufficient to close the orifice of the bore hole hermetically, still however so as to allow the boring tube to work, but yet so that the flowing water should be always forced down to the bottom of the bore hole to find its way to a vent: it would thus draw up and carry away all the detritus. If, in addition to the above, we consider the possibility of making the hollow stem of the boring rod of wood, and of balancing it so that it would weigh no more than the water in which it has to move, the problem of boring to depths of 1100 yards and upwards would appear to be solved.

In the square of St. Dominique at Perpignan, a boring had been carried on upon the old method for upwards of eleven months for the purpose of forming an artesian well, and the water had not been found. Fauvelle placed his new tube alongside the old boring tackle, and soon got down to a depth of nearly 100 yards, when an accident occurred which would have required some days to remedy. Fauvelle decided upon abandoning the bore hole already sunk so deep, and commencing a new one, satisfied that there would thereby be a saving in time. The rate of sinking was equal to four feet per hour of the time the hollow boring rod was actually at work, the depth of 560 feet having been obtained in 140 working hours, for a bore hole of about six inches in diameter.

M. Arago, who had seen the rods of Fauvelle at work, mentions how fully they answered, and that the large powerful tools at the bottom of the hollow boring rod cut easily through the hardest strata; he confirmed the fact of the large sized stones and gravel coming up with the ascending current, himself having watched them. He also mentioned that such was the opinion of the people in the vicinity of Perpignan, and so much was water wanted, that orders for the sinking upwards of 200 artesian wells had been given to Fauvelle. The introduction of this system into this country, especially if combined with the Chinese or percussive system of boring, as practised with bore holes of very large diameter, at the Saarbruch mines, and at many other places on the continent, must be productive of great benefit, and would not merely effect a saving of money and labour, but the paramount advantage of immediately solving the question of the existence of coal, minerals, water, &c."

[By reference to the last volume of this Journal, page 56, it will be seen that a patent was granted to Mr. R. Beart, July 12, 1844, for a method almost identical with that of M. Fauvelle.]—Ed. C. E. and A. Journal.

Sir John Guest asked Mr. Vignolles to explain the system of percussion boring, for the information of those gentlemen present who might not be acquainted with it.—Mr. Vignolles said, instead of boring with augurs or rods, there was a heavy weight suspended by a rope and pulley; and fixed to the bottom of the weight was a tool of the crown form, viz., a circular tool of iron, indented at the bottom. There was no description of rock on which he had tried it that this tool did not penetrate with facility. The prejudice of English workmen, however, had hitherto prevented its introduction in this country; but he had no doubt it would make its way, particularly if it could be combined with Fauvelle's system.—J. Lobb, Esq., Mayor of Southampton, wished to ask a question relative to the applicability of Fauvelle's plan to the boring of the Southampton artesian well They had got to the depth of 1,200 feet with a bore of 6 inches in diameter and the expense had been nearly 20,000*l.*; this system, however, seemed to, diminish the expense of boring in an extraordinary manner; and he wished to ask if it could be applied to the present boring at the Southampton Common?—Mr. Vignolles, as an engineer, had no hesitation whatever in saying that it could be applied without difficulty. If they wanted force to send the water down the tube, they might use a steam-engine.—Dr. Robinson suggested that a deputation from the Section should go to the works of the Southampton well, and inspect them.—Mr. J. Hill said that percussion had long been used in this country. They had used that plan whenever they came to hard substances in the Southampton boring. The rods were drawn up by a windlass, and dropped down a foot or six inches; and after the material was loosened the rods were drawn, and the pulverized material raised up by a cylinder.—Mr. Vignolles said this was different from the Chinese system of percussion, where a rope was used, which saved the trouble and loss of time in drawing the rods. The power required for sending down the water on Fauvelle's plan was much less than might be supposed.—The Marquis of Northampton suggested that a committee of the Geological Section should be invited to accompany the committee from this section.—Dr. Lankester expressed his warm approval of M. Fauvelle's plan, and his opinion of its applicability.—A conversation followed, in the course of which Sir John Guest said the weight of a hollow rod, three inches in diameter, and the iron a quarter of an inch thick, would be less than that of a solid rod of an inch diameter; the weight would be further lessened by the rod floating in water.

Mr. Sharp read a paper on improvements in the construction of gas-meters.

Mr. Ricardo explained the construction of a machine which he had used for registering the velocities of railway trains. An eccentric is keyed on to one of the carriage axles and gives reciprocating motion to a rod which turns a ratchet-wheel by engaging with each of its teeth in succession. By these means, a drum, provided with a paper for indicator-diagrams, is made to revolve with a velocity proportional to that of the train. A separate part of the machine contains the mechanism of a common-clock, attached to which is a tracing pencil, which moves with a velocity proportional to the clock's rate of going. Consequently, the diagrams register the velocity of the trains for every period of time during the transit of the train.

Resistance to Railway Trains.

This paper was of considerable importance, and we are the more glad to have the opportunity of expressing an opinion respecting the formula proposed, because it is the same as that of which Mr. W. Harding recently gave an account before the Institution of Civil Engineers.

Mr. Scott Russell commenced by briefly reviewing the labours of those who had gone before him in the investigation of the subject. The report on the experiments, instituted at the instance of the British Association, concluded by observing that the results were so anomalous, that no satisfactory law could be deduced from them. He had undertaken a large series of experiments, but only collected those on which he could place perfect reliance. The trains varied in size from one one to fourteen carriages. Mr. Russell then exhibited his results in three columns of figures; the first column showing the velocities in miles per hour, the second the resistance experimentally determined in pounds per ton weight of the train, the third the resistance determined by his formula.

It would be seen from the second column that it was not very easy to elicit a law: the resistance was very variable with respect to the velocity; for instance, in certain cases the resistance actually appeared to diminish as the velocity increased. The old theory had been that the total resistance was about 8 lb. per ton, and remained constant at all ordinary velocities. It had been found, however, that this theory was quite untenable. The next improvement was to add for the resistance of air a term varying as the square of the velocity. This, however, was still insufficient to represent the experimental results. He was therefore induced to propose a modification of the formula, which he by no means asserted to be theoretically correct, nor did it exactly coincide with the experimental results; but which, however, came nearer to them than did any of the old formulæ, and might be used till a better one was discovered.

Mr. S. Russell's formula is—

$$R = A p v^2 + B m v + C m$$

where R is the total resistance, A the area of the front of the train, v the velocity, m the weight of the train; B, p, and C empirical constants. The last term of this equation represented the resistance from the friction of the axles. The value of C, as determined by the experiments of Wood and the British Association, appeared to be six pounds per ton, so that the whole of the resistance = 6 times the number of tons weight of the train. The next element of resistance was that of the air, which depended rather on the surface exposed than on the weight of the train. The greater number of experiments under this head were few and inapplicable. Smeaton's were made by observing the rotation of thin disks, which presented no analogies to the present case. It appeared, however, to be pretty clearly established that the total resistance could be deduced from multiplying the area of the front of the train by the square of the velocity, and by multiplying this quantity again by a certain empirical constant, which he had represented by p.

After deducting these two resistances, namely, $A p v^2$ and $C m$, there still remained a considerable residue, which indeed was, in many cases, more than half the resistance determined experimentally. Now the general appearance of this residue was, that it was a quantity varying as the velocity multiplied by the mass of the train; and therefore v being the velocity of the train, m its mass, and B a constant, $B m v$ represented the remaining term of the expression for resistance to trains.

The whole argument turned on this question—Does the expression $B m v$ represent with sufficient accuracy the residue, after substracting from the total resistance, as experimentally determined, the theoretical quantities for friction and resistance of air? In answer to this question, Mr. Russell proceeded to examine the two columns of figures before him, one of them showing the theoretical, the other the practical, resistance. In many cases, the accordance was very exact: in others, he confessed, there were great discrepancies. There were anomalous results in both columns of figures; for instance, in the column of experiments, the resistance to the the train at 32 miles was actually less than it was at 31 miles. In fact, there were frequent instances in both columns of the resistance diminishing when the velocity increased: the resistance at a given velocity was often no greater than, and often less than, the next less velocity.

Mr. Scott next considered the physical causes which would account for the new term. A most important element of resistance was the concussion sustained by the wheels of the carriages as they passed over the joints of the rails. This concussion produced a noise and vibration of the earth, which was sometimes perceptible at extraordinary distances. It was frequently so great as to derange the position of the rails, and was a constant cause of wear and tear of the road. This was one most important element of his new term. Another was the lateral abrasion of the flanges of the wheels against the rails—this abrasion representing, of course, a loss of force. Another loss was occasioned by the vertical movement of the carriages on their springs, which was, from the imperfect elasticity of the springs, equivalent to a loss of *vis viva*. There were other elements of his "remainder" or new term, but these were the principal. In conclusion, Mr. Scott Russell stated that all the experiments were not his own; that some of them were the previous property of the British Association, made on trains descending inclines by their own gravity. The dynamometer which he had employed was an excellent one, made by Morin; it was placed between the tender and the first carriage. He exhibited the diagrams which had been actually drawn by this dynamometer, and which were traced in red ink by a camel's hair brush.

The following is the table referred to:—

Velocity in Miles per hour.	Resistance by experiment in lbs. per ton.	Resistance by formula in lbs per ton.
8	8·0	8·7
14	12·6	13·9
29	16·5	15·7
31	23·3	25·4
32	22·5	22·7
33	22·5	22·7
34	16·6	17·3
35	22·5	22.4
36	22 5	25·5
37	17·5	18·2
39	30·0	31·6
41	22·9	19·6
45	21·7	21·0
46	23·1	23·3
47	33·7	33·1
50	32·9	36·3
51	26·4	23·0
53	41·7	42·1
61	52·6	54·8

Dr. Robinson said that though great credit was due to Mr. Scott Russell for putting the investigation in an improved form, there were still several elements of resietance which he thought ought to be taken into consideration. He then proceeded to write on the diagram-board a formula, of which each term explained some kind of resistance, which he explained as he wrote down the corresponding expression. The loss from concussion at the joints should vary as $(\text{velocity})^2$. The resistance to the motion of the wheels, regarded as separate bodies acted on by the air, was two-fold; and arose, first, from their rotation, secondly, from their longitudinal motion. The one resistance would vary as the velocity; the other, as the square of the velocity. In like manner, the resistance from the air to the carriages themselves was composed of two terms; the one representing the resistance to the front of the train, the other to its sides.

Mr. Sharp thought that Mr. Scott Russell ought to have taken into account many contingencies which occurred in practice, such as the effect of curves in the railway. The axle-friction was far greater in some carriages than in others.

Mr. Roberts confirmed the latter statement: he had constantly observed that the wheels of carriages were out of their proper place, and considerably inclined to the axle. In many cases which he had examined, the divergence from the perpendicular was so great, that the resistance must have been enormous. The learned professor did not, however, appear aware that Mr. Russell's formula applied to the resistance of the *train* only, independently of the engine: nor did he seem to have a very clear idea of the line of argument pursued, for he took occasion during the discussion to observe that Mr. Russell had proved everything experimentally, and that "he had not taken anything for granted," whereas he had taken for granted an integral point of his argument, namely, that the accuracy of the first and third terms of his formula had been proved by the labours of preceding investigators.

After some further observations, Professor Willis closed the discussion by remarking on the reciprocal action of the pistons as a fruitful cause of resistance and loss of power.

[It remains only to give our own opinion on the result of Mr. Russell's labour. On a subject of such great moment to the engineer, a general account of the deductions to be made from the arguments employed in the discussion cannot fail to be acceptable. We must begin then by according to Mr. Russell the merit of having approached the subject in a philosophical spirit. He says that his conclusions are the results of a great number of careful experiments, but he does not dogmatise upon them. On the contrary, he tells us plainly, that his formula has been suggested for want of a better. With respect to the "remainder" term, which constitutes the novelty of his results, he rather asks whether it may not represent physical facts, that asserts that it actually does so. This is precisely the language of a true student of science. While, however, we feel that Mr. Russell has made a step in the right direction, we unhesitatingly deny that his formula will account even approximately for the resistance to trains. There appear sufficient reasons for questioning the accuracy of each of the three terms of his expression. The last ($C\,m$) makes the axle-friction independent of the velocity; whereas it depends materially on the velocity, as we will show. Mr. Russell says that the friction of the axle is proportional to the pressure, and he evidently takes it for granted that the only pressure is a vertical one, namely the weight of the carriage. This looks very like an error of principle, for it is obvious that if no horizontal pressure acted on the axle, the wheel would not move forward. The wheel is subject to two retarding forces,—the action of the rail on its periphery, and the action of the air on its whole surface. Now, these forces both depend on the velocity of the train, and their sum is equal to the accelerating horizontal force on the axle; on the principle that when a body is moving uniformly its accelerating and retarding forces are equal. The pressure, then, on the axle is a function of the velocity, and consequently the axle-friction also depends on the velocity. It may be further observed, with respect to the retarding force on the circumference of the wheel from the rail, that it is made up of three parts—rolling friction on the tire, lateral friction on the flange, and concussion at the joints of the rails. The effect of all these probably, or at all events of the latter of them, depends materially on the velocity, and also greatly affects the pressure, and consequently the friction, on the axle.

Next, with respect to the term ($A\,p\,v^2$), Mr. Russell here assumes that the whole resistance of the atmosphere varies as the square of the velocity of the train. Now it seems certain, that whatever law represents the resistance to the front of the train cannot apply to the wheels; for the latter rotate as well as move forward. The action of the air on them differs so greatly from its action on the rest of the train, that the resistance must be expressed by different functions of the velocity. Moreover, the symbol v ought to express not the actual velocity of the train, but the *relative* velocity of the train and the wind. For if the wind and the train were both moving in the same direction, with the same velocity, the resistance on the bodies of the carriages would be zero. And lastly, whatever function be adopted ought to be a discontinuous one, for this reason: if the wind moved faster than the train, it would urge the train forward and be changed from a retarding to an accelerating force. In this case, v (the relative velocity) would be negative; but v^2 would still remain positive, which it ought not to do. This contingency ought to be provided against. We know that the expression for the motion of a projectile in air is discontinuous: the resistance during the ascent of the projectile is not the same function of the velocity as during the descent.

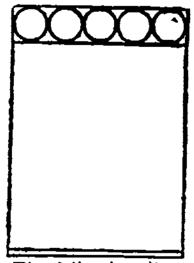
Lastly, in the term $B\,m\,v$, it is assumed, without sufficient data, that all the other resistances besides those of the air and at the axles, vary as the velocity simply. We may decide with absolute certainty, that this cannot correspond to physical facts. The concussion of the joints, for instance, is more likely to depend on the second than the first power of the velocity. It is shown in Moseley's Engineering (p. 594-6), that when a body in motion impinges directly on a body at rest, the mutual pressure at any period during impact is expressed by certain quantities, which represent the hardness of the materials, multiplied by the product of the mass of the moving body into the square of the velocity. There are many other ingredients of the calculation for which it would be difficult to prove that they vary as the velocity simply. It may be also observed, that Mr. Russell's formula frequently did not agree with his own experiments. In about a dozen cases there was an analogy; but the coincidence seems purely accidental, and it would be easy to invent a score of different formulæ which might be supported by similar comparisons.—[Editor C. E. and A. Journal.]

A paper on *Improvements in Steam Engines*, by Mr. Lamb was read. One object of the paper was to suggest an improved method of "blowing off." It was found by experiment that the scales which formed the concretion in boilers were boyed on the surface of the water when boiling, and that they were not precipitated to the bottom till ebullition had ceased. Mr. Lamb proposed to take advantage of this circumstance by putting the blowing off pipe near the surface of the water. The subject of the next paper was

THE MENAI AND CONWAY TUBULAR BRIDGES.

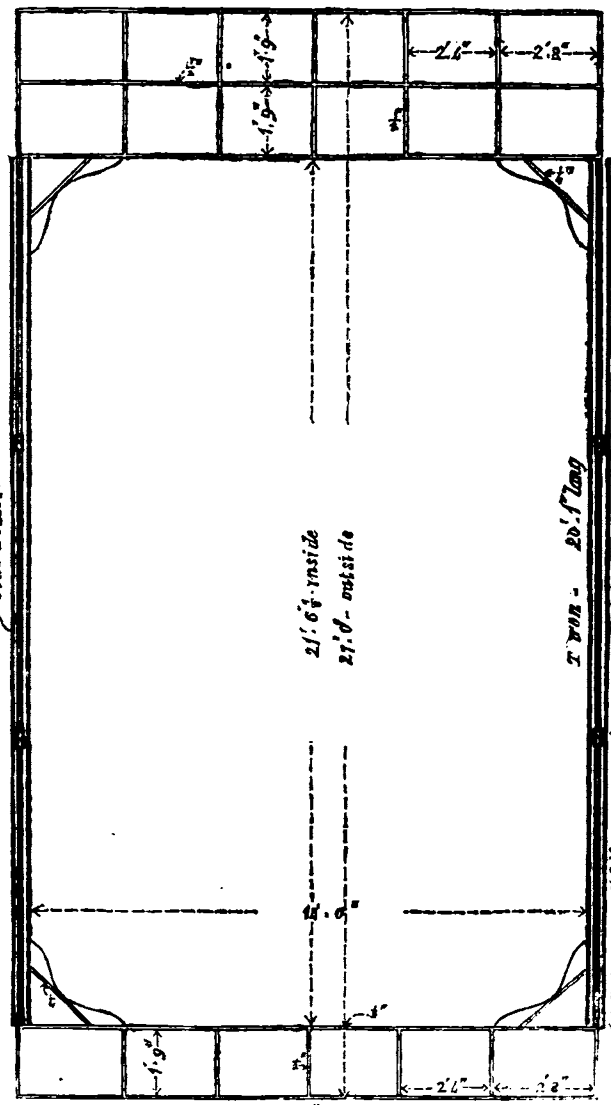
The subject was illustrated by a large number of diagrams, sections, and working drawings; a view of the Menai Bridge with two long and two shorter spans was shown, and on the table was a large model of the bridge which it is proposed to erect over the Conway before the Menai bridge is commenced. The model of the Conway bridge shows a single span; the abutments are two massive towers rising to about twice the height of the tube; the sides of the tube have a series of cruciform apertures for the admission of light and air.

Mr. FAIRBAIRN commenced by detailing the course of the experiments which had been made to ascertain the strongest form of the tube. The tube generally gave way on the upper side, and it was first attempted to strengthen it by making the top plate of corrugated iron. This being found insufficient, the next proposition was that the top of the tube should contain long tubes between two horizontal plates; the form of the section being that represented in the accompanying diagram.



This form was afterwards modified by making the top with rectangular cells or compartments, and a model of this form was made one-sixth the dimensions of the proposed bridge; that is to say, of one-sixth the length, breadth, and height, and with plates rolled as nearly as possible to one-sixth the thickness of those intended to be adopted.

The following diagram represents the section of the model at the middle, and also of the Conway Bridge for which the dimensions will be as follows:—



[Section of the Conway Bridge at the middle.]

Dimensions.

	ft.	in.
Height outside	27	0
" inside	21	6¼
Breadth outside	14	8
" inside	14	0
Thickness of side plates	0	4

Height of each of the three portions which are united to form the side plates	7	2½
Height of rectangular cells at top and bottom	1	9
Breadth of ditto	2	4
(Excepting those at the angles of the tube which are in breadth ..	2	8
Thickness of plates forming the cells		¼

In all the experiments on the large model the weights were suspended at the centre of it, from its lower side. In the first experiment the tube broke with a weight of 35½ tons. It was then thoroughly repaired and the sides were stiffened by vertical ribs attached at intervals throughout their length: by these means and the addition of another plate at the bottom the breaking weight was increased to 56 tons. It was observed in one case that the top of the tube bulged out transversely. The form of joint which was intended for the top of the tube was made by laying the ends of the plates together without uniting them; they were then to be simply overlapped by pieces of metal above and below to prevent them slipping past each other ———. Instead however of adopting this form, the maker of the model had by mistake used a joint of the following form ———, bolting the two plates where they overlapped. In consequence of this arrangement and the great pressure to which the upper side of the model was subjected, the plates slipped some considerable distance past each other, and slits were cut in them by the bolts. The section of the Conway bridge given above, shows one of the vertical stiffening plates attached to each of the sides of the tube. These stiffening plates are T iron ½ inch thick.

Mr. Eaton Hodgkinson said that his own decided conviction was that the best form for the top of the bridge was a series of long hollow cylinders such as those first described by Mr. Fairbairn. There were three forms proposed for the top—solid iron, rectangular compartments and cylindrical compartments. He certainly thought the latter form was the best. In fact the superiority was so great that no difficulty or expense in the manufacture ought for an instant to weigh as an objection to its adoption. The great object was perfect security, and to this every minor consideration of trouble or preliminary outlay ought to be sacrificed.

From the proportions which had been chosen he estimated that the strength to resist lateral pressure was one-fourth of the vertical strength. In his own models the proportions for the side plates were different, and he had laid his tubes on their side to compare the lateral to vertical strength. He found the latter was to the former in the proportion 26 : 15. This comparison he had instituted in order to ascertain the capability of the bridge for resistance to the action of wind. As however the proportions actually chosen for the Conway bridge differed from his own, he had suggested that the strength of the side plates should be increased, and this suggestion had been partially acceded to. He did not think that the top plate should be arched between the abutments as in that case the steam of the engine would rise to the top and have no means of escape. [This by-the-by is a very insufficient objection, and one which might be easily removed by some simple mechanical contrivance.]

Mr. Clark, who had been present during the performance of all the experiments, next read a paper. Each of the longer tubes of the Menai bridge would be 462 feet long, and weigh 1200 tons. It was intended to put all the parts of tube together at a place about a quarter of a mile from the intended position of the bridge. When the structure was finished it would be floated to its place on large barges, and finally raised by hydraulic presses at the two ends simultaneously. The Conway bridge had to be raised only 18 feet, and this work would be completed first. Mr. Clark then read some calculations respecting the strength of the bridge, but they bore so great an analogy to those which have been already published in this Journal, in the Notes on Engineering, that it is not necessary to repeat them. He said also that the tensile strength of the bottom would be proportional to the sectional area, and independent of either the width or thickness considered separately; so that provided the sectional area contained a given number of square inches, it was immaterial what proportion the thickness of the bottom plate bore to its width. [This is one of several grave errors which have been committed in the contrivance of the Tubular Bridge. We do not however consider it necessary to enter on the demonstration here, as it will be given in the Notes on Engineering.]

From the experiments it would appear that the sectional area of the two sides together ought to be equal to that of the bottom plate.

Mr. Fairbairn expressed some surprise that Mr. Hodgkinson should take to himself the credit of suggesting the cellular form for the top of the tube. He could assure him that he was mistaken on this point, as experiments on tubes with cellular tops had been commenced at Millwall before he arrived there. With respect to the pressure of the wind, it would be found that if it be taken at 50 lb. per square foot, the total lateral pressure on one side of the bridge amounts to 300 tons. The proposition of supporting the bridge by suspension chains had been finally abandoned. In order to deaden as much as possible the effect of vibrations from the passage of a train, the rails would be laid on vulcanised india-rubber 2 inches thick.

Dr. Robinson called attention to the difference between laying a load gradually on the bridge and drawing a load rapidly over it. If the impulses from the train were synchronous with the vibrations, the latter would be increased to a frightful extent. He himself had ascertained the vibration of a train at a distance of 15,000 feet by observing the effect on quicksilver. He thought that in the model different loads ought to be drawn through very rapidly to test effects corresponding to those of the passage of trains.

Mr. Fairbairn said he would certainly endeavour to follow out the suggestion.

Mr. Scott Russell said that it appeared to him that the principal question had not yet been discussed. The point to be considered was—not whether the bridge could be made strong enough to bear the weight on it; for there was no doubt that the engineers would keep on adding metal till they removed all chance of fracture—but the real question was whether the requisite strength was attained with a minimum quantity of metal: whether, in fact, the metal was disposed in the most advantageous manner. He had some doubts on this point. If two spans of the bridge were united at the bottom pier, it was clear that any deflection in one span would communicate its effect to those which adjoined it; so that there would be points of contrary flexure, and the line of the bridge would be alternately convex

and concave. In this case the top plate of the bridge would, in the neighbourhood of the pier, be subject to tension instead of compression, and conversely for the bottom plate of the bridge.

Mr. Hodgkinson said the consideration of vibrations from the rapid transit of a train was of the utmost importance. The effect of a train in motion could scarcely be calculated accurately. "I confess," added Mr. Hodgkinson, "that when I consider this subject my mind misgives me, and I cannot help feeling a few tremors." This announcement produced a sensation.

Mr. Roberts said that vibrations might be checked by altering the time of the impulses. It was a common practise of engine-drivers, when they found the engine began to "kick," as they term it, to accelerate or retard the train, and this generally destroyed the vibrations.

Mr. Fairbairn allowed that rectangular compartments for the top of the tube were not theoretically the best, but they were so practically. It was necessary to provide means for the entrance of workmen into every compartment to make any repairs that might be required, or to renew defective plates.

Dr. Robinson said that what was to be apprehended during the passage of trains was not a sudden impulse, but the accumulation of vibrations. It was well known that even a child might set a great bell in motion by continued efforts properly timed. If the impulses communicated by the bell-rope were synchronous with the vibrations of the bell itself, the extent of those vibrations might be increased till the bell got its full swing.

Mr. Hodgkinson said that it had been suggested that the top plates should be of cast iron. He objected to this proposition on the following grounds. From his own experiments on the strength of cast iron, and wrought iron columns to resist pressures applied in the direction of their lengths it appeared that the relative strength of the two materials depended entirely on the length of the columns. The columns might fail either by bending or by crushing. With short columns cast iron bore to wrought iron the strength of 17 : 10, but with long columns the strength of cast iron to that of wrought iron was at 14 : 50. This showed the superiority of the latter material for the upper plates of the tubular bridge.

MICHAEL ANGELO.

A correspondent of the *Literary Gazette* has furnished to that paper some particulars relating to the discovery of certain works by Michael Angelo and other artists of renown. The correspondent is described as a lady married into a collateral branch of the family of the great Italian. A minute search through the Buonarotti Gallery has led to the following results:—"Upon opening the door I found Michael Angelo's own original wax model of his superb David, looking even *more* majestic and imposing than the well-known gigantic statue on the Piazza del Gran Duca, which may be imputed to the fact of his having been stinted in the size of the block of marble. Besides this master-piece, the cupboard further contained two other wax models by Michael Angelo, one his Giorno, the other his Crepuscolo,—both of which are in the chapel called Cappello di Michel Angelo in the Church of St. Lorenzo. There were likewise in this same closet models in clay by Giovanni di Bologna; they are his first conceptions of his most celebrated groups and statues. Another in wax, by Baccio Bandinelli, besides another by an unknown hand. Then, at the bottom of all, under a thick veil of cobweb, I perceived a quantity of fragments, which appeared to me of surpassing beauty. I collected the pieces, and joined them together with boiling wax, thread, &c.; when, to my great delight, I found my fragments assumed the form of the torso and legs of a Satyr, which is one of the finest works of Art that can be imagined. The celebrated engraver Jesi and another artist chanced to call upon us, and both proclaimed the Satyr to be the work of Michael Angelo;—but *then*, we had no *proof* of such being the case. Now comes what I deem the marvellous part of the story. The following morning, I again occupied myself groping and poking about the gallery, particularly in an old cabinet or closet which they say Michael Angelo used to write in. At length, I pulled out a drawer, in which was a letter, dated 1660, from one Covr. Pansani, who begs the Proc. Buonarotti to accept a *Torso di Satiro*, the work of his great ancestor Michael Angelo.* * *—In this extraordinary manner have I obtained the proof of the authenticity of my *Satiro*."

DESIDERATA FOR THE MORE ADVANTAGEOUS STUDY OF MEDIÆVAL ARCHITECTURE.

Mr. Editor—In your August number I read the article on the "Future Development of Mediæval Architecture," with much interest and gratification, and no doubt very many of your other subscribers did the same, the good taste, the soundness of judgment, the freedom from all dogmatising or flippant treatment of opposite opinions, quite led me to anticipate from the paper a thorough knowledge of his subject in the author, and this the whole article fully sustained.

With a view to follow up the subject in a practical way, I will venture to put down a few thoughts that have for some time occurred to me, and which you may perhaps consider worthy of insertion in your valuable Journal. They relate to the necessity there still exists of some well digested compilation, to set forth the choicest examples of really good Mediæval architecture, both in the mass and combination, and also in the details. This may at first appear a startling assertion, when the number and vast variety of works already published and constantly issuing from the Press are considered, intended to bear upon that professed object.

So far as I am able to judge of any work I have yet seen, I think we have no grammar of the art, as it were, such as we have in all other studies, whereby the student may really begin at the right end as to what he has to learn, and arrive at the procurement of that elementary knowledge in the shortest possible time. I consider this latter, in their railway era, of real importance.

From the architectural student of the present day so much will be required, that whatever facilitates his path by enabling him promptly to acquire the mechanical, and helping him quickly to discover or to feel the beautiful, and as readily to repudiate the elaborated though expensive trifle, however ancient, will do much to help forward the future practitioner to a fuller attainment of the style in its highest excellence.

That much has been done within the last few years, to set up and induce the adoption of the style on a right foundation, must be admitted; and perhaps a condensation of, or a compilation from, existing publications might go far to accomplish what is wanted. Of books we have, I consider, far too many—that is, as to the good a student can derive from them; of those that profess to be initiatory, how much is there in the best of them of little or no avail for his purpose. We find a beauty of engraving—a costliness of drawing most engaging,—but there is in them all far too much beyond the energy or the attainments of a mere architectural student to expect him to work out; and, except the treat of frequently reviewing the plates and, perhaps, some general suggestions, he does not derive the help from the work which is most needed by him.

After much study of the architecture of the Middle Ages, I am satisfied the real practicable and imitative beauties for our adoption are confined to a much briefer epoch than many of its professors have been disposed to admit: and of these beauties—like all other truths or principles—the simplest, the most obvious, and least intricate of them, are those identical ones most capable of combination and expansiveness. Of the works issued by the several provincial societies, there are none that I have yet seen that will survive as conferring any abiding solid benefit on Pointed architecture; they all start from the same point, and none advance beyond a parallel degree or stage; indeed, it appears as though the pleasing illustration of the architecture of a district or archdeaconry was their only intention. Now this, from the nature of such associations may perhaps be essential to keep up an interest amongst subscribers; but I have long since thought that a portion of the funds at the command of these societies might be devoted to higher and more permanent advantages. Most of the elementary or instructive treatises that I am aware of have been undertaken as a trading matter, and as such they must necessarily combine as much for the money as possible, and they must further be made to suit the tastes of the greater number, and here appears to me to result their inadequacy. Without intending to disparage any work, it strikes me there needs in all of them a much sounder discrimination, to separate the precious from the vile; and, therefore, a society not publishing for profit could do what an individual publisher could not. In looking through even those works most recently issued, or in course of being so, I am surprised to find the omission of many choice examples infinitely more worth the drawing and engraving than some of the subjects given, and such examples, too, not at all inaccessible. Now, the collective knowledge of a society is likely to be able to gather a much more select assortment of specimens than an individual can be supposed to be aware of. I will repeat—what we want is far fewer, and far more select, subjects. The publishing of whole buildings cannot procure these, for in almost every structure there are many points which the student should be cautioned to avoid, as well as others he should be called upon to admire;—and therefore why publish faulty lessons instead of unexceptionable ones? Were the several societies moderately to contribute part of their funds to a delegated number of their respective bodies, some half dozen well qualified individuals might unite for the purpose of selecting examples wherever they were to be met with; to procure their accurate and detailed delineation, suitably figured; merely giving the place and where attainable, the date, and architect's or church builder's name, without encumbering the work with any topographical particulars, but giving, instead, the reasons for the excellency of the subject, the causes of beauty in the composition, or the feature. The examples need not be expensively engraved, but they should be drawn to a sufficiently large scale to be at once obvious and serviceable, as conveying their true portraiture, and to have a form and a substance imparted to them even more speakingly than is sometimes done in many of the exquisite examples of engraving frequently adopted in the present day.

The germ of the plan or method of selection is suggested by Pugin's lectures and Paley's moldings; but it ought not to be a sufficient recommendation that the examples be copied from an esteemed structure, or be of unquestionable antiquity; - its only recommendation should be its essential fitness and beauty; multiplicity of examples, except of the best character, should be most cautiously avoided.

After treating of details in their order, the work might proceed to give examples of combinations, still excluding or carefully repudiating every part not worth imitating,—and then at the conclusion, some examples of the massing of whole structures, which many of the Pointed buildings beautifully illustrate, and which Mr. Petit, in his work on Architectural Expression, has so happily developed from the very plainest structures. These might be accompanied with a few simple structures, showing why the effect of a certain mass is *rich*, and the effect of another *poor*.

The labour of the rising school of architects will have to be given to so many objects, that it will not do to direct the student to a choice example merely; but it must be to the very choicest of any two choice ones, that he may sieze the best first, and leave the second best, and go to something further,—that he may know more, day after day, how to weed his portfolio of questionable treasures in exchange for cardinal verities, and to give him time to digest these verities and get them thoroughly into him;—so that after a while he may trust to books less, and himself and his own correct principles more. The multiplication of books, as an architectural publisher admitted to me the other day, was the bane of the age, so far as the student was concerned.

On the basis of some such principles as these, Mr. Editor, do I consider Mediæval architecture should be studied;—to copy merely because the example is ancient, or because the original is associated with circumstances which can never be imparted to the imitation, is not to advance in architecture—but to retrogade.

If these remarks should lead to any practical good, I shall be glad; or should they suggest any hints to an inquiring and industrious architectural student, so as to show him what lies before him, I shall consider my time not mis-spent. I am, Mr. Editor,

One of your early Subscribers,

Nonnullus.

THE GAUGE COMMISSION.

Analysis of Evidence given before the Royal Commissioners appointed to investigate the subject of the diversity of Railway Gauges.

(*Continued from page* 214.)

George Parker Bidder, Esq.*: Is in the immediate management of the lines in Norfolk, and the Peterborough line. From his connexion with Mr. Stephenson, has more or less information of the lines with which he is connected. With respect to the great increase of cost which Mr. Gooch says exists upon the narrow gauge lines for the locomotive power of the goods trains, the cost upon the London and Birmingham and the Grand Junction being double what it is upon the Great Western, is prepared to dispute that fact entirely; but there are circumstances which might affect that comparison as to the particular character of the goods trade. On one line it may be necessary to have trains which may have to pick up goods at different stations, so as not to carry the same load from the terminus,

* The Editor has felt it his duty to append to this evidence some comments, which will be found in their proper places, inserted in brackets.

and at the same time to have the same engine power; and there may be a variety of other circumstances. For instance, on the Norfolk railway: at present the connection is not completed of the two railways at Norwich on account of a bridge of an original construction, a swing bridge; so that the fish is brought from Yarmouth to Norwich, then discharged, and carried across the river, then loaded again, and then brought to London, and those trucks go back light. Therefore, if you were to take the actual cost of the locomotive power for the goods there, you would have to charge two miles of locomotive power for one mile of effective traffic, and consequently, although the locomotive engines might be running at actually a less mileage than another line, yet in that sort of comparison, they might be made to appear to be working at a greater cost. Therefore, unless you have all the circumstances brought before you, any comparison of that nature appears to be not conclusive.

It does not appear that very much higher rates of speed would be required. There would be much more convenience from giving frequent departures, than from running particular trains at a very high velocity. And there is another question; after you have attained a speed of 40 or 45 miles an hour, the saving of time by the increase of speed does not go on *pro rata;* it is very much diminished. You save a great deal of time by an increase from 20 miles an hour to 40 miles an hour; but an increase from 40 to 50 miles an hour is not of that importance. With the present permanent way, where the rails are 70 to 75 lb. weight, you might travel certainly at 70 or 80 miles an hour.

The repairs are very much augmented by bad curves, and a wide carriage, or a wide engine, must be subject to greater torsion from curves than a narrow one. Cannot believe that it is possible that the repairs of the wide gauge carriage and engines can be so little as of the narrow. Has no experience of the repairs on the wide gauge, but on a bad curve line the repairs are very much augmented. On the Newcastle and Carlisle, the repairs of the engines, as compared with the North Shields, are about £250 per engine per annum.

Has a return of the performance of a goods engine in ordinary working on the Midland line between Derby and Rugby; and whether you take it as the actual weight moved or the evaporating power, it stands a favourable comparison with any engine referred to in the evidence of Mr. Gooch. In one trip the engine took from Rugby a gross load of 348 tons 16 cwt., to which you would have to add her own weight and that of her tender, about 35 or 36 tons. She took that load up 16 feet a-mile from Rugby, and she acquired a velocity for that 16 feet a-mile, of 15 miles per hour. If you compare that with a level line, it is equivalent to a gross load of very nearly 700 tons on a level. The quantity of water evaporated on that length was 35½ gallons per mile; that is equal to about 100 feet per hour. Now, from the experiments it appears, and it is consistent with one's notions, that the power of evaporation is directly, or nearly so, as the power of blast, that is, the number of strokes per minute, and the volume of that blast. From a return of an experiment on the Northern and Eastern, an engine which, at 30 miles an hour, evaporated not more than 70 or 80 feet per hour, evaporated 150 feet at 50 miles per hour.

[Mr. Bidder here assumes that the resistance to a train of 348 tons, on a gradient of 16 feet a-mile, is the same as that to a train of 700 tons on a level. The conclusion is independent of the velocity, and seems derived from taking the resistance of friction at 7 or 8 lb. per ton. This calculation omits the pressure on the blast pipe, which is a function of the velocity, and the resistance of the air, which is nearly as the square of the velocity, and depends, moreover, *not on the weight* of the train, but on the *surface* exposed to the action of the air. But setting all this aside, the amount of 7 or 8 lb. for friction is not even approximately correct, for it is certain that resistance from the unevenness of the rails, &c., is much greater at high than at low velocities. The idea that "the power of evaporation is directly or nearly as the power of the blast," is contradicted hereafter by Mr. Bidder's own figures. Besides, if this theory were true, *no* water at all would be evaporated when the engine was standing still, for then the blast is not in action.]

On the last experiment the train was reduced to 72 tons 12 cwt. gross, a little more than half the first load. The net speed realised was 43 miles per hour, and the quantity of water evaporated was at about the rate of 190 feet per hour. This engine was a long-tube engine; the tubes are 13 feet long, 15 inch cylinders, 22 inch stroke, 5 feet 6 inch wheels; the area of the fire-box is 49·786 feet, and the heating surface of the tubes 738 ft. Then the letter from which I take this goes on,—"To prove the temperature of the heat in the smoke box I suspended four pieces of metal, viz., one piece three parts tin and two parts lead, one piece one part tin and four parts lead, one piece lead, and one piece zinc, their melting points respectively being 334°, 470°, 590°, and 680°. These metals being suspended immediately above the top row of the tubes, about one inch from the tube plate. I found at the end of the journey that the three first-mentioned metals had melted, but the zinc did not melt in any of the three trips, proving the temperature of the heated air to be about 600°." Now that shows that the temperature of the steam in the boiler being about 312°, and the air, when escaping from the tubes, being about 600°, it is quite clear that every part of those tubes must have been available in heating the water, and in the evaporation of steam; and by a comparison, taking the different loads and comparing them with the experiments of the goods engines, which are of a similar construction, with the same area o fire-box, and the same tube surface, you will find, as nearly as can be, that the evaporating power is a function of velocity, and also the function of the area of the cylinder. This clearly shows that the long boiler not only increases the evaporating power, but increases the economy in the conversion of water into steam.

["This clearly shows" nothing of the kind. To get at anything like a trustworthy conclusion, the same experiment should have been made with a short-boiler engine, and the results compared. We are not told who made the experiments, or how they were made, and consequently do not know how far they deserve to be trusted. Our confidence, by the by, is not increased by reading that the fact the zinc did not melt proves "the temperature of the heated air to be about 600°": this makes well for Mr. Bidder's side of the question, but all that can be legitimately concluded is, simply, that the temperature was under 680°—it may have been 670°. The fact that the temperature of the air was about double that of the steam, shows that not nearly all the heat of the former was usefully applied. To economise the whole of it, the hot air must continue to act on the steam till it can impart no more heat to it—that is, till the temperature of both is the same. How can we tell, *a priori*, that if the experiment had been tried on a short engine, this result would not have been more nearly attained than with the long-boiler engine, especially if we are to conclude that "the evaporating power is a function of velocity and also the function of the area of the cylinder," and does not depend on the amount of heating surface. It is to be observed the words, "is a function of," are incorrectly used as synonomous with "is *proportional* to."]

"In those experiments are you well assured that there was no priming? —Yes, especially in the goods engine; because, if you take that particular experiment to which I have alluded, where she took 385 tons gross up 16 feet a-mile; if you take the area of the cylinders and see what quantity of steam must have passed through them in passing over that gradient, and see what was the volume of the steam at the requisite pressure to convey that train, you will find that the quantity of water is more than that which appears to have been consumed, which I attribute to the fact that they must have been using steam at rather a higher pressure than ordinary in the boiler.

"How did you ascertain the amount of evaporation; after the experiment was over, how did you ascertain the quantity of water?—They take the gauge of the tender, and the gauge in the boiler, and then they have the superficial area of the boiler at the different heights, and the area of the tender. It is ascertained with very great exactness, and great facility."

[Here Mr. Bidder assumes his proposition in order to prove it. He takes it for granted that there would be no priming, in order to show that there was none. First, with respect to the means of ascertaining the amount of evaporation: his method simply shows the quantity of water *got rid of*—not the amount converted into steam and usefully employed. The water *might* have passed away by leakage or priming,* or the steam might have escaped by the safety valve. But he is assured these contingencies could not have occurred, for he calculated the amount of work done, and the quantity of steam required to do it. He is certainly the first person who has been able to ascertain the resistance to a train with anything like the accuracy necessary for a calculation of this sort, and has increased the simplicity, if not the accuracy, of his operations by taking it for granted that 700 tons on a certain gradient are equivalent to 348 on a level. To find the quantity of water required to do the work, the recipe is to "take the area of the cylinders and see what quantity of steam passed through them," but who but Mr. Bidder could tell *a priori* how much that steam was dilated in coming from the boiler, and what was its precise effect when acting expansively—in other words, the exact nature of its mechanical action? Both problems are, considered separately, so intricate as to baffle all human ingenuity. The first, the resistance offered to the train depends on the wind, concussion at the joints of the rails, friction of the axles of the carriages, and other complicate mechanical actions, varying with every variation of velocity. The second, the mechanical effect of the steam it is equally impossible to predict. The relation of the power of the steam to the quantity of water used depends on the temperature and tension in the boiler and the temperature and tension in the cylinder; the latter varying not only at every stroke, but (when the steam is used expansively) at almost every part of the stroke. It is therefore quite impossible to take the two problems separately; they must be considered together, as De Pambour has considered them. We have quite sufficient proof, however, that Mr. Bidder's calculations were all wrong,

* De Pambour shows that of the whole quantity of water consumed, one-fourth is, on the average, wasted by being drawn into the cylinders in a liquid state. So much for there being no priming!

from his anomalous conclusion that *more* water was required than was actually expended! In accounting for this anomaly, he let us into a secret;—he confesses that he did not know the pressure in the boiler, which of course should have been an essential ingredient in his calculation.]

A law seems to exist that the power of producing steam is as the velocity, that is, the number of blasts and the volume in the cylinder; that is, as long as the fire-place will supply you with combustion to that amount; but as you increase the blast the combustion goes on in that ratio; and even with the Great Western experiments, and those taken with a short boiler, it is found almost invariably as the result, that 1 lb. of coke evaporates 7 lb. of water. With the long boiler we hardly ever get an effect of less than 8 lb. of water to 1 lb. of coke, and in some of these experiments it is as much as 10 lb. And we get economy in another way. In a comparison of engine power and of the consumption of coke, you may get a fallacy from not knowing to what extent there may be pilotage in one line or another. If an engine on one line has double the amount of engine piloting which there is on another, her consumption goes into the general mileage; whereas the consomption of coke while running may be very much less. On the Northern and Eastern, when that line was first opened to Broxbourne, their engines only consumed 20 lb. of coke while running, and yet the daily returns showed 36 lb.; that was from the quantity burnt at the stations. Now a long-boiler engine is economical in that respect, because, no doubt, from the length of tubes, the quantity evaporated while standing and the coke consumed is very much less; in fact, an engine with 13 feet tubes burns only half the coke standing that is consumed by an engine with 8 feet 6 tubes.

[In the first part of this paragraph the blast is supposed to increase the evaporation, but to also increase the consumption of coke *in the same ratio;* so that though more coke is burned in a hour, the effect of each pound of coke is not increased. In other words, the blast is supposed not to increase the *economy* in the use of the coke. Now, it has always hitherto been supposed that a strong current of air (and, therefore, of oxygen) rendered the combustion not only more rapid but more *perfect* also, and that where the supply of oxygen was insufficient, a great part of the fuel was wasted and passed away unconsumed, or without developing its evaporative power. It is, therefore, concluded that the rapidity of the current of air (within certain limits, of course,) increases the actual economy in the consumption of fuel. In the last sentence of the paragraph, the "quantity evaporated while standing" by a long-boiler engine is supposed to be less than by a short boiler engine; and yet the principal argument in favour of the long boilers has always been understood to be their increased amount of heating surface, which might be supposed to increase the quantity of water evaporated, whether the engine were standing or in motion.]

"Do you think any good would result from the use of corrugated metal for fire-boxes?—I do not think there would be any. They get apparently a larger surface; but I think the effect upon that surface must be weakened to the same extent as you happen to extend the gauge. With a certain amount of combustible matter in a pound of coke, if you get the whole of that out, which we do with a long-tube engine more effectually than they do with a shorter one, from the fact that we get 8 lb. of water evaporated instead of 7 lb., I do not see myself how you can do more than extract that matter and apply it usefully; it does not matter whether it is in the fire-box or in the tube."

[Mr. Bidder does not see any use in increasing the surface of the fire-box, because "you can do no more than extract the matter and apply it usefully." But, then, that is assuming that *all* the matter is applied usefully in the long-boiler engines; whereas, he himself has proved that this is not the case, from the fact that the temperature in the tubes is twice that of the steam.]

There is a great difference of opinion respecting the atmospheric resistance; the fact has come before me from the experiments not only with the locomotive engines but on the atmospheric railway, where I see the power that has been expended and the result, and I cannot account for the expenditure but by atmospheric resistance, or some resistance which is a function of the velocity. For instance, I take a locomotive engine, No. 6, on the Northern and Eastern. I put behind that engine a train of 100 tons, she will travel with that train at the pace of 30 miles an hour, and she will evaporate at the rate of 80 feet per hour. I reduce those 100 tons to 20, that engine goes at 50 miles an hour and evaporates at the rate of 150 feet per hour; and I find, as nearly as can be, that the same quantity of water is converted into steam per mile with the light train as with the heavy train, showing that the *pressure upon the piston is nearly the same*, and that the power has been absorbed by this great augmentation of resistance.

[The blunder marked by italics rivals the celebrated notion started in the investigation of the Norfolk railway accident (*ante* page 51), that an engine can be forced off the rails by the suddenly shutting off the steam. In the present case, Mr. Bidder evidently disregards the fact that the quantity of water drawn into the cylinder in a liquid state is much greater at high than at low velocities. Otherwise, how could he conclude that, because the same quantity of water was consumed during a slow as during a fast journey, the cylinder-pressure was the same in both cases? It is impossible to estimate the effective vaporisation by the water consumed; for even the mere circumstance of the boiler being fuller at one time than another will account for an enormous increase of priming. The inconsistency of this paragraph with that in which Mr. Bidder states that he is "well assured there was no priming" is also to be noted. *There* he was able to calculate the resistance to the train with the utmost exactness; all language of uncertainty was avoided,—we were told to "*see*" the resistance of a train in passing over a certain gradient, as if this *seeing* were the easiest process in the world. *Here*, however, the resistance is treated in quite a different manner—it is some very vague uncertain thing, which Mr. Bidder "cannot account for" but by supposing there is "some" force or another (he knows not what) functional of the velocity. *Here*, too, the resistance can only be ascertained from the vaporisation. *There* it could be calculated independently of the vaporisation—aye, and with that precision that the amount of priming could be deduced from the calculation. It is important to observe that at ordinary boiler pressures, steam occupies *from four to five hundred times* the space of the water from which it is produced. This shows how enormously the evaporation is exaggerated by neglecting the effect of priming.]

The following are extracts from Mr. Bidder's report on the results of the experiments tried with the broad and narrow gauge engines:—

"Before calling your attention to the facts shown in these experiments, which cannot be influenced by any circumstances, and which, in my opinion, are alone worthy of your notice, I will repeat that the object proposed was to ascertain the truth (and that alone) of statements which had respectively been made by Mr. Gooch and myself, as to the comparative power and economy of engines now in operation on the broad and narrow gauge lines, and more especially with respect to the importance of surface obtained by increasing the fire-box, or lengthening the tubes, and that any inference drawn from the results which shall bear on the merits of the two gauges will be foreign to the objects proposed, and false, as the circumstances of the experiments are not found to obtain in practice. Supposing, however, that they were, and that an increase of power were deemed desirable, I do not hesitate to say that that which is at present found ample for all purposes might be doubled, or more than doubled, on either gauge.* I shall now proceed to examine the evaporating power of the engines, as well as the relative economy of evaporation and efficient application of the steam evaporated. It will be recollected that on the part of the broad gauge, it was alleged (in reference to the statement that on the narrow gauge, not only economy but power was obtained by lengthening the boiler) that the area of the fire-box alone was the test of the power of the locomotive engine, and that 2 cubic feet of water per hour per superficial foot of fire-box have the capacity of evaporation of locomotive engines; and thus it was alleged, that the Great Western engines could evaporate nearly 200 cubic feet per hour, while the narrow gauge engines could only convert into steam 100 cubic feet, the comparative fire-box surfaces being as 97 feet to 50 feet. In order at once to test this principle, let us examine the facts shown in the experiments. By reference to the particulars of the experiment with 50 tons with engine A, on December 31st, 1845, between Darlington and York, a distance of 88½ miles, it will be found that the water evaporated is 20,520 lb., being at the rate of 232 lb. per mile. In the (up) journey the first mile, as well as the last 1½, were passed over slowly; as also were the first quarter and last mile on the return trip, in all 3¾ miles. In order, therefore, to get at the maximum average rate of evaporation on the trial, I take 20,250 lb., less 812 lb. (the water consumed in passing over the above 3¾ miles, at the rate of 232 lb. per mile), 19,700 lb., the weight of water evaporated by the engine in passing over the remaining 85 miles, which was effected in 106 minutes 12 seconds, being at the rate of 11,150 lb., 178 cubic feet per hour. I will now compare this with the experiment most resembling it in regard to the evaporation tried on the broad gauge. I take the experiment with 60 tons on December 17th. The total water evaporated was 24,640 lb. on 106 miles, or 232 lb. per mile; deducting from this 1,044 lb. for water due to 4½ miles passed over slowly, leaves 22,596 lb. of water evaporated in 112 minutes and 42 seconds, being at the rate of 11,820 lb., 189 cubic feet per hour, that is little more than the evaporation of the narrow gauge engine. When, however, we compare the coke, we find in the case of the broad gauge engine, that 7·8 lb. of water only were converted into steam by 1 lb. of coke, whilst the narrow gauge engine evaporated 9·6 lb., being a difference in regard to economy of fuel of 23 per cent. in favour of the narrow gauge engine."

* "In evidence given by Mr. Gooch, the average gross weight of passenger trains on some of the principal railways is given as follows:—

—	Great Western Railway.	Grand Junction Railway.	London and Birmingham Railway.	Birmingham and Gloster Railway.	South Western Railway.
Average gross weight in tons	67	43	42	38	36

The lightest of the trains included in the above average are express trains; there are now, therefore, engines in use on both gauges capable of taking trains of double the weight of those required in practice of the express speeds."

From the concluding sentence of this quotation, it is clear that Mr. Bidder's only test of the relative economy of the two engines is—not which does the greatest quantity of work for a given quantity of coke—but, which gets rid of the greatest quantity of water for a given quantity of coke: and, accordingly, he has drawn up a tabular account of the experiments, wherein, in the very cases in which the broad gauge engine evidently did the most work with a pound of coke, he concludes that because it did its work with a small quantity of water, *therefore* the engine was comparatively ineconomic! If the table were not actually printed and published, our readers might perhaps doubt whether we had fairly represented its contents. The following, however, is an exact copy:—

Experiments.	Engine.	Water evaporated per mile.	Coke consumed per mile.	Water evaporated per lb. of coke.	—
		lbs.	lbs.	lbs.	
No. 1 80 Tons.	Ixion ..	245	33·6	7·12	Broad gauge.
2 70 ,,	Ixion ..	238½	33·6	7·12	
3 60 ,,	Ixion ..	232	29·6	7· 8	
No. 1 50 Tons.	30th Dec., A.	291	31·2	9·3	Narrow gauge.
2 50 ,,	31st Dec., A.	232	24·	9·6	
3 80 ,,	31st Dec., A.	235·7	26·6	8·8	

The fifth column gives, according to Mr. Bidder's views, the figures by which the economy of the engines is to be tested. Let us take the first experiment in each case. In the narrow gauge experiment, No. 1, the train was 50 tons, and the consumption of coke 31·2 lb. per mile: in the broad gauge experiment the train was 80 tons, and the consumption of coke *not* 2½ lb. *more per mile*. It is obvious that the 2½ lb. will not alone account for the enormous difference between the two loads—namely 30 tons. The only conclusion which any rational unprejudiced man could draw would be that more work was got out of the coke in the one case than in the other. And this conclusion would be greatly confirmed by observing what Mr. Bidder omits mentioning, that the broad gauge train moved *fourteen miles an hour faster* than the narrow gauge train. And yet, because the water evaporated was less in one case than the other, we are provided with a fifth column of "water evaporated per lb. of coke," from which it is gravely inferred that the narrow gauge trip was performed the most economically! We must protest against this wholesale method of jumping at conclusions which shows a lamentable confusion of ideas respecting the mechanical action of steam

We said that Mr. Bidder's own figures contradicted his hypothesis that "the quantum of evaporation is a function of [*i. e.* is proportional to] the number of blasts per minute." Taking Nos. 1 and 3 of the broad gauge trips, which were respectively the slowest and fastest trips, the quantity of water in the first case was the *greatest* (viz., 245 lb.) and in the second the *least* (viz., 232 lb.). We get precisely the same result with the fastest and slowest of the narrow gauge journeys: so that if Mr. Bidder's table prove any relation of the evaporation to the blast at all, the conclusion must be the very reverse of his theory. It has been ascertained that if an engine be deprived of its blast pipe, the rate of evaporation will be reduced to about one-fifth; but from the few experiments instituted under this head, it would appear that under ordinary circumstances, when the blast is in action, its effect on the rate of evaporation varies as the fourth root of the velocity.

Before concluding these observations, we ought to offer some remarks on the particular circumstances under which the narrow gauge experiments were made. The following extracts from Mr. Gooch's report are not a little surprising "*The engine was on each occasion placed at Darlington over a powerful stationary blast for the purpose of getting very hot water in the tender and a bright fire to start with.*" By these means, the water in the tender was raised to 180°. In the experiments with goods trains, "*the engine was placed over the blast, and remained there an hour and a half. The tender containing warm water was taken from another engine and attached to the regular tender, and men were provided to bucket the water from one tender to another as the train was moving.*" Mr. Gooch plaintively observes that this contrivance would have been of great use in the broad gauge experiments.

The love of philosophical accuracy displayed by the conductors of the narrow gauge experiments precludes the supposition that *they* sanctioned these devices, which must therefore be attributed to the subordinate officers of the railway. But, at all events, they sufficiently account for the circumstance that the narrow gauge engines got rid of more water for each pound of coke (although they generally did less work for each pound of coke) than the broad gauge engines. It is, of course, more easy in the dead of winter to boil water previously raised to a temperature of 180° than water originally at the temperature of the atmosphere.

We must guard ourselves against the supposition that the experiments prove decisively the superiority of the broad gauge engines. In fact, they prove *nothing*. They were so few and so improperly conducted that no trustworthy conclusion can be derived from them. They ought to have been repeated several times over, under the superintendence of disinterested persons, whose object was—not to get up a series of showy results—but to exhibit, as nearly as possible, the *ordinary* working of either kind of engines. However, the observations here made will have, at least, one good effect: they will enable the reader to appreciate the philosophy given in evidence before public commissions on engineering questions, and to estimate the value of the experiments authoritatively sanctioned.

ON MASONRY.

(*From the Ecclesiologist.*)

The writer of this paper remembers an incident which puts in a rather striking light a very puzzling question about masonry, that must have often occurred to some or other of our readers. He had just been shown some of the famous quarries near Caen, by one of the proprietors; and having come out near a little Norman church, claimed his conductor's admiration for the effect of solid strength and lastingness which Romanesque ashlar, particularly when of Caen stone with the hoary grey of seven centuries upon it, always presents.* The answer was not what he expected. Instead of joining in his praises, his guide began to lament that the ancients could not do better, because they could not draw stones of any considerable size from the quarries. They had made good use, he allowed, of the small broken bits of stone they could dig out: but our mechanical advantages enabled us, with larger blocks, to adopt a more perfect kind of masonry. Now it is difficult to answer this. There is no doubt that some of the finest buildings of antiquity are constructed of stones of immense size. The Pantheon may be quoted for this; and every one will remember the huge blocks that must have been quarried for monolith columns. The general decline of art shows itself in this respect perhaps as well as others. There is a great gap between such a building as the Porta Nigra of Treves, and the best of early Romanesque masonry. Art in all its branches was, it seems, almost to die: in order perhaps that Christian Art might be less a development than a new creation. The Pharos in Dover castle is a fine specimen of Roman excellence: its builders could not get hewn stone; but they so bound their flint rubble with bands of brick, that the tower stands like a rock. Close by is the desecrated church with a good deal of undoubted British masonry in its shell. Here too, there is "Roman brick" in the quoins, &c.; but the general inferiority of the masonry to the real Roman work is very striking. Then, again, the fine Romanesque ashlar in the chapel of the Norman keep in the same fortress, is a specimen of the reviving art of masonry; but it is in kind like that of the little parish church near the Caen quarries.† The stones are all small, though beautifully and effectively used: there is no single stone to tempt you to measure its length and width, and to exclaim at its bulk: which seems to be the general effect produced on people's minds by modern masonry. As a matter of fact, it must, we suppose, be granted, that the architects of the Romanesque and Early-Pointed styles could not procure large stones: they were compelled to use even fine building stone, like that (which they so highly valued) of Normandy, in small masses, as they could inartificially obtain it from the quarries. So late as 1841 there was not a single crane at Caen, by which to ship the stone, had it been extracted in very large blocks,—a fact that may assist us to comprehend the great mechanical disadvantages under which the mediæval architects laboured. But though their stone was in such small pieces, how beautifully they used it! Of course, there is a great deal of ancient work that is very bad; although what has stood for six or seven centuries, may seem fairly entitled to entire exemption from any blame. But as a general rule, early masonry—at least after the later Romanesque had superseded the Anglo-Saxon kind—is surprisingly excellent: not only for solidity, but for keeping and harmony. It suits the style. The eye is satisfied entirely, without knowing or inquiring why. You admire the design, and feel almost unconsciously that it is worthily embodied in its material exhibition. You are neither induced to examine and commend the ingenuity with which the difficulties of a bad building stone are overcome, nor are you called on to join in the vulgar admiration of "such big blocks." In a word, you forget such a mere detail in the whole: but when you can descend from the whole into particulars, you find them all that can be wished.

There is so much that might be said about masonry, that we are unwilling to open the subject from a consciousness of our own ignorance. No

* This effect may be partly judged of from an examination of the drawings of Than church, in the elder Pugin's "Normandy."

† Not nearly enough attention has been paid to the subject of masonry, if only to determine dates. Let any one compare the excellent ashlar of this chapel, and the wretched rubble of St. Sepulchre's Cambridge, which is later in point of age; or even with the White Chapel in the Tower of London.

question more deserves study, and few are less attended to. The Cambridge Camden Society very early called attention in its church-schemes to the nature of masonry and jointing, but with small results. The nature of building stones, and the peculiar treatment of each, particularly as regards mouldings,—in granite for example, where from the hardness of the stone they are of necessity superficial, and in Kentish rag, where they are broad and coarse because the stone will scarcely take an edge,—are points for further investigation. At present, we propose only to make some general remarks, chiefly on the treatment of Kentish rag, which seem called for because this stone is coming happily into more frequent use in London.

In the beginning of the present revival of Church Architecture, the masonry, where brick was not used, was quite of the modern kind. Squared stones, as large as could be easily procured, were laid very neatly and closely, with as much regularity as was possible. This kind of masonry is by itself enough to spoil the effect of a Pointed building; as will be evident to any one comparing the new Pointed work at King's College, Cambridge, with the masonry of the chapel on the opposite side of the quadrangle. The same defect goes through all the modern Pointed work in Cambridge. It is curious to notice how truly small stones seem to be appropriate to the requisites of Pointed architecture. An arch is the skilful adjustment of stones not long enough to go across, so as to span over a space and support a weight. Hence a metallic development of architecture would probably reject the arch, because a strong metal bar may be of any length, and would be sufficiently strong for the top of almost any aperture. Whence it seems to be a gross unreality to cut a whole window-head, with arch and tracery, out of one block of stone large enough to cover the whole window opening. Yet this mockery has been resorted to in the New Houses of Parliament,—to mention a rather conspicuous instance. But without any reference to principles, few will doubt that, for whatever reason, the small masonry of ancient work is far more effective than the finest building on the modern plan with huge stones laid in regular courses. Some have thought that this difference arises from the fact that the smallness of parts gives increased scale to the whole; others, that from the regularity of courses in modern masonry there comes a too great preponderance of the horizontal lines in the building. But this question we cannot now discuss. Suffice it to say, that it is now becoming generally acknowledged that there is a great difference between Pointed and Classical masonry, and that the smaller size of the stones and the irregularity in laying them are main characteristics of the former style. But of the attempts to copy ancient masonry there are few which are not great failures. It was easily seen that the primness of modern quoining was not only tame and dull but utterly unlike old work; but it was not found so easy to remedy the fault. Builders began to try irregular quoining, and we soon saw prodigies of irregularity. On one side of the angle there would be three stones of different lengths running into the wall; then two running into it on the other side; then perhaps one, and again three, on no plan or principle whatever. The quoins became distressingly jagged; and after being pained one wonders why it need be so jagged. A more close observation of ancient work would enable us to detect some principle of order in its seeming irregularity. We believe that the very natural and reasonable alternation of long and short stones,—which is seen in its primitive simplicity in Anglo-Saxon masonry, of which indeed it is considered a great characteristic,—was always retained, though not in so harsh and cramped a form. The mason took long and short stones alternately, but was not careful to make them all tail into the wall of the same length, nor even to keep them of the same thickness.

Perhaps this is one great reason why brick quoins to a random wall are so particularly ugly, as brick can scarcely be used for quoins unless with the strictest uniformity.

So much for quoins. With respect to walling, the days are happily fast going when people were not satisfied without at least a scored stucco substitute for large ashlar. Architects are beginning to venture upon using local stones, rag and rubble. This is a very great change for the better in all respects.; and it is proportionately a matter of regret that these materials should not be rightly treated. For example, that useful stone, Kentish rag, has been already several times used in London; as at St. Michael's Chester-square, St. John, Charlotte street, and Christ Church, Broadway. No one can doubt that this is a great gain over brick or stucco: this ragstone being both very durable and of a good colour. It would also be an economical material if used as the ancient architects used it; but in these churches it is used in regular square blocks, producing no better effect than that of bricks of a new colour, and being very costly to boot. For no stone is less adapted for squaring than this, owing to its hardness and its decided grain. Any one who would visit the quarries near Maidstone and watch the process of squaring would be astonished at the waste. The small pile of squared material contrasts most strikingly with the huge heap of refuse stone, which, being rejected as unfit for building, is used merely for road-mending, for which purpose it is transported to great distances. And besides this waste, a good deal of labour has often been spent upon refuse stones, which, when nearly squared, have been shattered by some unlucky cross-grained blow. But to what purpose is this expensive squaring in a stone which seems only adapted for cleavage? In effect, a random wall, properly treated, is far better than one of squared blocks. All Saints, Maidstone, is built, we are aware, of squared rag; but it is squared in thinner layers than is now usual. St. Peter and St. Paul, Lingfield, is an example of the extremely bad appearance of very large and unwieldy masonry.* As for the expensiveness of this squaring process, the reader may judge when he is told that the stone may be drawn from the quarries in a natural way for half-a-crown a ton: the squared stone costs eight shillings and sixpence a ton. It really becomes a duty of church-builders to take care that their architects do not waste so much money in a process which is at best so unsuccessful and unsatisfactory.

There have been, however, several attempts, particularly in the neighbourhood of Maidstone, to use Kentish rag properly, that is, as irregular (or random) walling. But here again we have to find the same fault as with most modern attempts at irregular quoining. The irregularity is overstrained. There is not one stone at rest; not one seems to have a bed. They lie at all angles: some even stand on their points, merely propped by the contiguous stones. The masonry looks more like an intricate puzzle than anything else. Instead of this, in ancient random walling we may trace this principle,—always to lay every stone in its best bed, lifting up any part of it which may want thickening by means of thinner pieces. Regular courses are not studiously attempted; but any stone that comes to hand is laid in, provided it has a good plain bed.

These brief remarks must suffice, upon the use of Kentish rag more particularly, in quoining and walling. Many of them also apply however to other stones; for example, to the beautiful Bramley-Fall stone of Yorkshire, which is squared in the new church of St. Saviour, Leeds, for the walling as well as for the dressings.

As a general rule then we would give this advice to church-builders:—use the material of which the neighbouring churches are mostly built, and in the way in which they are built. If we study carefully the method of masonry employed formerly, we shall avoid both needless expense and eccentricity. For example, if flint is the material most easily procured, let us use flint; but only as it was used in old churches. We will not now enter on the nature of flint masonry, but would contrast only the absurd modern plan of using *black* mortar, from a fear of the wide joints in white, with the old way of "garretting" flint-work, that is, of inserting small flint-shivers in the mortar of the joints. But we purposely keep ourselves more particularly to the use of rag-stone; and upon this we may, in conclusion, remark that, without attempting to solve the general question started at the beginning of this paper, as to the supposed unreality of using small stones for masonry when we can get large ones, we may surely lay down that it is wrong and absurd to spend much money in squaring stones, the nature of which does not easily yield to the process, and which have lasted so well and with such good effect as used in random work by ancient builders. What we want for church-work is that the material should be good and substantial, and the best that we can afford. We do not object even to brick in a bad stone district, and where the funds are small. Only let the brick be honestly and intelligently used. On the other hand we see no objection to importing Caen stone for rich and stately churches in any district; though perhaps we shall rather rejoice than lament that the architects of Carlisle and Chester used the perishing red sandstone of their neighbourhood. For nothing can be more fitting than that we should press into the service of God whatever suitable materials His wonderful Creation may offer us. The very difference of material is a sign of the unity of the purpose to which they are consecrated, namely, His honour in His sanctuary. We would use flint, granite, sandstone, and ragstone, each in its proper district, in the spirit of the hymn, "Benedicat terra Dominum: Benedicite montes et colles Domino."

* All Saints, Maidstone, is built altogether in a very costly style, and has no pretension to random walling; the quoins and jambs are all in the same squared rag. The new churches we are criticising have their dressings in Caen stone, and the squared rag is used as if for random work. This is a great absurdity. One ought always to quoin with the strongest stone: if, therefore, one can afford to square so strong a stone as rag for the walling, it ought to be also used for the quoins. To use a soft stone like Caen for quoins to walling of a strong rag-stone is preposterous.

BRITISH ASSOCIATION.

Session 16*th*, *held at Southampton, September*, 1846.

Address of the President.

Sir R. MURCHISON, after complimenting the late President for his distinguished abilities and efficient services, addressed the association as follows:—

Ladies and Gentlemen,—After 15 years of migration to various cities and towns in the United Kingdom, you are for the first time assembled in the South-Eastern districts of England, at the solicitation of the authorities and inhabitants of Southampton. Easily accessible on all sides to the cultivators of science, this beautiful and flourishing sea-port is situated in a district so richly adorned by nature, so full of objects for scientific contemplation, that, supported as we are by new friends in England, and by old friends from the farthest regions of Europe, we shall indeed be wanting to ourselves, if our proceedings on this occasion should not sustain the high character which the British Association has hitherto maintained.

For my own part, though deeply conscious of my inferiority to my eminent predecessor in the higher branches of science, I still venture to hope that the devotion I have manifested to this Association from its origin to the present day, may be viewed by you as a guarantee for the zealous execution of my duties. Permit me then, gentlemen, to offer you my warmest acknowledgments for having placed me in this honourable position: and to assure you, that I value the approbation which it implies as the highest honour which could have been bestowed on me—an honour the more esteemed from its being conferred in a county endeared to me by family connexions, and in which I rejoice to have made my first essay as a geologist.

The origin, progress and objects of this our "Parliament of Science" have been so thoroughly explained on former occasions by your successive Presidents, particularly in reference to that portion of our body which cultivates the mathematical, chemical and mechanical sciences, that after briefly alluding to some of the chief results of by-gone years, with a view of impressing upon our new members the general advances we have made, I shall in this discourse dwell more particularly on the recent progress and present state of natural history, the department of knowledge with which my own pursuits have been most connected, whilst I shall also incidentally advert to some of the proceedings which are likely to occupy our attention during this meeting.

No sooner, gentlemen, had this association fully established its character as a legitimate representative of the science of the United Kingdom, and by the reports which it had published, the researches which it had instituted, and the other substantial services which it had rendered to science, had secured public respect, than it proceeded towards the fulfilment of the last of the great objects which a Brewster and a Harcourt contemplated at its foundation, by inviting the attention of the government to important national points of scientific interest. At the fourth meeting held in Edinburgh, the Association memorialised the government to increase the forces of the Ordnance Geographical Survey of Britain, and to extend speedily to Scotland the benefits which had been already applied by that admirable establishment to the south of England, Wales and Ireland. From that to the present it has not scrupled to call the notice of the Ministers of the day to every great scientific measure which seemed, after due consideration, likely to promote the interests or raise the character of the British nation. Guided in the choice of these applications by a committee selected from among its members, it has sedulously avoided the presentation of any request which did not rest on a rational basis, and our rulers, far from resisting such appeals, have uniformly and cordially acquiesced in them. Thus it was when, after paying large sums from our own funds for the reduction of large masses of astronomical observations, we represented to the government the necessity of enabling the Astronomer Royal to perform the same work on the observations of his predecessors, which had accumulated in the archives of Greenwich, our appeal was answered by arrangements for completing so important a public object at the public expense. Thus it was when contemplating the vast accession to pure science as well as to useful maritime knowledge, to be gained by the exploration of the South Polar regions, that we gave the first impulse to that project of the great Antarctic expedition, which, supported by the influence of the Royal Society and its noble President, obtained the full assent of the government, and led to results which, through the merits of Sir James Ross and his companions, have shed a bright lustre on our country, by copious additions to geography and natural history, and by affording numerous data for the development of the laws that regulate the magnetism of the earth.

The mention of "Terrestrial Magnetism" brings with it a crowd of recollections creditable to the British Association from the perspicuous manner in which every portion of fresh knowledge on this important subject has been stored up in our volumes, with a view to generalisation, by Colonel Sabine and others; whilst a wide field for its diffusion and combination has been secured by the congress held at our last meeting, at which some of the most distinguished foreign and British magneticians were assembled under the presidency of Sir John Herschell. It is indeed most satisfactory for us to know, that not only did all the recommendations of the Association on this subject which were presented to our government meet with a most favourable reception, but that in consequence of the representations made by Her Majesty's Secretary of State for Foreign Affairs to the public authorities of other countries which had previously taken part in the system of co-operative observation, the governments of Russia, Austria, Prussia, and Belgium, have notified their intention of continuing their respective magnetical and meteorological observations for another term of three years.

In passing by other instances in which public liberality has been directed to channels of knowledge which required opening out, I must not omit to notice the grant obtained from our gracious Sovereign, of the Royal Observatory at Kew, which, previously dismantled of its astronomical instruments, has been converted by us into a station for observations purely physical, and especially for those details of atmospheric phenomena which are so minute and numerous, and require such unremitting attention, that they imperiously call for separate establishments. In realising this principle, we can now refer British and foreign philosophers to the observatory of the British Association at Kew, where I have the authority of most adequate judges for saying they will find that a great amount of electrical and meteorological observation has been made, and a systematic inquiry into the intricate subject of atmospheric electricity carried out, by Mr. Ronalds, under the suggestions of Professor Wheatstone, to which no higher praise can be given than that it has, in fact, furnished the model of the processes conducted at the Royal Observatory at Greenwich. This establishment is besides so useful through the facilities which it offers for researches into the working of self-registering instruments which are there constructed, that I earnestly hope it may be sustained as heretofore by annual grants from our funds, particularly as it is accomplishing considerable results at very small cost.

Transactions of Vol. 1845.—*Physical Science.*

Our volume for the last year contains several communications on physical subjects from eminent foreign cultivators of science, whom we have the pleasure of reckoning amongst our corresponding members, and whose communications, according to the usage of the Association, have been printed entire amongst the reports. In a discussion of the peculiarities by which the great comet of 1843 was distinguished, Dr. Von Boguslawski of Breslau has taken the occasion to announce the probability, resting on calculations which will be published in Schumacher's "Astronomische Nachrichten," of the identity of this comet with several of a similar remarkable character recorded in history, commencing with the one described by Aristotle, which appeared in the year 371 before our era; should his calculations be considered to establish this fact, Dr. Von Boguslawski proposes that the comet should hereafter be distinguished by the name of "Aristotle's Comet." This communication contains also some highly ingenious and important considerations relating to the physical causes of the phenomena of the tails of comets.

Dr. Paul Erman of Berlin, father of the adventurous geographical explorer and magnetician, who was one of the active members of the magnetic congress at Cambridge, has communicated through his son some interesting experiments on the "electro-dynamic effects of the friction of conducting substances," and has pointed out the differences between these and normal thermo-electric effects. Baron Von Senftenberg (who is an admirable example of how much may be done by a liberal zeal for science combined with an independent fortune) has published an account of the success with which self-registering meteorological instruments have been established at his observatory at Seutenberg, as well as at the national observatory at Prague.

Of our own members, Mr. Birt has contributed a second report on "Atmospheric Waves," in continuation of the investigation which orginated in the discussion by Sir John Herschell, of the meteorological observations which, at his suggestion, were made in various parts of the globe, at the periods of the equinoxes and solstices, commencing with the year 1843.

In a communication to the meeting of the Association at York, Colonel Sabine traced with great clearness (from the hourly observations at Toronto) the effect of the single diurnal and single annual "Progressions of Temperature," in producing on the mixed vapours and gaseous elements of the atmosphere, the well-known progressions of daily and yearly barometrical pressure. To the conclusions which he then presented, and which apply, perhaps generally, to situations not greatly elevated in the interior of large tracts of land, the same author has added, in the last volume, a valuable explanation of the more complicated phenomena which happen at points where land and sea breezes, flowing with regularity, modify periodically and locally the constitution and pressure of the atmosphere. Taking for this data the two-hourly observations executed at the Observatory of Bombay by Dr. Buist, Colonel Sabine has succeeded in demonstrating for this locality "a double daily progression of gaseous pressure," in accordance with the flow and re-flow of the air from surfaces of land and water which are unequally affected by heat. And thus the diurnal variation of the daily pressure at a point within the tropics, and on the margin of the sea, is explained by the same reasoning which was suggested by facts observed in the interior of the vast continent of North America.

Among the many useful national objects which have been promoted by the physical researches of the British Association, there is one which calls for marked notice at this time, in the proposal of Mr. Robert Stephenson to carry "An iron tube or suspended tunnel over the Menai Straits" to sustain the great railway to Holyhead. This bold proposal could never have been realised, if that eminent engineer had not been acquainted with the great progress recently made in the knowledge of the strength of materials, and specially of iron; such knowledge being in great measure due to investigations in which the Association has taken and is still taking a conspicuous share, by the devotion of its friends and the employment of its influence—investigations which have been prosecuted with great zeal and success by its valued members, Mr. Hodgkinson and Mr. Fairbairn.

Whilst on this topic I may observe, that in the recent improvements in "Railways" the aid of scientific investigation was called for by the civil engineer, to assist him in determining with accuracy the power to be provided for attaining the "High Velocities" of fifty and sixty miles an hour; and it was found and admitted by the first engineers, that the very best data for this purpose, and indeed the only experiments of any practical value, were those which had been provided for some years ago by a Committee of the British Association, and published in our Transactions. The Institution of Civil Engineers thus gave testimony to the practical value of our researches by adopting their results.

However imperfect my knowledge of such subjects may be, I must also notice that the last volume of our Reports contains two contributions to experimental philosophy, in which subjects of the deepest theoretical and practical interest have been elucidated, at the request of the Association, by the labours of its foreign coadjutors.

That some substance of a peculiar kind everywhere exists, or is formed in the atmosphere by "Electrical Agency," both natural and artificial, had long been suspected, especially from the persistency of the odour developed by such agency, and its transference by contact to other matter. Professor Schonbein, to whom I shall hereafter advert as the author of a new practical discovery, is, however, the first philosopher who undertook to investigate the nature of that substance; and, though the investigation is not yet complete, he has been enabled to report no inconsiderable progress in this difficult and refined subject of research.

A request from the Association to Professor Bunsen, of Marburg, and our countryman, Dr. Lyon Playfair, coupled with a contribution of small amount towards the expenses involved in the undertaking, has produced a report "On the conditions and products of iron furnaces," which is of the greatest value in a commercial view to one of the most important of our manufactures, and possesses, at the same time, a very high interest to chemical science in some of the views which it develops. On the one hand, it exhibits an entirely new theory of the reduction, by cyanogen gas as the chief agent, of iron from the ore; on the other, it shows that, in addition to a vast saving of fuel, about two cwt. of sal-ammoniac may daily be collected at the single establishment of Alfreton, where the experiments were made; thus leadidg us to infer that in the iron furnaces of Britain there may be obtained from vapour which now passes away, an enormous quantity of this valuable substance, which would materially lessen the dependence of our agriculturists on foreign guano. It is, indeed, most gratifying to observe, that in pursuing this inquiry into the gaseous contents of a blazing furnace of great height, our associates traced out, foot by foot, the most recondite chemical processes, and described the fiery products with the same accuracy as if their researches had been made on the table of a laboratory. Weighed however only in the scales of absolute and immediate utility, the remarkable results of these skilful and elaborate experiments give them a character of national importance, and justly entitle the authors and the body which has aided them to the public thanks.

Natural History.

After this glance at the subjects of purely physical science treated of in the last volume of our Transactions, let us now consider the domains of natural history; and as one of the cultivators of a science which has derived its main support and most of its new and enlarged views from naturalists, let me express the obligation which geologists are under to this Association, for having aided so effectively in bringing forth the zoological researches of Owen, Agassis, and Edward Forbes. These three distinguished men have themselves announced, that in default of its countenance and assistance, they would not have undertaken, and never could have completed, some of their most important inquiries. Agassiz, for example, had not otherwise the means of comparing the ichthyolites of the British Isles with those of the Continent of Europe. Without this impulse, Owen would not have applied his profound knowledge of comparative anatomy to British fossil saurians; and Edward Forbes might never have been the explorer of the depths of the Ægean, nor have revealed many hitherto unknown laws of submarine life, if his wishes and suggestions had not met with the warm support of this body, and been supported by its strongest recommendations to the naval authorities.

These allusions to naturalists, whose works have afforded the firmest supports to geology, might lead me to dilate at length on the recent progress of this science, but as the subject has been copiously treated at successive anniversaries of the Geological Society of London, and has had its recent advances so clearly enunciated by the actual President of that body, who now presides over our Geological Section, I shall restrain my "esprit de corps" whilst I advert to some of the prominent advances which geologists have made. When our associate Conybeare reported to us, at our second meeting, on the actual state and ulterior prospects of what he well termed the "archæology of the globe," he dwelt with justice on the numerous researches in different countries which had clearly established the history of a descent, as it were, into the bowels of the earth—which led us, in a word, downwards through those newer deposits that connect high antiquity with our own period, into those strata which support our great British coal-fields. Beyond this, however, the perspective was dark and doubtful—

"Res altâ terrâ et caligine mersas."

Now, however, we have dispersed this gloom, and by researches first carried out to a distinct classification in the British Isles, and thence extended to Russia and America, geologists have shown that the records of succession, as indicated by the entombment of fossil animals, are as well developed in these very ancient or palæozoic strata as in any of the overlying or more recently formed deposits. After toiling many years in this department of the science, in conjunction with Sedgwick, Lonsdale, De Verneuil, Keyserling, and we have reached the very genesis of animal life upon the globe, and that no further "vestigia retrorsum" will be found beneath that protozoic or Lower Silurian group in the great inferior mass of which no vertebrated animal has yet been detected, amid the countless profusion of the lower orders of marine animals entombed in it. But however this may be, it is certain that in the last few years all Central and Eastern Europe, and even parts of Siberia, have been brought into accordance with British strata. France has been accurately classified and illustrated by the splendid map of Elie de Beaumont and Dufrenoy; and whilst, by the labours of Deshayes and others, its tertiary fossils have been copiously described, the organic remains of its secondary strata are now undergoing a complete analysis in the beautiful work of M. Alcide d'Orbigny. Belgium, whose mineral structure and geological outlines have been delineated by D'Omalius, d'Halloy and Dumont, has produced very perfect monographs of its palæozoic and tertiary fossils, the first in the work of M. de Koningk, the second in the recently published monograph of M. Nyst. Germany, led on by Von Buch, has shown that she can now as materially strengthen the zoological and botanical groundworks of the science, as in the days of Werner she was eminent in laying those mineralogical foundations which have been brought so near to perfection by the labours of several living men. So numerous in fact have been the contributions of German geologists, that I cannot permit myself to specify the names of individuals in a country which boasts so many who are treading closely in the steps of an Ehrenberg and a Rosè. As distinctly connected, however, with the objects of this meeting, I must be permitted to state that the eminent botanist Gœppert, whose works, in combination with those of Adolphe Brongniart in France, have shed so much light on fossil plants, has just sent to me, for communication to our Geological Section, the results of his latest inquiries into the formation of the coal of Silesia—results which will be the more interesting to Dr. Buckland and the geologists of England, because they are founded on data equally new and original. Italy has also to a great extent been presented to us in its true general geological facies, through the labours of Sismonda, Marmora, Pareto, and others; whilst our kinsmen of the far West have so ably developed the structure of their respective States, that our countrymen Lyell has informed us, that the excellent map which accompanies his work upon North America is simply the grouping together of data prepared by native State geologists, which he has paralleled with our well-known British types.

If then the astronomer has, to a vast extent, expounded the mechanism of the heavens; if lately, through the great telescope of our associate the Earl of Rosse, he has assigned a fixity and order to bodies which were previously viewed as mere nebulæ floating in space, and has also inferred that the surface-cavities in our nearest neighbour of the planetary system are analogous to the volcanic apertures and depressions of the earth; the geologist, contributing data of another order to the great storehouse of natural knowledge, has determined, by absolute and tangible proofs, the precise manner in which our planet has been successively enveloped in divers cerements, each teeming with peculiar forms of distinct life, and has marked the revolutions which have interfered with these successive creations, from the earliest dawn of living things to the limits of the historic æra. In short, the fundamental steps gained in geology, since the early days of the British Association, are so remarkable and so numerous, that the time has now come for a second report upon the progress of this science, which may I trust be prepared for an approaching, if not for the next meeting.

Intimately connected with these broad views of the progress of geology is the appearance of the first volume of a national work by Sir Henry De la Beche and his associates in the "Geological Survey of Great Britain." Following, as it does, upon the issue of numerous detailed coloured maps and sections, which for beauty of execution and exactness of detail are unrivalled, I would specially direct your attention to this new volume as affording the clearest evidence that geology is now strictly brought within the pale of the fixed sciences. In it are found graphic descriptions of the strata in the south-west of England and South Wales, whose breadth and length are accurately measured, whose mineral changes are chemically analysed, and whose imbedded remains are compared and determined by competent palæontologists. The very statistics of the science are thus laid open, theory is made rigourously to depend on facts, and the processes and produce of foreign mines are compared with those of Britain.

When we know how intimately the Director-General of this survey and his associates have been connected with the meetings of the British Association, and how they have freely discussed with us many parts of their researches—when we recollect that the geologist of Yorkshire, our invaluable Assistant General Secretary, around whom all our arrangements since our origin have turned, and to whom so much of our success is due, occupies his fitting place among these worthies—that Edward Forbes, who passed as it were from this association to the Ægean, is the palæontologist of this survey; and again when we reflect, that if this association had not repaired to Glasgow, and there discovered the merits of the survey of the Isle of Arran by Mr. Ramsay, that young geologist would never have become a valuable contributor to the volume under consideration—it is obvious from these statements alone, that the annual visits of our body to different parts of the empire, by bringing together kindred spirits, and in testing the natural capacity of individuals, do most effectually advance science and benefit the British community. Whilst considering these labours of the government geologists, I shall now specially speak of those of Professor E. Forbes in the same volume, because he here makes himself doubly welcome, by bringing to us as it were upon the spot the living specimens of submarine creatures, which through the praiseworthy enthusiasm of Mr. McAndrew, one of our members, who fitted out a large yacht for natural-history researches, have been dredged up this summer by these naturalists from the southern coast, between Land's End and Southampton. As a favourite yachting port like Southampton may, it is hoped, afford imitators, I point out with pleasure the liberal example of Mr. McAndrew, who not professing to describe the specimens he collects, has on this, as on former occasions, placed them in the hands of the members best qualified to do them justice, and is thus a substantial promoter of science.

The memoir of Edward Forbes in the Government Geological Survey is, in truth, an extension of his views respecting the causes of the present distribution of plants and animals in the British Isles, first made known at the last meeting of the British Association. As this author has not only shown the application of these ideas to the researches of the British Geological Survey, but also to the distribution of animals and plants over the whole earth, it is evident that these views, in great part original, will introduce a new class of inquiries into natural history, which will link it on more closely than ever to geology and geography. In short, this paper may be viewed as the first attempt to explain the causes of the zoological and botanical features of any region anciently in connexion. Among the new points which it contains, I will now only mention that it very ingeniously (and I think most satisfactorily) explains the origin of the peculiar features of the botany of Britain—the theory of the origin of Alpine Floras distributed far apart—the peculiarity of the zoology of Ireland as compared with that of England—the presence of the same species of marine animals on the coasts of America and Europe—the specialities of the marine zoology of the British seas called for by this Association—the past and present distribution of the great Mediterranean Flora;—and, lastly, it applies the knowledge we possess of the distribution of plants to the elucidation of the superficial detritus, termed by geologists, the "Northern Drift."

Amid the numerous subjects for reflection which the perusal of this memoir occasions, I must now restrict myself to two brief comments. First, to express my belief that even Humboldt himself, who has written so much and so admirably on Alpine Floras, will admit that our associate's explanation of the origin of identity removes a great stumbling-block from the path of botanical geographers. Secondly, having myself for some years endeavoured to show that the Alpine glacialists had erroneously applied their views, as founded on terrestrial phenomena, to large regions of Northern Europe, which must have been under the sea during the distribution of erratic blocks, gravel, and boulders, I cannot but consider it a strong confirmation of that opinion when I find so sound a naturalist as Edward Forbes sustaining the same view by perfectly independent inferences concerning the migration of plants to isolated centres, and by a studious examination and comparison of all the sea shells associated with these transported materials. And if I mistake not, my friend Mr. Lyell will find in both the above points, strong evidences in support of his ingenious climatical theories. Recent as the blocks and boulders to which I have alluded, may seem to be, they were however accumulated under a glacial sea, whose bottom was first raised to produce that connexion between the Continent and Britain, by which the land animals migrated from their parent East to our western climes; a connexion that was afterwards broken through by the separation of our islands, and by the isolation in each of them of those terrestrial races which had been propagated to it. This latter inference was also indeed thoroughly sustained by the researches of Professor Owen, communicated to this Association: first, in the generalisation by which his report on the extinct mammals of Australia is terminated, and still more in detailed reference to our islands in his recently published work "On the Extinct Fossil British Mammalia"—a work which he has stated in his dedication originated at the call of the British Association. Professor Owen adds, indeed, greatly to the strength of our present meeting, by acting as the president of one of our sections, which having in its origin been exclusively occupied in the study of medicine, is now more peculiarly devoted to the cultivation of physiology. Under such a leader, I have a right to anticipate that this remodelled section will exhibit evidences of fresh vigour, and will clearly define the vast progress that has been made in general and comparative anatomy since the days of Hunter and of Cuvier, for so large a part of which we are indebted to our eminent associate.

Assembled in a county which has the good fortune to have been illustrated by the attractive and pleasing history of the naturalist of Selborne, I am confident that our fourth section, to whose labours I would now specially advert, will yield a rich harvest, the more so as it is presided over by that great zoologist who has enriched the adjacent Museum of the Naval Hospital at Haslar with so many animals from various parts of the world, and has so arranged them to as to render them objects well worthy of your notice. The report of Sir John Richardson in the last volume, on the Fishes of China, Japan, and New Zealand, when coupled with his account in former volumes of the Fauna of North America, may be regarded as having completely remodelled our knowledge of the geographical distribution of fishes; first by affording the data, and next by explaining the causes through which a community of ichthyological characters is in some regions widely spread, and in others restricted to limited areas. We now know, that just as the lofty mountain is the barrier which separates different animals and plants, as well as peculiar varieties of man, so the deepest seas are limits which peremptorily check the wide diffusion of certain genera and species of fishes; whilst the interspersion of numerous islands, and still more the continuance of lands throughout an ocean, ensures the distribution of similar forms over many degrees of latitude and longitude.

The general study, indeed, both of zoology and botany, has been singularly advanced by the labours of the Section of Natural History. I cannot have acted for many years as your General Secretary, without observing, that by the spirit in which this section has of late years been conducted, British naturalists have annually become more philosophical, and have given to their inquiries a more physiological character, and have more and more studied the higher questions of structure, laws, and distribution. This cheering result has mainly arisen from the personal intimacy brought about among various individuals, who, living at great distances from each other, were previously never congregated; and from the mutual encouragement imparted by their interchange of views and their comparisons of specimens. Many active British naturalists have in fact risen up since these meetings commenced, and many (in addition to the examples already alluded to) have pursued their science directly under the encouragement we have given them. The combination of the enthusiastic and philosophic spirit thus engendered among the naturalists has given popularity to their department of science, and this section, assuming an importance to which during our earliest meetings it could show comparatively slender claims, has vigourously revived the study of natural history, and among other proofs of it, has given rise to that excellent publishing body, the Ray Society, which holds its anniversary during our sittings. Any analysis of the numerous original and valuable reports and memoirs on botanical and zoological subjects which have enriched our volumes is forbidden by the limits of this address, but I cannot omit to advert to the extensive success of Mr. H. Strickland's report on Zoological Nomenclature, which has been adopted and circulated by the naturalists of France, Germany and America, and also by those of Italy headed by the Prince of Canino. In each of these countries the code drawn up by the Association has been warmly welcomed, and through it we may look forward to the great advantage being gained, of the ultimate adoption of an uniform zoological nomenclature all over the globe.

Whilst investigations into the geographical distribution of animals and plants have occupied a large share of the attention of our Browns and our Darwins, it is pleasing to see that some of our members, chiefly connected with physical researches, are now bringing these data of natural history to bear upon climatology and physical geography. A committee of our naturalists, to whom the subject was referred, has published in our last volume an excellent series of instructions for the observation of the periodical phenomena of animals and plants, prepared by our foreign associate M. Quetelet, the Astronomer Royal of Belgium. Naturalists have long been collecting observations on the effects produced by the annual return of the seasons, but their various natural history calendars being local, required comparison and concentration, as originally suggested by Linnæus. This has now for the first time been executed by the Belgian Astronomer, who followed out a plan suggested by himself at our Plymouth meeting, has brought together the contributions and suggestions of the naturalists of his own country. When M. Quetelet remarks, "that the phases of the smallest insect are bound up with the phases of the plant that nourishes it; that plant itself being in its gradual development the product, in some sort, of all anterior modifications of the soil and atmosphere," he compels the admission, that the study which should embrace all periodical phenomena, both diurnal and annual, would of itself form a science as extended as instructive.

Referring you to M. Quetelet's report for an explanation of the dependence of the vegetable and animal kingdoms on the meteorology and physics of the globe, and hoping that the simultaneous observations he inculcates will be followed up in Britain, I am glad to be able to announce, that the outline of a memoir on physical geography was some months ago put into my hands by Mr. Cooley, which in a great degree coinciding with the system of M. Quetelet, has ultimately a very different object. M. Quetelet chiefly aims at investigating the dependence of organised bodies on inorganised matter, by observing the periodical phenomena of the former. Mr. Cooley seeks to obtain an acquaintance with the same phenomena for the sake of learning and registering comparative climate as an element of scientific agriculture. Speaking to you in a county which is so mainly dependent on the produce of the soil, I cannot have a more favourable opportunity for inculcating the value of the suggestions of this British geographer. The complete establishment of all the data of physical geography throughout the British Islands; i. e. the registration of the mean and extremes of the temperature of the air and of the earth; the amount of conduction, radiation, moisture, and magnetism; the succession of various phases of vegetation, &c. (with their several local corrections for elevation and aspect), must certainly prove conducive to the interests of science, and are likely to promote some material interests of our country.

A minute knowledge of all the circumstances of climate cannot but be of importance to those whose industry only succeeds through the co-operation of nature, and it may therefore be inferred that such a report as that with which I trust Mr. Cooley will favour us, if followed up by full and complete tables, will prove to be a most useful public document. Imbibing the ardour of that author, I might almost hope that such researches in physical geography may enable us to define, in the language of the poet,

"Et quid quæque ferat regio, et quid quæque recuset."

At all events, such a report will tend to raise physical geography in Britain towards the level it has attained in Prussia under the ægis of Humboldt and Ritter, and by the beautiful maps of Berghaus.

Though our countryman, Mr. Keith Johnston, is reproducing, in attractive forms, the comparative maps of the last-mentioned Prussian author, much indeed still remains to be done in Britain, to place the study of physical geography on a basis worthy of this great exploring and colonising nation; and as one of the highly useful elementary aids to the training of the youthful mind to acquire a right perception of the science, I commend the spirited project of a French geographer, M. Guerin, to establish in London, a geoarma of vast size which shall teach by strong external relief, the objects and details of which he will in the course of this week explain to the geographers present.

Reverting to economical views and the improvement of lands, I would remind our agricultural members, that as their great practical Society was founded on the model of the British Association, we hope they will always come to our Sections for the solution of any questions relating to their pursuits to which can be given a purely scientific answer. If they ask for the explanation of the dependence of vegetation upon subsoil or soil, our geologists and botanists are ready to reply to them. Is it a query on the comparison of the relative value of instruments destined to economise labour, the mechanicians now present are capable of answering it. And if, above all, they ask us to solve their doubts respecting the qualities of soils and the results of their mixtures, or the effects of various manures upon them, our chemists are at hand. One department of our Institution is in fact styled the Section of Chemistry and Mineralogy, with their applications to Agriculture and the Arts, and is officered in part by the very men, Johnston, Daubeny, and Playfair, to whom the agriculturists have in nearly all cases appealed. The first mentioned of these was one of our earliest friends and founders; the second had the merit of standing by the British Association at its first meeting, and there inviting us to repair to that great University where he is so much respected, and where he is now steadily determining, by elaborate experiments, the dependence of many species of plants on soils, air, and stimulus; whilst the third has already been alluded to as one of our best contributors.

If in reviewing our previous labours I have endeavoured to gain your attention by some incidental allusions to our present proceedings, I have yet to assure you, that the memoirs communicated to our secretaries are sufficiently numerous to occupy our sections during the ensuing week with all the vigour which has marked our opening day. Among the topics to which our assembling at Southampton gives peculiar interest, I may still say that if foreign and English geologists should find much to interest them in the Isle of Wight, the same island contains a field for a very curious joint discussion between the mathematicians and the geologists, with which I became acquainted in a previous visit to this place. It is a discovery by Colonel Colby, the Director of the Trigonometrical Survey, of the existence of a considerable attraction of the plumb-line to the south, at the trigonometrical station called Dunnose, on Shanklin Down. The details of this singular phenomenon, which has been verified by numerous observations with the best zenith sectors, will be laid before the Sections. In the meantime, we may well wonder that this low chalk range in the Isle of Wight should attract, in one parallel at least, with more than half the intensity of the high and crystalline mountain of Schehallion in the Highlands of Scotland, whilst no other chalk hill in the South of England exhibits such a phenomenon. Can those of our associates, who like Mr. Hopkins have entered the rich field of geological dynamics, explain this remarkable fact, either by the peculiar structure and distribution of the ridge of upheaved strata which runs as a back-bone from east to west through the island, or by referring it to dense plutonic masses of rock ranging beneath the surface along the line of displacement of the deposits?

The Southampton Well.

Another local subject—one indeed of positive practical interest—that stands before us for discussion is, whether, by persevering in deepening the large shaft which they have sunk so deep into the chalk near this town, the inhabitants of Southampton may expect to be eventually repaid, like those of Paris, by a full supply of subterranean water, which shall rise to the surface of the low plateau on which the work has undertaken? On no occasion, I must observe, could this town be furnished with a greater number of willing counsellers of divers nations whose opinions will, it is hoped, be adequately valued by the city authorities. The question whether this work ought to be proceeded with or not, will however, I apprehend, be most effectively answered by those geologists who are best acquainted with the sections in the interior of this country, and with the levels at which the upper greensand and subcretaceous strata there crop out and receive the waters, which then flow southwards beneath the whole body of chalk of the hills in the south of Hampshire.

Naval Architecture.

Considering that we are now assembled in the neighbourhood of our great naval arsenal—that some of its functionaries, including the Admiral on the station, have honoured us with their support, and that, further, I am now speaking in a town whose magnificent new docks may compete with any for bold and successful engineering, I must say a few words on our naval architecture, the more so as we have here a very strong Mechanical Section, presided over by that ingenious mechanician Professor Willis, supported by that great dynamical philosopher and astronomer Dr. Robinson. Duly impressed with the vast national importance of this subject, and at the same time of its necessary dependence on mathematical principles, the British Association in its earliest days endeavoured to rouse attention to the state of ship-building in England, and to the history of its progress in France and other countries, through a memoir by the late Mr. G. Harvey. It was then contended, that notwithstanding the extreme perfection to which the internal mechanism of vessels had been brought, their external forms or lines, on which their sailing so much depends, were deficient as to adjustment by mathematical theory. Our associate Mr. Scott Russell has, as you know, ably developed this view. Experimenting upon the resistance of water, and ascertaining with precision the forms of vessels which would pass through it with the least resistance, and consequently with the greatest velocity, he has contributed a most valuable series of memoirs, accompanied by a great number of diagrams, to illustrate his opinions and to show the dependence of naval architecture on certain mathematical lines. Employed in the meantime by merchants on their own account, to plan the construction of sailing ships and steamers, Mr. Scott Russell has been so successful in combining theory with practice, that we must feel satisfied in having at different meetings helped him onwards by several money grants; our only regret being that our means should not have permitted us to publish the whole number of diagrams of the lines prepared by this ingenious author.

But however desirous to promote knowledge on this point, the men of science are far from wishing not to pay every deference to the skilful artificers of our wooden bulwarks, on account of their experience and practical acquaintance with subjects they have so long and so successfully handled. We are indeed fully aware that the naval architects of the government, who construct vessels carrying a great weight of metal, and requiring much solidity and capacious stowage, have to solve many problems with which the owners of trading vessels or packets have little concern. All that we can wish for is, that our naval arsenals should contain schools or public boards of ship-building, in which there might be collected all the "constants of the art," in reference to capacity, displacement, stowage, velocity, pitching and rolling, masting, the effect of sails, and the resistance of fluids. Having ourselves expended contributions to an extent which testify, at all events, our zeal in this matter, we are, I think, entitled to express a hope, that the data derived from practice by our eminent navigators may be effectively combined with the indications of sound theory prepared by approved cultivators of mathematical and mechanical science.

Statistics.

I cannot thus touch upon such useful subjects without saying, that our Statistical Section has been so well conducted by its former presidents, that its subjects, liable at all times to be diverted into moral considerations, and thence into politics, have been invariably restricted to the branch of the science which deals in facts and numbers: and as no one individual has contributed more to the storehouse of such valuable knowledge than Mr. George Porter (as evidenced even by his report in our last volume), so may we believe that in this town with which he is intimately connected, he will contribute to raise still higher the claims of the section, over which he is so well qualified to preside.

If in this discourse I have referred more largely to those branches of science which pertain to the general division of natural history, in which alone I can venture to judge of the progress which others are making, let me however say, that no member of this body can appreciate more highly than I do, the claims of the mathematical and experimental parts of philosophy, in which my friend Professor Baden Powell, who supports me on this occasion as a Vice-President, has taken so distinguished a part. No one has witnessed with greater satisfaction the attendance at our former meetings of men from all parts of Europe the most eminent in these high pursuits. No one can more glory in having been an officer of this Association when it was honoured with the presence of its illustrious correspondent Bessel, than whom the world has never produced a more profound astronomer. If among his numerous splendid discoveries he furnished astronomers with what they had so long and so ardently desired—a fixed and ascertained point in the immensity of space, beyond the limits of our own sidereal system, it is to Bessel, as I am assured by a contemporary worthy of him, that Englishmen owe a debt of gratitude for his elaborate discussion of the observations of their immortal Bradley, which, in his hands, became the base of modern astronomy.

Foreign Contributors.

Passing from this recollection, so proud yet so mournful to us all as friends and admirers of the deceased Prussian astronomer, can any one see with more delight than myself the brilliant concurrence at our present meeting of naturalists, geologists, physiologists, ethnologists, and statists, with mathematicians, astronomers, mechanicians, and experimental philosophers in physics and in chemistry? Surely, then, I may be allowed to signalise a particular ground of gratification among so many, in the presence at this meeting of two individuals in our experimental sections, to one of whom, our eminent foreign associate, Oersted, we owe the first great link between electric and magnetic phenomena, by showing the magnetic properties of the galvanic current; whilst the other, our own Faraday, among other new and great truths which have raised the character of English science throughout the world, obtained the converse proof by evoking electricity out of magnets. And if it be not given to the geologist whom you have honoured with this chair, to explain how such arcana have been revealed, still as a worshipper in the outer portico of the temple of physical science, he may be permitted to picture to himself the delight which the Danish philosopher must have felt when, on returning to our shores, after an absence of a quarter of a century, he found that the grand train of discovery of which he is the progenitor, had just received its crowning accession in England from his former disciple, who, through a long and brilliant series of investigations peculiarly his own, has shown that magnetic or dia-magnetic forces are distributed throughout all nature.

And thus shall we continue to be a true British Association, with cosmopolite connexions, so long as we have among us eminent men to attract such foreign contemporaries to our shores. If then at the last assembly we experienced the good effects which flowed from a concentration of profound mathematicians and magneticians, drawn together from different European kingdoms—if then also the man (Mr. Everett) of solid learning, who then represented the United States of America, and who is now worthily presiding over the Cambridge University of his native soil, spoke to us with chastened eloquence of the benefits our institution was conferring on mankind; let us rejoice that this meeting is honoured by the presence of foreign philosophers as distinguished as those of any former year.

Let us rejoice that we have now among us men of science from Denmark, Sweden, Russia, Prussia, Switzerland, Belgium, Italy, and France. The King of Denmark, himself personally distinguished for his acquaintance with several branches of natural history, and a warm patron of science, has honoured us by sending hither, not only the great discoverer Oersted, who evincing fresh vigour in his mature age, brings with him new communications on physical science, but also my valued friend, the able geologist and chemist Forchhammer, who has produced the first geological map of Denmark, and who has presented to us a lucid memoir on the influence exercised by marine plants on the formation of ancient crystalline rocks, on the present sea, and on agriculture.

As these eminent men of the north received me as the General Secretary of the British Association with their wonted cordiality at the last Scandinavian Assembly, I trust we may convince them, that the sentiment is reciprocal, and that Englishmen are nearly akin to them in the virtues of friendship and hospitality which so distinguish the dwellers within the circle of Odin.

Still adverting to Scandinavia, we see here a deputy from the country of Linnæus in the person of Professor Svanberg, a successful young experimenter in physics, who represents his great master, Berzelius—that profound chemist and leader of the science of the North of Europe, who established on a firm basis the laws of atomic weights and definite proportions, and who has personally assured me, that if our meeting had not been fixed in the month of September, when the agriculturists of Sweden assemble at Stockholm, he would assuredly have repaired to us. And if the same cause has prevented Nilsson from coming hither, and has abstracted Retzius from us (who was till within these few days in England), I cannot mention these distinguished men, who earnestly desired to be present, without expressing the hope that the memoirs they communicate to us may give such additional support to our British ethnologists as will enable this new branch of science, which investigates the origin of races and languages, to take the prominent place in our assemblies to which it is justly entitled.

The Royal Academy of Berlin, whose deputies on former occasions have been an Ehrenberg, a Buch, and an Erman, has honoured us by sending hither M. Heinrich Rose, whose work on chemical analysis is a text-book even for the most learned chemists in every country; and whilst his researches on the constitution of minerals, like those of his eminent brother Gustave on their form, have obtained for him so high a reputation, he now brings to us the description of a new metal which he has discovered in the Tantalite of Bavaria.

Switzerland has again given to us that great master in palæontology, Agassiz, and also our old friend Professor Schonbein, who in addition to his report on ozone, to which I have already referred, has now brought to us a discovery of vast practical importance. The "gun-cotton" of Schonbein, the powers of which he will exhibit to his colleagues, is an explosive substance, which, exercising a stronger projectile force than gunpowder, is stated to possess the great advantages over it of producing little or no smoke or noise, and of scarcely soiling fire-arms; whilst no amount of wet injures this new substance, which is as serviceable after being dried as in its first condition. The mere mention of these properties, to which our associate lays claim for his new material, is sufficient to show its extraordinary value in all warlike affairs, as also in every sort of subterranean blasting.

Professor Matteucci of Modena, who joined us at the York meeting, and then explained his various new and delicate investigations in electro-physiology, again favours us with a visit, as the representative of the Italian Philosophical Society of Modena and of the University of Pisa. This ingenious philosopher, who has measured the effect of galvanic currents in exciting through the nerves mechanical force in the muscles, doubtless brings with him such interesting contribution as will add great additional interest to the proceedings of the Physiological Section.

Having already spoken of the rapid progress which the sciences are making in Belgium, through the labours of our associate Quetelet and others, it is with pleasure I announce that M. de Koningk, the palæontologist, who has mainly contributed to this advance and to the solid foundation of the geology of his country by his excellent work on palæozoic fossils, has been sent to us by his own government.

Among these sources of just pride and gratification, no one has afforded me sincerer pleasure than to welcome hither the undaunted Siberian explorer, Professor von Middendorf. Deeply impressed as I am with the estimation in which science is held by the illustrious ruler of the empire of Russia, I cannot but hope that the presence of this traveller, so singularly distinguished for his enterprising exploits, may meet with a friend in every Englishman who is acquainted with the arduous nature of his travels. To traverse Siberia from south to north, and from west to east; to reach by land the extreme northern headland of Taimyr; to teach us, for the first time, that even to the latitude of 72 deg. north, trees with stems extend themselves in that meridian; that crops of rye, more abundant than in his native Livonia, grow beyond Yakutak, on the surface of that frozen subsoil, the intensity and measure of cold in which he has determined by thermometric experiments, to explain, through their language and physical form, the origin of tribes now far removed from their parent stock; to explore the far eastern regions of the sea of Okhotsk and of the Shantar Isles; to define the remotest north-eastern boundary between China and Russia; and finally to enrich St. Petersburgh with the natural productions, both fossil and recent, of all these wild and untrodden lands, are the exploits for which the Royal Geographical Society of London has, at its last meeting, conferred its Gold Victoria Medal on this most successful explorer. Professor Middendorf now visits us to converse with our naturalists most able to assist him, and to inspect our museums, in which, by comparison, he can best determine the value of specific characters before he completes the description of his copious accumulations; and I trust that during his stay in England he will be treated with as much true hospitality as I have myself received at the hands of his kind countrymen.

It is impossible for me to make this allusion to the Russian empire without assuring you that our allies in science on the Neva, who have previously sent to us a Jacobi and Kupffer, are warmly desirous of continuing their good connexion with us. It was indeed a source of great pleasure to me to have recently had personal intercourse in this very town with that eminent scientific navigator Admiral Lutke, in whose squadron his Imperial Highness the Grand Duke Constantine was acquiring a knowledge of his maritime duties. Besides the narrative of his former voyages, Lutke has since published an account of the periodical tides in the Great Northern Ocean and in the Glacial Sea, which I have reason to think is little known in this country. Having since established a "hypsalographe" in the White Sea, and being also occupied from time to time in observations in Behring's Straits, the Russians will soon be able to provide us with other important additions to our knowledge of this subject. Separated so widely as Admiral Lutke and Dr. Whewell are from each other, it is pleasing to see, that the very recommendation which the last-mentioned distinguished philosopher of the tides has recently suggested to me, as a subject to be encouraged by this Association, has been sealously advocated by the former. Let us hope then that this meeting will not pass away without powerfully recommending to our own government, as well as to that of his Imperial Majesty, that a systematic and simultaneous investigation of the tides in the Great Ocean, particularly in the Northern Pacific, be the object of special expeditions,—a subject (as Admiral Lutke well observes) which is not less worthy of the attention of great scientific bodies than the present inquiries into terrestrial magnetism; and one which, I may add, this Association will doubtless warmly espouse, since it has such strong grounds for being satisfied with the results which it has already contributed to obtain through its own grants, and by the researches of several of its associates.

Lastly, in alluding to our foreign attendants, let me say how well our nearest neighbours have responded to our call, who, imitating the example of their enlightened monarch, have proved by their affluence to Southampton, that in the realms of science, as in public affairs, there is that "entente cordiale" between their great nation and our own, of which, at a former meeting, we were personally assured by the profound Arago himself.

No sooner was it made known that the chair of chemistry at this meeting was to be filled by Michael Faraday, than a compeer worthy of him in the Academy of Sciences of Paris was announced in the person of M. Dumas. To this sound philosopher it is well known that we owe, not only the discovery of that law of substitution of types, which has so powerfully aided the progress of organic chemistry, but also the successful application of his science to the arts and useful purposes of life; his great work on that subject, "La Chimie appliquée aux Arts," being as familiar in every manufactory in England as it is upon the Continent.

Nor, if we turn from chemistry to geology, can such of us as work among the rocks be backward in our expressions of thankfulness, in witnessing the goodly attendance of our brethren of the hammer from France, headed by M. ———, who have come to examine, in our own natural sections of the Isle of Wight, the peculiar development of their Paris basin, the identity of their chalk and our own, the fine sections of our green sand and of the Wealden formation of Mantell, and to determine with us "in situ" the strict relations of their Neocomian rocks with those peculiar strata which at Atherfield, in the Isle of Wight, have been so admirably illustrated by Dr. Fitton and other native geologists, and of which such beautiful and accurate diagrams have been made by Captain Ibbotson.

It is utterly impossible that such gatherings together of foreign philosophers with our own should not be productive of much advantage; for he must indeed be a bad statist in science who knows not that numerous are the works of merit which are published in periodicals, or in the volumes of societies of one country, which remain altogether unknown in another; and still less can be acquainted with the present accelerated march of science, who is not aware that the germs of discovery which are lying ready in the minds of distant contemporaries must often be brought into action by such an interchange of thought. The collision of such thoughts may indeed be compared to the agency of the electric telegraph of our Wheatstone, which concentrates knowledge from afar, and at once unites the extremities of kingdoms in a common circle of intelligence.

But although the distinguished foreigners to whom I have adverted, and others, including our welcome associate M. Wartmann, the founder of the Vaudois Society, and M. Prevost, of Geneva, on whose merits I would willingly dilate if time permitted it, are now collected around us; many, among whom I must name M. de Caumont, the President of the French Society for the advancement of Science, have been prevented from honouring us with their presence, because the national meetings in their several countries also occur in the month of September. To remedy this inconvenience, I ventured, when addressing you six years ago at the Glasgow meeting, to express the hope, that each of the national European societies might be led to abstain during one year from assembling in its own country, for the purpose of repairing by its own deputies to a general congress, to be held at Frankfort or other central city under the presidency of the universal Humboldt. Had the preparation of the "Cosmos," and other avocations of that renowned individual permitted him to accept this proposition, which I have every reason to believe the British Association would have supported, I am convinced that many benefits to science would have resulted, and that each national body, on re-assembling the following year in its native land, would have more vigorously resumed its researches.

Adhering still to my project, I beg my countrymen and their foreign friends now present, to sustain this proposition for centralising in a future year the representatives of the various branches of science of different countries, when they may at once learn the national progresses respectively made, and when, at all events, they can so appoint the periods of their national assemblies as to prevent those simultaneous meetings in France, Germany, Scandinavia, Italy, Switzerland and England, which are so much to be deprecated as interfering with a mutual intercourse.

Finally, my fellow-labourers in science, if by our united exertions we have done and are doing good public service, let me revert once more to the place in which we are assembled, and express on your part the gratification I know you experience in being on this occasion as well supported by the noblemen, clergymen, and landed proprietors around Southampton, as by its inhabitants themselves—an union which thus testifies that the British Association embraces all parties and all classes of men.

Seeing near me Her Most Gracious Majesty's Secretary of State for Foreign Affairs, the Speaker of the House of Commons, and other persons of high station and very great influence, who willingly indicate by their presence the sense they entertain of the value of our conferences and researches, let us welcome these distinguished individuals as living evidences of that good opinion of our countrymen, the possession of which will cheer us onward in our career. And above all, let us cherish the recollection of the Southampton meeting which will be rendered memorable in its annals by the presence of the illustrious Consort of our beloved Sovereign, who participating in our pursuits, in many branches of which his Royal Highness is so well versed, thus demonstrates that our association is truly national, and enjoys the most general and effectual support throughout British society, from the humblest cultivators of science to the highest personages in the realm.

Royal Naval Steam-yard, Plymouth.—The total acres of ground to be included in the establishment at Morice Town, is about 75 acres. The contractors have now employed on the works 750 men, 110 horses, 3 steam-engines, with 12 miles of railway. 630,000 cubic feet of stone (granite and lime-stone) are on the ground, and they are working seven of the principle quarries of the country. The works will go forward with the greatest rapidity, and it is expected that a steamer will be admitted into one of the basins within three years and a half from this time. The coffer dam, which the enterprising contractors, Messrs. Baker and Son, have undertaken on their own responsibility, is 2,000 feet long, within which the seawall of the same length is to be built. There will be two immense basins, the north basin, 650 feet by 625 feet, and the south basin, 625 feet by 560 feet, each having a depth of 27 feet of water at all times, and will allow of 18 first-class vessels to be fitted out, or 25 of all classes, exclusive of those in the docks. The two basins contain 16 acres. There will be three large docks; one (the north dock) 360 feet long by 94 feet wide for first-rates; another 406 feet long by 82 feet wide, for the largest steamers; and the third (the south dock) 300 feet long by 82 feet wide.

REVIEW.

Experimental Researches on the Strength and other Proportions of Cast Iron. By Eaton Hodgkinson, F.R.S. London: Weale, 1846. 8vo. pp. 200. Five plates.

The first part of this work which is a new edition of Tredgold's Treatise with additional notes by Mr. Hodgkinson, appeared in 1842; the second part now before us is entirely written by Mr. Hodgkinson, and though it is published as a separate volume, the pagination is continued on from the preceding one. The principal distinction between the two works is that the former treated of the effects produced upon bodies by forces small compared with those necessary to produce fracture, whereas the present volume refers almost exclusively to the ultimate strength of cast iron, or the capability of resisting fracture.

The subject is divided into four parts, the strength to resist, 1st, longitudinal tension; 2nd, longitudinal compression; 3rd, transverse pressure (the case of girders); 4th, tension; the course of experiments under each head is explained at length, and the results tabulated: a mathematical investigation of the theory of the strength of beams is also given.

The first part of the work which considers the tenacity of cast iron occupies but a small space, as the subject offers comparatively little difficulty to the experimenter—the following concluding remarks will sufficiently show the nature of the results.

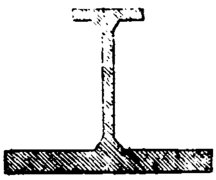
"With these facts before the reader, he will, I conceive, be unable to see how the mean tensile strength of cast iron can properly be assumed at more than 7 or 7½ tons per square inch; but some of our best writers have, by calculating the tensile strength from experiments on the transverse, arrived at the conclusion that the strength of cast iron is 10, or even 20 tons, or more. Mr. Barlow conceives it to be upwards of 10 tons (Treatise on Strength of Timber, Cast Iron, &c., p. 222), and Mr. Tredgold makes it at least 20 (art. 72 to 76). The reasoning of Mr. Tredgold, by which he arrives at this erroneous conclusion, with others resulting from it, will be examined at length under the head 'Transverse Strength.' Navier, too, (Application de la Mécanique, article 4,) calculates the tensile strength of cast iron from principles somewhat similar to those assumed by Tredgold, and finds it much too high."

In considering longitudinal compression the experiments are divided into two classes, those upon long and those on short pillars, as the former usually broke by bending, and the latter by crushing; and consequently the laws for the two cases widely differ. Under this head we find the following interesting results.

"The strength of a pillar in the form of the connecting rod of a steam engine was found to be very small; indeed, less than half the strength that the same metal would have given if cast in the form of an uniform hollow cylinder. The ratio of the strength, according to my experiments, was 17578 to 39645. A pillar irregularly fixed, so that the pressure would be in the direction of the diagonal, is reduced to one-third of its strength, the case being nearly similar to that of a pillar with rounded ends, the strength of which has been shown to be only ⅓rd of that of a pillar with flat ends. Tredgold, art. 283 of his work on Cast Iron, and in his Treatise on Carpentry, following the idea of Serlio in his Architecture, recommends circular abutting joints, to lessen the effect of irregularity in the strains upon columns, from settlements and other causes; but this, we see, is voluntarily throwing away two-thirds of the full strength of the material to prevent what may often be avoided."

The question of transverse strength occupies the greater part of the book. The first point ascertained is how far bars of cast iron will bear the long continued pressure of weights which are not sufficient to break them immediately. The effect of temperature and defect of elasticity are next considered, and lastly the general laws of the transverse strength of beams. The experiments instituted are extremely numerous, the results tabulated are derived from researches extending over a great number of years, and are of course invaluable. The information given with respect to bars of rectangular section is so full and complete as to almost exhaust the subject; when however Mr. Hodgkinson investigates the strength of beams varying in their rectangular section, and endeavours to ascertain the form of uniform strength, he leaves room for further inquiries. Before commenting on this most important part of the subject, we must let our author explain for himself the mode of investigation which he has adopted.

"The ribs in the model were first made equal, as in the beam of strongest form according to the opinion of Mr. Tredgold (Section IV., art. 37); and when a casting had been taken from it, a small portion was taken from the top rib, and attached to the edge of the bottom one, so as to make the ribs as one to two; and when another casting had been obtained, a portion more was taken from the top, and attached to the bottom, as before, and a casting got from it, the ribs being then as one to four. In these alterations the only change was in the ratio of the ribs, the depth and every other dimension in the model remaining the same. Finding that all these beams had been broken by the bottom rib being torn asunder, and that the strength by each change was increased, I had the bottom rib successively enlarged, the size of the top rib remaining the same. The bottom rib still giving way first, I had the top rib increased, feeling that it might be too small for the thickness of the middle part between the ribs. The bottom rib was again increased, so that the ratio of the strengths of the bottom and top ribs was greater than before; still the beam broke by the bottom rib failing first, as before. As the strength continued to be increased more than the area of the section, though the depth of the beam and the distance between the supports remained the same, I pursued, in the future experiments, the same course, increasing by small degrees the size of the ribs, particularly that of the bottom one, till such time as that rib became so large that its strength was as great as that of the top one, or a little greater, since the fracture took place by a wedge separating from the top part of the beam. I here discontinued the experiments of this class, conceiving that the beams last arrived at, were in form of section nearly the strongest for cast iron."



The form of the strongest section thus ascertained was, as shown in the adjoined diagram; the ratio of the sectional area of the top and bottom was as 1 : 6; so greatly does the compressive strength of cast iron exceed its tenacity. The depth of this beam was uniform throughout. but thickness lessened towards each end, so that the *plan* of each flange was lens-shaped, the curves being portions of a parabola. This form has been shown theoretically to be that which makes a beam of uniform depth equally strong in every part.

The omissions in Mr. Hodgkinson's inquiry, or rather the subjects in which he has left room for further inquiry, appear two-fold. In the first place, the object of his experiment was confined almost entirely to ascertaining the proper proportion of the two flanges to each other; and secondly, the flanges were always thin, compared with their width, and of a rectangular section. The proper form and dimensions of the vertical rib, seem to have been comparatively neglected; and it was not ascertained whether for a given quantity of material, additional strength might not be attained by making the bottom flange *of greater vertical depth in proportion to its width.*

The strongest beam is that of uniform strength, or that which when it tends to break has that tendency in every part; consequently the best form is that for which the beam tends to give way in both flanges, and the vertical rib simultaneously. Moreover, the tendency to give way must be equally exhibited in every part of each of these members: the beam when the load is placed at its centre, must not tend to give way sooner in the middle than towards the ends, nor to fail in the flanges sooner than in the rib. Now Mr. Hodgkinson's beams always broke in the middle, and the failure was always in one of the flanges.

It is a great mistake to suppose that the vertical rib ought to be as thin as possible. Where nearly the whole strength is contained in the flanges, the rib need not usually possess much strength towards the centre, but it ought to be increased in strength towards the extremities; and the law of increase has been clearly shown in a former page of this Journal (*ante* p. 174). The consideration of the exact nature of the forces acting on the vertical rib, seems to have been overlooked in our theoretical books; and it ought to be made the subject of an altogether new class of experiments.

The next question on which it appears to us further experiments are wanted, relates to the possibility of improving the sectional form of the flanges themselves. It has been usually considered that they ought to be two thin wide laminæ, and the object for adopting this form is, that the material may have the greatest possible leverage about the neutral axis. Mr. Hodgkinson evidently falls in with this notion, which, as we think, arises from erroneous conceptions of the action of the vertical rib. We are strongly inclined to pronounce the bottom flange in the section given above, *too thin for its width*, It does not seem very hazardous to predict that, all other things remaining the same, the strength would be greatly increased by doubling the thickness of this flange.

It seems clear that the part of the metal in the immediate neighbourhood of the vertical rib will be more acted upon than the outer or more projecting parts of the flange. These are comparatively inefficient; for to suppose that all parts of the flange, because nearly at the same distance from the neutral line, therefore exert the same elastic force—what is this but assuming in another form the old exploded notion of the incompressibility or inextensibility of the material? The parts projecting the greatest distance beyond the vertical rib will be least acted upon, and consequently the great object ought to be to collect the material of the flanges as closely about the upper and lower edges of the rib as is compatible with other considerations. Under this head also new experiments might be advantageously instituted.

In the theoretical investigation of the transverse strength of beams, Mr. Hodgkinson does not adopt the theory of John Bernoulli, Mariotte, Prof. Moseley, and others, that the elastic forces of the fibres are proportional to their distance from the neutral axis, but represents those forces by an expression $ax-\phi(x)$ *where* $\phi(x)$ is "a function representing the diminution of the force in consequence of the defect of elasticity." He is disposed to conclude from experiment that for cast iron this function would be of the form bx^2.

The present treatise shows clearly enough that the old assumption leads to erroneous results. We may furnish the following proof in addition to those given by him. We recently had the curiosity to apply the formulæ given by Professor Moseley (p. 507 & 513) for the deflection of beams to several cases of the experiments relative to the Menai Bridge, detailed in this Journal, p. 147, and found the deflections so calculated six or seven times as great as those actually observed. This seems to us quite sufficient proof that the old theory is not to be trusted; it is indeed founded on an assumption which it would be very difficult to prove, that the centre of curvature for all the filaments of the beam, and for the bounding surfaces, coincides with the centre of curvature of the neutral line.

But although Mr. Hodgkinson has probably made an improvement in the theory in the particular here alluded to, we by do means assent to one of the assumptions on which this theory proceeds, namely, that the parts of the section will be extended or compressed according to their distance from the neutral. We think that enough has been said to show that the bottom flange cannot be in a state of uniform tension throughout at equal distances from the neutral axis. At all events this ought to be proved before it is assumed.

It should be mentioned that the works before us contains a large portion of the results already communicated in reports to the British Association. The theory of the strength of materials is daily assuming a more complete form; in fact there is scarcely any branch of the philosophy of engineering of which so much is known. The subject is one which has been illustrated by the splendid talents of Euler, Bernouilli, and many others of almost equal celebrity: but the merit must undoubtedly be awarded to Mr. Hodgkinson, of having *realised* the investigations, and of having given to them that certainty and method which alone can render them useful to the practical engineer.

WILLIAM OF WYKEHAM.

The annual volume of the Archæological Institute is just published. It refers almost exclusively to the architecture of Winchester. The following extract, from a paper by Mr. Cockerell, will show that we are not singular in our notions of the necessity of faithfulness in architecture. The extract refers to the artistic merits of one who, if worthier notions of the fundamental principles of art were generally entertained, would be esteemed incomparably the greatest of English architects:—

"The chief expression of Wykeham's architecture is its constructive character; throughout we trace the sound builder, the able mason, the ingenious carpenter, whose well-designed operations satisfying the mind, carry with it the fancy, by natural consequence, in harmonious consent; and an unsought felicity follows as a matter of course. He wrought out his design through the model, and an intimate knowledge of the materials. and careful consideration of the wants and requirements on the spot. His cornices and labels and water tables explain their purposes of carrying off the wet; the buttresses are never for ornament alone, but proportioned to the support and durability of the edifice. No parasitical excrescences obtrude themselves ostentatiously, no parts and prettinesses are indulged which may not be accounted for by a natural grace and logical fitness. . . . . . He was one of the first to recognise the utility of the four-centred arch, and to employ its depressed form where a superincumbent floor made it convenient. It is probable that he did not encourage that fashionable adoption of it, which introduced it (under Edgington, his predecessor in the see of Winchester) into the cathedral itself, for we find uniformly the two-centred arch in his halls and chapels; while the four-centred was confined to situations of limited elevation. He was one of the first to condemn the tenuity, elongation, and weakness, real and apparent, of the Lancet and Decorated style, and to introduce the so-called Perpendicular, which, fortified by its mullions or constructive subdivision of skeleton framing, or network, the enormous openings then demanded by the growing fashion of fenestral decoration; as Chaucer says,

richly peint
With lives of many divers seint.

He abandoned the high-pitched shingle roofs, excluding sun and air, and was one of the first to employ the low pediment, and roof covered with lead; and in his works we first discover the hammer-beam roof in all its varieties—a system of the highest ingenuity and constructive economy, both for space and material, as well as beauty and power, as exhibited in Westminster Hall, Eltham Palace, Windsor Hall, and our college chapels and halls.

BARKER'S MILL.

Sir—Perhaps through your valuable journal you would be kind enough to decide the following argument:—*Doctor Barker's Mill.* One gentleman argues "that the power is obtained by the resistance of the atmosphere to the egress of the water, thereby causing a reaction."

The other gentleman denies such to be the cause, and says, "that it would revolve with greater power if placed in vacuum." Leaving it for you to decide, with many apologies. I remain, Sir, your obedient servant,

A Constant Reader.

In Barker's Mill the supply of water is obtained from a cistern placed at a considerable height above the revolving tubes or arms, which, if the orifices of them were stopped, would sustain a hydrostatic pressure acting equally in all directions, and proportioned to the depth below the surface of the water in the reservoir. When, however, the orifices are opened, there is, in each revolving tube, a predominating pressure on one side of it; for it is clear that the internal area of one side of the tube exceeds that of the other sides by a quantity equal to the area of the orifice.

The motion is in the direction of that side of the tube which sustains the greatest pressure. The external air is a cause rather of retardation than acceleration, on account of its resistance to each arm on the side opposite to the orifice. It may be easily conceived that if the atmospheric pressure accelerated the motion, an increase of that pressure would increase the accelerating force. If this view were correct, the arms ought to revolve more rapidly if immersed in mercury, which certainly would not be the case.

Very similar to Barker's mill in its mode of action is the rocket used in pyrotechny and for military purposes. Here the ignited powder generates an elastic gas, which presses on one end of the chamber containing it, but escapes by the open end; the motion is, of course, in the direction of the end subjected to the elastic pressure. The external air tends to retard the escape of the gas, and, to a certain extent, increases its pressure by partially confining it; but the accelerating force so gained is far more than compensated for by the resistance which the air acting on the external surface of the rocket offers to the motion—a resistance varying nearly in the square of the velocity.

The revolving steam-machine of Hero, of Alexandria, is another instance of the application of the same mechanical principles as those of Barker's Mill.

The apology with which our correspondent concludes his note is quite unnecessary; we know no better way of serving the interests of our subscribers than by considering questions like the present as they arise, and contributing as far as we can to the solution of them.

ST. MICHAEL HEAVITREE.

Mr. Editor—In this month's Journal, at p. 291, under the head of St. Michael Heavitree, is a small paragraph relative to the new church there, which was designed by me, and executed under my sole superintendance. The paragraph is altogether erroneous; and how it could have crept into your paper, generally so accurate, I am a loss to think. Who Mr. Alexander is I cannot think, no such a person was ever in any way connected with the matter. Will you please in your next number to correct this. If you can find, next month, space for a few concise particulars relative to the church, which is a large one, and esteemed highly in this city, you would oblige, and I would with pleasure send them.

Your very faithful Servant,
David Mackintosh, Architect.

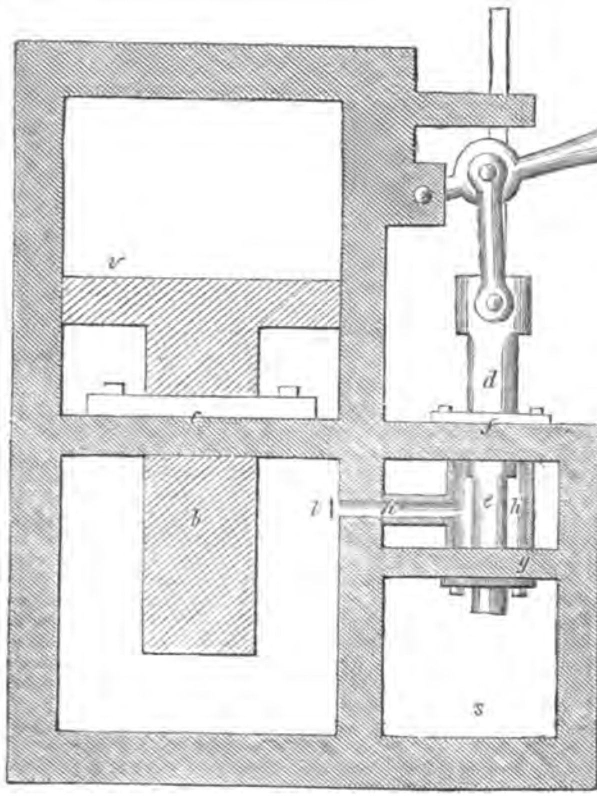
Exeter, Sept. 2, 1846.

For the following additional particulars we are indebted to Mr. Mackintosh, who has forwarded them at our request:—

This church has been rebuilt on an extensive scale, and in a most substantial and permanent manner. The style is that of the Fifteenth Century, and all the peculiar characteristics of the ancient church (a small edifice of early perpendicular date) have been carefully maintained and restored. The dimensions within the walls are as follows:—chancel 25 ft. 0 in. by 16 ft.; nave 86 ft. by 22 ft.; north and south aisles each 94 ft. by 13 ft. 6 in., with a southern porch in the second bay from the west end. The height from the stone flooring to the summit of the open roof internally is 44 ft. 6 in. The vestry is placed at the eastern end of the north aisle; externally the walls above the plinth are built with lime stone of a blue grey tint, from Chudleigh, and the windows, string courses, battlement, mouldings, and other dressings are of Caen stone. The plinth is of granite; the walls 3 ft. in thickness, and the gables are surmounted by floriated crosses of rich character. The church internally is remarkable for the high pitch of its fine open roof, consisting of 13 pair of grained principals with circular ribs of oak, wrought and moulded, and enriched with carved bosses coloured and gilt after ancient ones in the old church; the principals spring from richly carved stone cubals, and the columns and arches separating the nave from the ailes, are a restoration in every point as regards detail of those in the old church. They are especially rich and varied in their foliage and capitals, and are carved with much spirit and vigour—illustrations of these capitals are intended to be published by the Exeter Architectural Society in their transactions. There is a fine chancel arch, richly moulded in Caen stone, on the north side of which is placed the pulpit, hexagonel in form, and an elaborate specimen of stone carving, executed by Rowe, of Exeter; it abounds in rich foliage, varied in each compartment, and carved in bold relief, having niches surmounted by crocketted canopies over figures of the four Evangelists and St. Michael the Archangel. There is a fine eagle carved in old oak, and an open Litany desk. The eagle was carved by Mr. Winsor, who is the senior verger of Exeter Cathedral. All the carved works in this edifice are admirably executed, and prove the great advance lately made in the correct execution of wood and stone carving. At the east end of the chancel it was at first intended to have restored the former window, but on inspection, being found much decayed, as well as of a somewhat debased architectural character. The Rev. Dr. Warren, of Portview, liberally presented a new window of four lights, and the Rev. Arthur Atherley (the Vicar) has munificently filled the same with stained glass at his own expense. The design of this glass, which has been executed in a most satisfactory manner by Mr. Robert Beer, of Exeter, a talented and rising artist, comprises figures of the four Evangelists under storied canopies having scrolls at their feet, on which are texts having reference to the Supper of our Lord. In the upper tracery are placed the Phœnix and Pelican; the Symbols of the Evangelists; the Virgin and Infant Jesus; and St. Michael (the patron Saint of the Church) in conflict with the Dragon. The south window of the chancel has a fine figure of the Virgin bearing in her hand her emblem, the Lily. In the south aisle there is a good specimen of a memorial window of three lights. The first and third are bordered after a specimen in Exeter Cathedral, in a flowing pattern and blue glass, with the "Crown" quarry within, the centre bordered in ruby glass with the "Trinity flower" quarry, the family arms, and badge of the order of the Bath being inserted. At the bottom of the window the names of the father and his two sons, buried in the adjoining church yard are recorded, and the scripture "blessed are the dead which die in the Lord" runs through the lights. The font is the gift to the church by an old parishioner; it is of Caen stone, large, aud highly enriched; it is placed near the western entrance. The bowl is octagonal, having each panel filled with ornamental tracery, varied in each compartment; the sides of the shaft are likewise panelled with cinque foil beaded arches, and springing from the shaft to support the bowl, are a band of angels with expanded wings, bearing shields. For the present the old tower still remains, but it is hoped, ere long, to add an adequate tower and spire, which when complete, will render this one of the largest and finest churches in the county of Devon. The contracter for the whole of the works was Mr. John Henshole, of Heavitree, who has fulfilled all his obligations in the most satisfactory manner. The works have been well done and unworthy imitations avoided.

DIFFERENTIAL HYDRAULIC PRESS.

I think it must be evident to all who have thought on the subject, how much superior the Hydraulic Press is to the Screw, where enormous pressure is required; but even in the hydraulic press, as at present made, if we wish to increase its power to a great extent there appears but three ways of accomplishing it, all of which are liable to objection: the first plan is to increase the size of the large piston and cylinder, thus making it more expensive and unwieldy; the second is by diminishing the size of the smaller piston, but if this is carried too far it will be in danger of bending or breaking under the pressure which is applied to it; the third is to obtain greater leverage upon the small piston, which if carried too far will also be in danger of injuring it. But it appears to me that it is possible to diminish the acting part of the piston to almost any extent, while its strength remains the same, by the plan which is given in the figure, in which *b* is the large piston working in the stuffing box *c*, and carrying the press-board *s* upon it; *d e* is the small piston or forcing pump thicker at the part *d*, than at *e*, and works in the two stuffing boxes *f* and *g*, and is nearly at the top of its stroke. *h* is the pump cylinder communicating with a reservoir in this cylinder, the small piston works, descending through a water-tight collar into the space *s*, which is open to the air. *k* is a pipe communicating with the large cylinder at the end of which is a valve *t* opening outwards. Then if we suppose the cylinders to be full of water, and the piston at the top of its stroke, when it is pushed down it will force a quantity of water into the large cylinder, *nearly equal to*



the difference of the solidity of the two parts of the piston d e, which will be a very little if the two parts *d* and *e*, are nearly alike; thus giving it the advantage of a small piston while it still possesses the strength of a large one. I have not marked the handle and other parts as they do not differ from the usual construction.

A Working Mechanic.

Newcastle-on-Tyne.

[The above suggestion is very ingenious, and appears likely to prove valuable. As the principle of the press in its improved form is to pump into the main cylinder a quantity of water equal in volume to the *difference* between the solid contents of the two pump-pistons we have ventured to apply the name Differential Hydraulic Press

During the military operations of the French in Algeria it was necessary to export from France hay for the cavalry horses, and in order to compress the hay into the smallest possible compass, it was subjected to the action of the hydraulic press. But it was found that the operation was excessively slow, as during the first part of it a very large quantity of water was pumped in with little or no resistance from the compression of the hay. A similar difficulty frequently occurs on less important works than that of maintaining a new colony, and a very simple addition to the pump here described would probably remedy the evil.

Let the cylinder to be continued down into the space *s*, and let this lower cylinder communicate by a pipe, having a stop-cock, with the reservoir, and also by a pipe similar to *k*, with the main cylinder. When the pressure at *v* is small a large quantity of water may be pumped in at each stroke, and if the stop-cock be open, the upper and lower pump pistons will both draw water. When the pressure at *v* becomes great, the stop-cock may be closed and water will be forced from the upper pump cylinder only.

By this contrivance two relative rates of working are obtained. Three or more rates of working might be obtained by having three or more sizes of the pump-piston and a corresponding number of cylinders.]

REGISTER OF NEW PATENTS.

If additional information be required respecting any patent, it may be obtained at the office of this Journal.

HEATING BY HYDROGEN.

Joseph Pierre Gillard, of Rue Martignac, Paris, professor of mathematics and philosophy, for "*Improvements in the production of Heat in general.*"—Granted February 11th, 1846; Enrolled August 11th, 1846.

The improvements relate to the application of pure hydrogen for heating apartments, steam engines, furnaces for smelting, and other purposes. The hydrogen is obtained by driving jets of steam through red hot retorts containing thin iron plates, when the oxygen of the steam forms an oxide on the iron, and the hydrogen of the water is set free and carried off by pipes to suitable gasometers. Another process for obtaining hydrogen is by injecting steam, with pulverized coal or coke, into red hot retorts, by which means carbonic acid and carburetted hydrogen gases are formed; these gases are carried off by pipes to a purifier containing lime-water, when the carbonic acid is absorbed, and the carburetted hydrogen carried with another jet of steam through a second red-hot retort, when the carbon is decomposed and united with the oxygen of the steam forming carbonic acid, and at the same time the hydrogen of both the steam and the carburetted hydrogen is liberated; thus pure hydrogen is obtained, which is carried off to the gasometer, and at the same time the carbonic acid is passed to a second purifier, where it is absorbed.

For heating apartments two pipes and two gasometers are employed, one furnished with hydrogen, and the other filled with atmospheric air; the pipes are so conveyed to jets at the spot, that the gases may be mixed before the combustion takes place. Two volumes of air to one of hydrogen will be required for proper combustion.

For locomotive engines, there are to be introduced into the space occupied by the fire-box, four or five retorts, as first described, for obtaining hydrogen; and the tender is to have two or three gasometers, to hold the hydrogen and atmospheric air, from which the gases are to be conveyed by pipes to burners in the engine, for heating the retorts red hot, and at the same time the water in the boiler. When the steam from the engine-boiler has passed through the cylinders, instead of its escaping into the open air, it is to be conducted by pipes to the retorts, where it is decomposed, and the hydrogen passes from the retorts by pipes to the gasometers in the tender for supplying the engine.

ZINC PAINT.

James Murdock, of Staples-inn, Middlesex, mechanical draughtsman, for "*an Improved process for preparing a certain material for the purpose of painting.*" (A communication).—Granted February 11; Enrolled Aug. 11, 1846.

This invention relates to obtaining pure oxide of zinc, to be used for painting instead of white lead. Zinc, or zinc ore, is put into a fire-clay retort, open at both ends; at one end the charge of zinc or ore is placed and then sealed up; the other end is left open, and communicates with a chamber. When the retort is heated, the zinc passes off in a state of vapour, and as it comes in contact with the atmosphere it unites with the oxygen of the air, and forms the oxide of zinc, the vapour floating in the chamber like a white cloud. For the purpose of collecting the oxide, a series of fine wire sieves are placed in a passage leading into another chamber; this chamber communicates with the large chimney of the retort furnace, and thereby causes a strong draught of air to pass from one chamber to the other, through the wire sieves; in doing this, the current of air carries with it the fine particles of the oxide of zinc, and deposits them on the wire sieves, which are occasionally shaken to prevent their being clogged.

MOTIVE POWER.

James Nasmyth, of Arundel-street, Middlesex, gentleman, for "*certain Improvements in engines or machinery for obtaining and applying motive power.*"—Granted Feb. 16th; Enrolled August 16, 1846. (Reported in *Patent Journal.*)

These improvements consist in the construction and working of engines in a novel manner, by the agency of steam or other elastic fluids, or other means, whereby a greater amount of power is obtained than by means ordinarily employed. In this improved plan, two, three, or more cylinders may be employed, as may be required, and the power of the motive agent, whether it be steam, air, or gases, or any other pressure, is made to act alternately, first at one end of the train of cylinders, and then at the opposite end, that is to say, if there be two cylinders connected together by a tube, the motive agent is admitted alternately above the piston and at the upper end of each cylinder, each being in vacuo alternately. If more than two cylinders are used, they are put in connection with each other by means of tubes, the additional cylinders, whatever may be their number, are always in pleno (that is to say), they are filled with air, or some other elastic or non-elastic fluid, the pistons of which cylinders move up and down simultaneously with the two end cylinders. The pistons of the two end cylinders or of those which are alternately in vacuo as before explained, are actuated alternately by the introduction of the motive agent into the cylinders above the piston. On the opposite side of the piston the space which intervenes between the pistons of the two steam cylinders, is occupied with air or any other elastic, or non-elastic fluid, not susceptible of condensation. It will be understood that the tubes which connect the cylinder together, as well as the additional cylinders, which are placed between the two end ones, are also kept full of air or other elastic or non-elastic fluid, not susceptible of condensation; therefore the power received by the piston of either of the two end cylinders, which are alternately in vacuo, is simultaneously transmitted to any other piston or pistons in any other cylinders which may be situated between the two end ones, and these additional cylinders may be placed at any distance or in any position that may be required, always provided that the communication is kept up by means of tubes.

If two cylinders only be employed, they are connected with each other below the piston by a tube, steam only being admitted above the pistons alternately; therefore when the steam exerts a force to depress the one, the opposite piston is acted on by the exhaustion from the condenser, also by the elastic or non-elastic fluid rushing from one cylinder to the other.

When air compressed, or any other elastic fluid, is employed as the motive agent, it is admitted in the same manner as steam, and the same effect will result from the same arrangement of cylinders and the connecting tubes, whether the cylinders be two or more; with this difference, that the air which has followed the piston must be withdrawn by air-pumps out of the cylinder, in order that there may be a vacuum above the piston.

LOCOMOTIVE ENGINES.

ROBERT NISBET, of Lambden, Esq., for "*certain Improvements in Locomotive Engines and Railways.*"—Granted February 19; Enrolled August 19, 1846.—*Reported in the Patent Journal.*

These improvements consist in making such additions to engines and railways, as to enable a train to ascend, at a very slightly diminished speed, almost any incline. A toothed circle or ring is bolted, or otherwise secured to the rim of each driving wheel of the locomotive engine, or, if necessary, a circle of teeth may be attached to each side, the diameter of which, at the pitch line, must of course be the same as the diameter of the sole or bearing periphery of the wheel. Racks corresponding with these toothed rings are laid down at the inclined portions of the railway, and may either be secured to seats formed in the chairs for their reception, or bedded on separate longitudinal sleepers laid for that purpose; they are continued beyond where the gradient commences, to the distance equal to the length of the longest train likely to travel thereon; at the beginning, or where the toothed rings first take into these racks, the pitch line is placed below the level of the rails, and the teeth at the same point are bevelled off on one side to a sharp edge. From this it gradually rises until it attains a proper level, and the teeth at the same time are bevelled less in proportion as they rise, until they assume a proper shape. This arrangement will facilitate the junction of the rings with the racks, and prevent any possibility of the teeth of the one coming opposite the teeth of the other.

On railways intersected with many crossings, he prefers making use of only one circle of teeth to each wheel; this he places on the inside, as where the flange passes there will be room for it; also by cutting a portion of the rail away, through which it may pass freely.

By another arrangement, the toothed rings are secured to the driving wheels by means of four short links, on which they swing, placed at equal distances on the circumference, and will admit of their being raised two or three inches, so as to clear the rails in crossings, or any other obstructions likely to be met with. The toothed rings, in this case, are acted on by a lever, over which the driver has control, who raises or depresses them accordingly,

He states that he is aware that toothed wheel and racks have before been applied to railways, throughout their entire length, and which method of propulsion he does not claim. But he claims the fixing of toothed circles or rings to the driving wheels of locomotive engines, for the purpose of ascending inclines, and also for retarding in its descent. (This is not new. —Ed. C. E. and A. Journal.)

VENTILATION OF MINES.

WILLIAM PRICE STRUVE, of Swansea, civil engineer, for "*Improvements in ventilating mines.*"—Granted March 11; Enrolled Sept. 11, 1846.

The improvements relate to an apparatus for exhausting the air out of mines, for the purpose of ventilating them and withdrawing explosive gases formed therein. The patentee proposes to effect these objects by an apparatus, that will draw a continued current of air through the upcast shaft of the mine, consisting of two large cylindrical tanks built of masonry or other suitable material, partially filled with water; within the tanks are to be suspended two inverted chambers similar to gasometers. From each tank two air-tight enclosed passages are to be formed leading to the upcast shaft, one passage to lead from the top of the tank above the inverted chamber, and the other passage to lead from the underside of the inverted chamber, just above the water line; each of these passages are to be furnished with valves opening inwards, and also with valves opening outwards to the external air, the valves to be of the same area as the upcast shaft, and are recommended to be made in compartments of plates of metal faced with leather, bolted on to a framing, the leather forming a hinged joint.

For working the apparatus a horizontal shaft is set in motion by a steam engine, or other power. This shaft passes through the sides of the tanks to the centre, and at each end of the shaft is fixed a crank, attached to a connecting rod; the upper end of the rod is fixed to the centre of the inside of the top of the inverted chamber. When the shaft is set in motion, the cranks, which are set at each end of the shaft opposite to each other, are made to rotate, and by them the connecting-rod causes the inverted chambers to be raised and lowered alternately, so that at each stroke of the engine a quantity of air is displaced equivalent to the capacity of the two inverted chambers. By this arrangement the air is withdrawn from the upcast shaft to each tank through the inlet valves, first under the inverted chamber, then over it, and as the chamber rises the air is expelled out of the tank above the chamber through the outlet valve, and at the same time the interior of the chamber is being filled with air from the upcast shaft, and when the chamber descends the outlet valve is closed, and air is drawn from the upcast shaft through the inlet valve to the upper part of the tank above the chamber, and at the same time the air is forced out of the interior of the inverted chamber through the outlet valve. Thus a continued current of air is being withdrawn from the mine through each tank.

ELECTRIC TELEGRAPHS.

HENRY HEIGHTON, M.A., of Rugby, Warwickshire, for "*Improvements in electric telegraphs.*"—Granted Feb. 3; Enrolled Aug. 3, 1846.

This invention relates to the introduction of an apparatus to supply the place of the magnetic needle now used for electric telegraphs. The apparatus consists of a glass tube fitted with brass caps at top and bottom, and having a strip of metallic leaf (gold leaf is recommended as best) passing through the centre of the tube, loosely hung in metallic contact with the brass caps; the upper extremity of the leaf being fixed at right angles to its lower end, so that the leaf, from whatever direction seen, will present at some part its flat surface to the eye. The brass caps are placed in a circuit suitable for electro-telegraphic communication. Near to the leaf (as on the outside of the glass) is placed either of the poles of a magnet. The effect of this arrangement is, that when a current of voltaic electricity is caused to pass through the circuit, and thereby, the metallic leaf, the latter is deflected to one side or the other, according to the direction of the current; and the distinct motion so obtained may be repeated and combined and used for the purpose of designating letters or figures or other conventional signals. One of the apparatus is to be placed at each terminus of telegraphic communication, and others may be placed at intermediate points, each to be provided with a voltaic battery and one of the key-boards used in single magnetic-needle electric telegraphs.

NOTES OF THE MONTH.

Bavaria Canal.—This canal, which has been opened for a few months, promises to be of the highest importance to commerce, by it the Rhine and Danube, and consequently the Black and North Seas are united. A vessel can transport its cargo from London or Rotterdam across Bavaria, Austria, Hungary, and Wallachia, as far as Trebizond and Constantinople, This canal, bearing the name of *Ludwigts Kanal*, was executed by the King of Bavaria.

Telegraphic Wires.—A new coating has been applied to the wires of the Munich and Augsburg railway telegraph, the invention of Professor Steinheil, of Munich, it possesses the properties of protecting the wires from lightning.

We are happy to announce, observes the *Athenæum*, that the Budrun Marbles, secured to us by the exertions of Sir Stratford Canning, have arrived from Asia Minor, and are now safely deposited in the British Museum. The pieces of frieze of which this most interesting collection consists have been removed from the walls of the Turkish fort into which they were built; and where they have, from time to time, been noticed by European travellers—though no very critical account of them has ever been published. Budrun, as is well known, occupies the site of the ancient Halicarnassus; and it has, with great probability, been supposed that these sculptures formed part of the celebrated mausoleum erected, in that city, by Artemisia, Queen of Caria, to the memory of her husband, Mausolus, B.C. 350—and have, like the frieze of the Temple of Victory, at Athens, been used by the Turks as the building materials of a fort erected on the site of this monument. If this opinion be correct, these sculptures have an historical value scarcely less than those of the Parthenon: for we learn from ancient writers that the frieze of the Mausoleum was the work of four of the most celebrated artists of the day,—Bryaxis, Leochares, Scopas, Timotheos,—or, according to Vitruvius, Praxiteles. The Budrun Marbles would thus represent the style of a period in the history of Greek sculpture, of which, from the want of dated monuments, our knowledge is most uncertain,—the century preceding the reign of Alexander the Great, and distinguished in the history of art as the Praxitelian period. We will describe these sculptures as far as a first hasty examination will enable us. The subject, like that of the Phygaliau and Lycian friezes, is a battle with Amazons. At the first glance, we are struck by the masterly composition of the groups, the knowledge and skill which distinguish the Athenian school. As the eye dwells longer and compares more critically, we perceive certain perculiarities distinguishing the style from that of the older Greek friezes with which we are acquainted. With no trace of the careless, barbaric ignorance so apparent in the Lycian friezes, with more elaborate and skilful execution than the Phygalian, these sculptures still want the simplicity, repose, and unconscious beauty of the art of Phidias. Though the general composition is finely conceived, the design and treatment are not without mannerism. The true proportions of the figures, when compared with those of the Elgin sculptures, appear unnaturally elongated; and the graceful flow of the draperies is singularly contrasted with the poverty and meagreness of some of the anatomical details and the constraint of the attitudes. We are at once reminded of Pliny's description of the new style introduced by Lysippus;—who, in order to give greater height to his figures, substituted a greater dryness of treatment for the squareness, and full muscular development of the earlier school. With this change in the type commenced that general decadence in Art which may be traced step by step in the coins of the Seleucidæ, and other successors of Alexander; and which, from the evidence of the Budrun marbles, according to their presumed date, must have been already introduced B.C. 350. This is rather an earlier epoch than that from which the decline of sculpture is usually dated: and it must be confessed that the Budrun friezes, when compared with the reliefs of the choragic monument of Lysicrates, a contemporary work, and other sculptures considered to be of the same period, exhibit far more strikingly the characteristic of decadence; and might, in the absence of all historical data, be assigned with great probability to the century after the death of Alexander, B.C. 329. We will not, however, here anticipate a discussion involving the historical research and critical knowledge of art which will be required to solve the question whether the Budrun Marbles can be identified with the friezes of the Mausoleum. The surface of the sculpture is tolerably preserved—the marble not of very fine quality.

Launch of an Iron Steamer at Liverpool, built by Messrs. Vernon and Co., took place on the 8th of September, she is named the Haddington, and is built for the Peninsular and Oriental Steam Navigation Company. Her dimensions are length between perpendiculars, 221 feet, over all 240 feet, breadth of beam 35 feet, depth of engine room 21 feet tonnage, new measurement 200 tons. The engines are of 450 horse, constructed on the direct action principle by Messrs. Bury, Curtis and Kennedy, of Liverpool.

The Norman Tower at Bury.—The great eastern arch is removed, and the superstructure will be supported by shores until the insertion of the new arch is completed.

Excavations in the Acropolis.—The Archæological Society of Athens are busily pursuing the work of investigation. We trust they may be enabled to set at rest the disputed points respecting the architecture of the interior of the Parthenon.

The Electric Telegraphs of the United States extend to 1659 miles.

The Railway Monopoly.—A correspondent of the *Times*, under the signature "Cato," gives the following illustration of the effect of low fares. The charges on the Glasgow and Ayr line are—1st class, 1½d.; 2nd class, 1¼d.; 3rd class, ¾d. per mile. The returns last year were ninety thousand pounds, the expenses thirty-six thousand pounds, leaving a profit of fifty-four thousand pounds, or nearly *sixty per cent. of the gross returns!*

The London and North Western Company are about to carry the mail to between London and Liverpool in five hours, including stoppages.

The Doncaster Station of the Great Northern Railway will, with necessary buildings and premises, occupy 35 acres.

Brighton to Havre.—Great efforts are about to be made to effect rapid communication between these towns. Under the auspices of the Rouen and Brighton Railway Companies, it is proposed to deepen the harbour at Havre, and to construct a floating breakwater off Brighton Pier. When these works are completed it is expected that passengers will be able to embark and disembark at all states of the tide and wind; and the journey from Paris to London will occupy 12 hours.

The Folkestone Pier progresses rapidly.

The Portland Breakwater.—Active preparations are being made for the commencement of the works, and the transmission of materials.

The Works at Devonport are carried on with great activity. There will be two basins, each 625 feet long; two docks, 309 feet long; another dock, 406 feet long; and a factory, 800 feet by 320 feet.

The Gas Companies at Bristol have reduced the price of gas to 6s. per 1,000 cubic feet.

Glastonbury Market Cross is completed.

The Manchester Parks appear to have cost 30,000*l.*

Rouen Railway.—The commission appointed to investigate the accident from the use of liquid hydrogen gas to light the Post-office carriage have reported thereon, the continued use of that method of lighting will probably lead to frequent explosions.

Draw-Bridge on the Brighton and Hastings Line.—There is a draw-bridge on this line, near Lewes, similar to that over the Arun, described Vol. VIII., p. 269. An engine-driver, a few weeks ago, mistaking, or neglecting the signal to stop, endeavoured to cross the river when the bridge was drawn back, and, consequently, drove the engine into the water. No one was injured.

The Brighton Railway Company intend to run express trains to London in one hour and a quarter, instead of one hour and a half, as heretofore.

The New Guildhall at Bristol is in the late Tudor style. The front is built of Bath stone and elaborately ornamented; but the building is said to be ill-ventilated and ill-lighted. Mr Pope is the architect.

St. James's, Bristol, is being restored under the direction of Mr. Fripp. The ancient architecture is chiefly Norman, and the architect appears to be treating it in a very unceremonious manner. He has removed an ancient piscina to make way for an arcade at the east end, of his own design, and some of the pillars which have swerved from the perpendicular he has coated with plaster to make them *look straight*.

Museum of Economic Geology.—A site has been prepared for the new building by pulling down some houses in Piccadilly, near St. James's church; but there are great complaints of the dilatory manner in which the works proceed.

Blackburn Exchange Buildings.—The competing designs having been examined by Mr. Cockerell, R.A., the first prize has been awarded to Messrs. Dickson and Brackspear; the second to Messrs. Bank and Clarke; the third to Mr. Wilson, of Bath.

The Liverpool Dock Works.—The expenditure for the year ending June 24, 1846, is £321,491 for new works.

Kemerton Church.—Archdeacon Thorpe's liberal offer to rebuild the north aisle and erect a spire, at the expense of £1,500, provided the parish would contribute £500, has been accepted by the parishioners after some opposition.

Government Offices, Whitehall.—The remains of the ancient chapel of Cardinal Wolsey are about to follow the fate of St. Stephen's Chapel. Is St. Margaret's Church to be the third sacrifice to the "Westminster Improvements"? Verily it becomes us well to sneer in the Nineteenth century at the iconoclastic fury of the Puritans! Had we less self-complacency in comparing our architecture with that of our ancestors, the following quotation from a recent number of the *Builder*, might be listened to.—"The recommendation of a select committee to remove St. Margaret's Church we protest against strenuously; restore it—improve it—make it a fitting adjunct to the neighbouring buildings, but don't think of destroying it.

The Academie des Beaux-Arts at Paris lately awarded the prizes of architecture. The subject proposed for competition was the construction of a Museum of Natural History. The successful candidates were—first, M. Normand, 24 years; second, M. Monge, 25 years; and, third, M. Ponthieu, 29 years of age.

Manchester Soirée.—The Manchester annual *soirée* this month, with Lord Morpeth in the chair, boasts of an attractive platform assemblage, whose names and eloquence will, no doubt, crowd the spacious rooms, and bring fruitful contributions to encourage the worthily ambitious literature of this populous place.

Wellington Statue.—Mr. C. R. Cockerell, R.A., the architect, has addressed a letter to the *Times*, on the subject of this statue, and added, "one more voice to the outcry already so justly raised against the erection of the statue on the arch at Hyde Park corner." He calls it a solecism in art, seriously involving the honour of the country. "The solecism consists," he says, "in the proposition to place a statue of colossal dimensions as an ornament to a triumphal arch of disproportionate magnitude, so that the ornament and the principal are in danger of changing places, and the major may become the subordinate of the minor; and again, in proposing to place that ornament on an axis at right angles with that of the arch itself." An unparalleled hero, it is said, may have an unparalleled position; but in questions of this nature, he properly observes *we* naturally turn to classical examples. *We!* We wish the committee would! All Bellori's examples in his book on the triumphal arches of Rome are against this infatuated sub-committee; the architect of the arch, Mr. Decimus Burton himself, is against its being there; the artists, the journals, and the good sense of the country have denounced it. "Had the sub-committee condescended," he says, "to seek the advice of professional men, the disgrace they are preparing for themselves, and the trouble to the public in replacing this fine work in an accessable and proper site might have been spared."

New Harbour at Holyhead.—The obstacles which have hitherto prevented the commencement of the public works in this harbour, are now, it is said, entirely removed, and the works are to be immediately begun. Captain Beechey, of the surveying steamer the Firefly, with the assistance of Mr. Rendell, and a number of divers from Portsmouth, made a most minute survey of the sea ground (that is to form the harbour; which has proved to be equal to that of any harbour in the kingdom. Hitherto an opinion was entertained by many nautical men that it would always be a dangerous harbour, on account of the supposed rocky nature of its anchorage; but the present survey has dissipated this idea; for, with the exception of one or two small insignificant rocks, there is excellent holding ground within the entire space to be inclosed for the new harbour.

At the Academie of Sciences, Paris, a paper from M. Jobard was received on the Chinese system of boring wells by means of a rope instead of metallic rods. He states that M. Goublet-Collet has adopted this system with the best results in Champagne; and that the cost is only 3 fr. per foot, without any increase according to depth. The whole of the apparatus costs only 500 fr.—B. Biot, in his own name and in those of Messrs. Bahioet and Pouillet, read a favourable report on an apparatus, constructed by M. Rumkorff, to facilitate the exhibition of the optical phenomena produced by transparent bodies when they are placed between the opposite poles of a magnet of great power.

*Paris Academy of Sciences.—Sept.*14.—A communication was received from Mr. Morse, giving an account of the extent of the telegraphic lines already established in the United States of America. It is as follows:—

	Miles.
Albany to Buffalo	350
New York to Boston	220
Do. to Albany	150
Do. to Washington	230
Washington to Baltimore	40
Baltimore to Philadelphia	97
Philadelphia to New York	88
New York to Newhaven	84
Newhaven to Hartford	30
Hartford to Springfield	20
Springfield to Boston	98
Albany to Rochester	252
Total	1659

Mr. Morse states, in his letter, that the electric telegraph is now the chief mode of transmitting all the news of the Government and the important correspondence of merchants and of the public generally. Its influence has, he says, been already felt by the press. The journals of the large towns, which were taken in the country on account of their giving the most recent news, have lost a great number of their subscribers; whilst there has been a very large increase in the circulation of the journals of the small towns near the extreme points of the electric telegraphs.

New Volcano.—A letter, dated Aug. 14th, from Lieut. Barker, of the East India Company's steamer Victoria, states, that on that day smoke was observed to issue from the summit of Saddle Island, lat. 15° 7′ N., long. 42° 12′ E. The account adds: "The weather at the time was very squally, with thunder and lightning. Saddle Island is one of a group called Zebayer Islands, in the Red Sea, in the direct track of vessels proceeding up and down, and are all of volcanic origin; but there is neither record nor tradition of their having been in active operation. Jibble Seer, in lat. 15° 32′ N., and long. 41° 55′ E., was observed to be smoking when visited by the officers of the Benares during the survey of the Red Sea, but never since. There is a tradition among the Arab pilots of its having been on fire some fifty years ago, and it bears among many of them the name of Jibble Dookhan or Hill of Smoke, and has the appearance of having been in active operation at a much later period than the Zebayer Islands."

The "Great Western" Locomotive is taken off the line to be repaired, though it has been but a short time in use.

The "Great Britain" Steam-ship has gone ashore off Ireland. All the passengers were rescued.

The Marley Tunnel, South Devon Line.—Fifty yards have fallen in, and four men have been killed by the accident.

Newcastle and Berwick Railway will consist of six arches of 125 feet span. The quantity of iron required is 6,000 tons.

On the Glasgow and Greenock Railway, 3rd class passengers pay one farthing per mile.

Ipswich and Bury Line.—The embankments on the Stowmarket Marsh have sunk into the morass (which is 80 feet deep), and disappeared.

St. Mary's, Truro.—Some time back, the pillars of the chancel were restored by the vicar. The effect was so good, that several parishioners undertook to restore each one pillar of the nave. The improvements are very encouraging.

All Saints, Wigan.—Very extensive repairs are in progress. The architecture is Perpendicular.

Holy Trinity, Hull.—This noble church has been the subject of a costly renovation. The capitals of the pillars are gilded, the ceiling is coloured blue with stars of gold, and new church furniture has been provided,

St. John's Gate, Clerkenwell.—The reparation progresses slowly. All that the funds suffice for is the rebuilding the parapets in brickwork, and pointing the stonework where it is not too much decayed.

Whitfield, in Glossop.—A new church in the Early English style is nearly completed: it has a lofty enriched steeple.

The New Music Hall, in Liverpool, has been commenced. It is to be in the Italian style, and will contain 2,300 people. Mr. Cunningham is the architect.

Manchester.—The Infirmary is enlarged. Two large Catholic churches are being built.

The Brussels and Antwerp Telegraph is open to the public. The charges are, for communicating from 1 to 20 words, *five francs*; reply, *one penny*; sending it to the residence of the inquirer, *five pence*. In England the charges are from twelve to twenty times dearer. How much better (is the old remark) do they manage these things on the Continent! But John Bull has plenty of money, and can afford to spend it. On all the lines terminating in London five shillings is the *lowest* charge for a telegraphic message; and 8d. per mile is usually charged for sending a porter to communicate the message in any part of London.

NOTES ON FOREIGN WORKS.

The Water-cities of China.—The French commissioners lately returned from that country, have added much to our present knowledge of those curious habitations of the Chinese. That country is literally paved with human beings, hence great numbers have chosen the waters for an abode—their they are born, live, and die. Canton, for example, has a floating city on the Tchou-Kiang. Eighty thousand barges are there at anchor, and form regular districts and streets. Allowing to each barge only ten inhabitants, which is surely not enough in a country where families are very numerous, this river-city will have a population of nearly a million of souls. The cities in the interior resemble rather ants' nests than any thing else. The wonder of all is the city of Sou-tchou, on the Imperial Lake, 180 miles from the sea, with which it communicates by a marine canal, accessible to the largest vessels. M. Hedde, one of the commissioners, has visited it, and states the number of its inhabitants at twenty-five millions (?) Of these, ten millions live on the waters—viz., in the port and the canals of the city. Up to a certain age, the children in these water-cities have a sort of wooden buoy attached to their shoulder, which preserves them if they fall in the water. Not only men, but even animals live on these barges, and ducks, to an enormous extent, fill up the decks and holds of barges and vessels.

Panoramas of the Principal Cities of Russia.—The attention of the people of Moscow had been attracted, during the summers of 1844 and 1845, towards a person, who every day established himself on the platform of the steeple of Ivan-Veliki, and remained there until sun-set. This height commands a view of the holy city and fifteen leagues around it. They knew, in fine, that this curious personage was M. Acaric Baron, a French artist, who painted a panorama of the old city of the Czars. The higher classes of Moscow thus took an interest in the artist. Such was the renown of his praeverance and skill, that the Emperor wanted to see him, and M. Acaric-Baron received orders, as soon as his beautiful cartoons were completed, to repair to St. Petersburg. His Majesty, after the inspection of the work, ordered that the panorama of Moscow should be placed in one of the rooms of the Imperial palace. M. Acaric obtained, moreover, permission to publish his work on stone, and the Emperor and Prince Leuchtenberg headed the list of subscribers. It is now spoken of, that M. Acaric will receive commands to paint the panorama of St. Petersburg and the other large cities of Russia.

Art in Italy.—The Italian Academies, like those of other countries, lay under the imputation (right or wrong, we shall not decide), that the truly vivifying and pregnant spirit has departed from them. It is to be taken into account, however, that while all other instructional institutions aim only at the affording of the *current* stock of knowledge and acquirements, art-academies, on the other hand, are only then praised, if they have produced extraordinary talents. More than ever, Italy is engaged in the exploration of her subterranean treasures; and soon, the art-specimens of her old inhabitants—the Etruscans and others—will cover the presses and tables of our museums. As to the general mode of exhibition, we may rejoice at the greater adherence to historical arrangement now generally resorted to; while, on the other hand, those merely arbitrary shiftings of the specimens of art in the Vatican, or the pasting of a row of tickets on them (requiring the constant purchase of new catalogues), as has been done at Naples, are far from being commendable. Even the, perhaps well-intentioned, transposition of the antiques in the Villa Albani inspires us with grief, when we think that the former arrangement had originated with Winkelmann. The picture galleries of Italy lose, at times, by the circumrotation of men's fortunes, their fairest gems; and thus that splendid picture of Francesco Francia, of the Ercolani Palace at Bologna, has gone to Russia. Others, however, refuse any offer, as for instance, the Duke of Terranuova, in Naples, who praises his Holy Family, by Raphael, painted for one of his ancestors, like a family relic. On the other hand, many hitherto forgotten or buried pictorial treasures are brought to light, as, for instance, the paintings of Gritto at Florence, in the Bargello, or the Last Supper of Raphael in the convent of St. Onofrio delle Monache, in the same city. Collections which, hitherto, were scarcely considered of any note, like the Royal Palace at Turin, are better known and appreciated, and at Rome a new one has sprung up, which has made a splendid beginning, with the acquisition of the great Altar piece of Filippo Lippi. In several galleries the lighting from above has been introduced; if, however, this is not done efficiently, it will always be unsatisfactory, especially were pictures of small size are to be viewed. Moreover, such a *half-light* from above will make pictures appear in another light than that in which they were painted, and in which the artist intended them to be seen.

Late Excavations in Italy.—M. Alessandro François, known by his former sucesses in the above enterprise, has began of late some excavations at Chinsi, in the so-called Nun's bush, and his tact is so correct, that after he had traced his lines, by the work of only six excavators, after the short space of two hours, the vestiges of an ancient tomb were found. Further exertions laid open the row of tombs, which led to the subterranean chamber. To penetrate, however, to this, full six days of incessant labour were required, as the Hypogœum lay at a tremendous depth. This consists of three rather large rooms, of which the first is adorned with wall-pictures. Two, however, only have been preserved. One represents a chase—two men and a dog pursuing a hare. The other consists of two persons, who are received by another, sitting, with a certain air of solemnity. A flute player stands beside them. The pictures are made in an exceedingly delicate and free manner. In the middle of the first tomb there are also paintings—viz., two red tents, whose ends are extended by two genii. The pictures of the ceiling are in a perfect state of preservation, being red *cassetons* with a dark border. The minor contents of these tombs were also interesting, as besides several *pateræ* with charming designs, fragments of works in bronze and gold, and a very fine vase of *Olerite* with fine relievo designs, were discovered. The Princess of Canino continues to explore the environs of Civita Vechia, the ancient city of the Vulci. They have been resumed this year near Ponte Rotto, on the banks of the Fiora—the locality where, last year, the fragments of some splendid bronze chariots were discovered. The worknen have this time found a large sepulchral chamber, in which two huge sarcophagi were met with. The one is of that rock called *nenfro*, and the other of marble, or rather alabaster—the latter being ten yards long, and on the lid are two figures of natural size. The main tomb is covered all around with basso-relievos of fine design, well preserved. They represent scenes of combats, and also some of those figures, often to be met with, where bulls are delaniated by lions and griffins. On the upper rim is an Etruscan inscription! Such sarcophagi have never before been found at Vulci. Very interesting and extraordinary is the following: It has been found here, that in the walls on which sepulchral vases have been, most probably, placed in the time of the Romans, fragments of vases with very fine designs had been used as an admixture of the *cement* or *mortar* of the walls. It is obvious, that at a period when such could have been done, the value and estimation of these Etruscan vases must, for some reason or other, have been completly exploded.

The Donau-Main Canal.—The Monument.—This great undertaking, uniting (at least, for smaller craft) the German Ocean with the Black Sea—projected by Charlemagne and carried out by Lewis of Bavaria—has been fully concluded by the erection of a monument at the place where its construction had been the most difficult and expensive—the Burgberg, near Erlangen. The canal had to pass close to the banks of the Regnitz, between two vertical walls, whose distance is 24 feet, and which are, at some places, 30 feet high. For the sake of widening the space taken up by the Bamberg-Nüremberg road, it had to be extended in the direction of the canal, part of the Burgberg to be cut, and the considerable terraces protected by walls, rising in several stories. The space between Erlangen and the Burgberg, about 4,000 feet in length, occasioned considerable trouble and expense, as a dyke 2,100 feet long, and of an average height of 15 feet, had to be made up to the banks of the Swabach. This dyke is protected by a wall 1,500 feet long, which, like some Roman structures of the kind, is dressed with hewn stones. On this spot the monument is erected, whose foundation consists of blocks from the quarries of Kehlheim, some weighing 25 tons. It is Schwanthaler who made the designs, executed by some of his best pupils. The material selected for the four statues is also the splendid Jura-limestone of Kehlheim, and they were cut out, in their rough state, in the quarry itself, as the block for the statue of the Danube alone weighs 40 tons. The two reclining statues are 17 feet, and the two standing ones 14 feet, in length. The execution of this work occupied four years, and it was though fit that they should be first objects to be conveyed on the canal, along its whole extent, from Kehlheim to Bamberg. The monument is 48 feet high and 42 feet broad, and its basement bears the following inscription in bronze: "Donau and Main—für die Schiffarth verbunden—ein Werk von Karl dem Grossen versucht, durch Ludwig I., König von Bayern neubegonnen und vollendet." Beside this inscription is a bronze trident and an oar, adorned with wreaths. At the base, a copious stream of water issues from a bronze lion's head. The statue of the Rhine represents a vigorous man, whose upper part is uncovered, and exhibits a powerful, manly chest; the features are stern, and the head, adorned with garlands of vine, is turned towards that of the Danube, represented under the form of a virgin, reclining in placid repose. Commerce and Industry are reptesented by two other female figures. The whole appearance of the monument, whose background is formed by a somewhat receding mountain covered with oak trees, is imposing and noble.—And to show, in fine, that it is understood now on all hands, that industry, commerce, and the arts can never exist isolatedly to any perfection, the die-siker of the king, M. Neuss, of Augsburg, has executed a fine medal tn commemoration of the above great achievement for the communication of middle Europe.

Panama Canal.—The French *Moniteur* states, that the proceedings between the French-English Company for the canalizing of the straits of Panama and the government of New Grenada, have arrived at that point, that nothing but some minor matters remain to be settled. It was M. Klein, agent to the Company, who had negotiated at Bagota with the President of New Grenada.

Effects of the late Earthquake in Italy.—A great many scaffoldings yet to be seen in the streets of Leghorn, attest the severity of the shocks; and the damage caused in that city alone is valued at two millions of livres. In Pisa it was necessary to demolish whole houses.

A whole Mountain of Grecian Antiquities to be Purchased!—A German traveller in Asia Minor seriously puts forth the suggestion, for any friend of antiquities to purchase the mount near Priene, on the banks of the Meander. On the plateau of the hill lay a world of ruins of the old show-buildings, amongst which are the huge ruins of the famous temple of Athene. Our informant says, that with two thousand dollars, a mountain of, columns, marble slabs, frieses, &c., could be acquired.

LIST OF NEW PATENTS.

GRANTED IN ENGLAND FROM AUGUST 25, 1846, TO SEPTEMBER 24, 1846.

Six Months allowed for Enrolment, unless otherwise expressed.

Alfred Krupp, principal of the house of Frederick Krupp, of Essen, Prussia, but now of Leicester-square, for "certain Improvements in the manufacture of spoons, forks, and other similar wares, and in the machinery, or apparatus, employed therein, parts of which are also applicable to other manufacturing processes."—Sealed August 26.

Thomas Wroughton, of Eltham place, Kennington, gentleman, for "certain Improvements in apparatus and instruments for ventilation and respiration."—August 26.

Henry Bessemer, of Baxter-house, Old St. Pancras road, engineer, "certain Improvements in railway engines and carriages, parts of which improvements are applicable to the propelling of steam vessels, and to motive purposes generally."—August 26.

Richard Clarke Burleigh, of Bath, gentleman, for "certain Improvements in artificial light."—August 28.

Arthur Howe Holdsworth, of Brookhill, Dartmouth, Devon, Esq., for "Improvements in buoys and giving buoyancy to boats."—August 29.

James Boydell, of Oak-farm-works, near Dudley, ironmaster, for "Improvements in applying apparatus to carriages to facilitate the draught."—August 29.

William Air Forster, of Glasgow, leather merchant and boot maker, for "an Improved mode of making belts for driving machinery, traces, reins, and other articles of leather, felt, or parchment, and for an improved apparatus or machinery for the same."—August 29.

Alexander Debain, manufacturer, of Paris, France, for "certain Improvements applicable to keyed musical instruments."—August 29.

James Roose, of Darleston, Stafford, tube manufacturer, for "Improvements in the manufacture of welded iron tubes."—August 29.

Henry Henson, of Hampstead, Middlesex, gentleman, for "certain Improvements in railways, and in railway carriages, having for their object the better accommodation and security of the public."—August 31.

James Warren, of Montague-terrace, Mile-end-road, gentleman, for "Improvements in the manufacture of cast screws."—August 31.

Frederick Henry West, of the City-road, Middlesex, gentlemen, for "certain Improvements in securing corks in bottles, jars, and other vessels to contain liquids and other matters, and also improvements in such bottles and other vessels."—August 31.

Nicholas Harvey, of Hayle Foundry, St. Erth, Cornwall, for "certain Improvements in filtering of water for steam engines and boilers."—Sept. 3.

James Coles, of Harley-street, Cavendish-square, Middlesex, surgeon, for "Improvements in apparatus for the prevention and treatment of distortions of the spine and chest, also for treatment of diseases of the spine and other disorders where a recumbent position of the patient is required."—September 3.

George Senior, of Bradford, York, gentleman, for "certain Improvements in washing cleansing, scouring, and bleaching silk, cotton, wool, and fibrous substances generally, also in dyeing, combing, carding, spinning, felting, milling, or otherwise treating or preparing fibrous substances generally."—September 3.

Peter Armand Leconte de Fontainmoreau, of New Broad-street, London, for "certain Improvements in the machines for the manufacture of bricks and other plastic products;" being a communication from a foreigner residing abroad.—September 3.

Charles Ylery, of Rue St. Lasare, Paris, France, engineer, for "Improvements in ascertaining and regulating the speeds and times of railway trains."—September 10.

Moses Poole, London, gentleman, for "Improvements in treating vegetable fibres to render them applicable to the manufacture of paper." (Being a communication.)—September 10.

Charles Richardson, of Dalston, Middlesex, gentleman, for "certain Improvements in making and refining of sugar, and in the machinery and appartus employed therein." (Being a communication.)—September 10.

David Davies, of Wigmore-street, Cavendish-square, Middlesex, for "certain Improvements in steps for carriages and other purposes."—September 17.

Richard Ford Sturges, of Birmingham, Britannia ware manufacturer, for "Improvements in filtering apparatus, and in apparatus for making tea-pots, and other vessels of metal."—September 17.

James William Bowman, of Great Alie-street, Middlesex, for "Improvements in reburning animal charcoal."—September 17.

William Palmer, of Sutton-street, Clerkenwell, manufacturer, for "Improvements in the manufacture of lamps and candlesticks, and in gas and other pillars and pipes."—September 17.

Henry Franklin, of Marstone Mortaine, Bedfordshire, for "Improvements in the manufacture of bricks, tiles, and other like articles."—September 17.

Frederick Brown, of Luton, Bedfordshire, ironmonger, for "Improvements in ovens for kitchen-ranges."—September 17.

William Edward Newton, of 66, Chancery-lane, for "Improvements in preserving fruit and vegetables."—September 17.—(A communication.)

Henry Wrigg, of Upper Holloway, Middlesex, civil engineer, for "certain Improved means or methods of diminishing draught and friction in carriages and other conveyances."—September 17.

James Lamb, of Canal Road, Kingsland-road, for "Improvements in the manufacture of clogs."—September 24.

Alfred Vincent Newton, of Chancery-lane, for "Improvements in the method of hardening and tempering various articles made of steel, or of iron and steel combined;" being a communication.—September 24.

Henry Deacon, of Eccleston, Lancashire, engineer, for "Improvements in the construction of flattening kilns."—September 24.

Charles Fox, of London Works, near Birmingham, engineer, for "Improved machinery for shearing, cutting, and punching metals."—September 24.

Charles Chinnock, of Seymour-place, Little Chelsea, for "Improvements in folding and securing letters, envelopes, and covers."—September 24.

Edmund Nevot, of Lombard-street, gentleman, for "Improvements in the manufacture of paper, being a communication."—September 24.

Peter Armand Lecomte de Fontainmoreau, of No. 15, New Broad-street, city, for an "Improvement or Improvements in the mode of manufacturing corks," being a communication.—September 24.

CORRESPONDENTS.

Next month will be noticed "Peschel's Elements of Physics," "Castle's Surveying," "Mullins on Peat Bog, and the construction of Roads, Railways, and Canals in Bog," and a Tract by Sir Howard Douglas, entitled, "A Reply to some Observations in a review of the pamphlet entitled, Metropolitan Bridges and Westminster Improvements in the *Civil Engineer and Architect's Journal*, September 1846."

ERRATUM.—The last sentence on page 306 is editorial, and does not belong to Mr. Roberts's remarks. It belongs to the next paragraph.

TRABEATE AND ARCUATE ARCHITECTURE.

The adoption of technical terms in any art usually results from a sacrifice of one or other of the two essential requisites of a perfect nomenclature—perspicuity and conciseness. A new compendious term which supplies the place of a long periphrasis affords to the initiated the advantage of brevity—while to the uninitiated it is liable to appear pedantic and obscure. So that the addition to the list of technicalities of an art already containing a large number of them should not be made except where the new term supplies the place of long and continually recurring phrases, and is of itself sufficiently significant to be remembered without difficulty.

Now, in developing the principles of constructive architecture, we are constantly presented with this fact—that the architecture of every age and country of the world is separated as regards mechanical structure into two classes—that in which the masonry sustains vertical pressures only, and that in which both vertical and lateral pressures are sustained. The former consists of horizontal entablatures supported by vertical imposts, unjointed blocks or architraves resting at their ends on piers, and rectangular frame-work formed of transverse beams or joists sustained by upright timbers. In the other great division are contained all structures in which the intervals between two piers, columns, or abutments, or between the sides of an embrasure or other opening in a wall, are spanned by an arch consisting of many stones so shaped and united as to be capable of resisting the pressure of superincumbent weights. In the science of Mechanics the principles of these two methods of construction are distinguished thus—in the first method—that in which spaces are spanned by one single block or beam, the material is influenced by two equal and opposite forces of tension and compression—in the latter method where spaces are spanned by more than one block, the internal forces of the material are generally of the nature of compression only, but there are moreover lateral forces external to the system, exerting outward thursts or pressures which must be sustained by external appliances.

It is immediately obvious that these different mechanical principles must, where the decoration is dependent on the construction, produce altogether different architectural forms. Where the embrasures or intercolumniation are spanned by a single block, the difficulty of procuring single blocks of great length will render it necessary that the piers or columns should be comparatively close together, and as the pressures are wholly vertical, the only requisite for strength is that the columns be not crushed by the weight on them, and no great precautions need be taken to prevent them from being overturned by lateral pressures. Consequently, in the one mode the columns will be of nearly uniform thickness throughout their height, and the intercolumniations will be narrow: in the other mode, the intercolumniation may be increased and the piers will have enlarged bases.

These considerations in their utmost generality, distinguish all architecture into two grand classes: and when we regard the value and exceeding comprehensiveness of the classification, it does not seem unreasonable to demand that distinctive appellations should be appropriated to it, and be received among the recognised terms of architectural nomenclature. For the names of the two classes no words seem more natural than those contained in the title of the present paper, and accordingly we assume that all architecture is divided into two kinds—Trabeate and Arcuate.

Trabeate architecture is the most ancient. Very little reflection will show that a system of construction, identical with that of the primitive timber hut, would be the earliest adopted, and that the arch, a structure requiring much mechanical skill in the workman, and much theoretical, or at least experimental, knowledge in the architect, would be one of the appliances of later art. The early history of the arch is very obscure; it is however certain that neither Pelasgic, Babylonian, Egyptian, nor Grecian architecture present any trace of arcuate construction: the earliest examples which have had any important influence on modern art are certainly to be found among the Romans. The nature of this influence is admirably described in the following passages from Professor Willis's Architecture of the Middle Ages.

"After the arch and the vault had enabled the Romans to construct buildings with small materials, it is curious to observe the struggle by which the arch forced itself into the Decorative construction. At first, the arch is used sparingly, and only in cases of necessity. It is either hid under the plaster, or it is kept subservient and as if the architect were ashamed of it as a clumsy and economical expedient, all the resources of the Decorative construction are employed to *conceal* the important place it holds in the mechanical structure of the building. Gradually we find the vault first, and then the arch, assuming a more prominent place only to produce *that discordant effect which must ever result from the attempt to harmonise two contending principles.*

"For when the arch is employed, the diagonal strains must be provided for; and as the Decorative system of the Greeks was founded upon a mechanical structure that only exerts perpendicular pressures, it is clear that the diagonal ones must be concealed by huge rectangular masses, decorated so as to appear as if sustaining vertical pressures only, unless we choose to invent new forms for the diagonal props. The Romans attempted concealment, and hence introduced discordance between the decoration and mechanism of the structure. The Gothic builders, in later times, more wisely adapted their decoration to the exact direction of the forces required by the vaulted structure."—p. 17.

Every word of this extract demands the most attentive consideration. No other comment is here requisite than the citation of a few instances of that violation of the principles of faithful architecture which the Romans exhibited in their attempts to combine arcuate with trabeate construction. In the Coliseum the weight of each story is in reality sustained by tiers of arches: in addition to these, however, there are entablatures between the stories which, as well the columns between the arches, are merely affixed to the building for show, and have no constructive purpose. The same remark applies to the Triumphal arches, one and all: and these moreover involve the additional solecism of being treated not as members of a building, but as integral buildings of themselves—they have all the strength and solidity requisite for sustaining an immense superstructure, but like the monumental columns known by the names of Pompey and Trajan, are isolated and sustain nothing but their own mass, or at most that of statues of which the weight is ridiculously disproportionate to the solidity of the supports. This species of solecism has found great favour in our own country, and is exhibited on a large scale in the Barriere de l'Etoile, at Paris.

Much, however, of the architecture of the Romans was free from the incongruity described by Professor Willis, and even where it exists there is frequently discernible in spite of it (not in consequence of it), great beauty and pictorial effect, which cannot be overlooked without an intolerant adherence to systematic principles. It will, however, be our business to show hereafter that the Romans *gained* nothing by this sacrifice of purity and harmony—that equal vigour, variety, and depth of shadow may be attained without violating the principles of constructive decoration which were observed in Greek and Pointed architecture.

The opinion of the authority cited above is confirmed (with a modification similar to that which we have just suggested,) by Professor Whewell, who, in his "Notes on German Churches," speaks of "the Roman introduction of the arch into Grecian architecture" as follows:—

"In this manner, then, were produced two planes of decoration; one consisting of the traditional scheme of the structure; the other, behind it, containing the real construction—the arch and the impost mouldings. And though this combination is, in reality, *incongruous and inevitably transitional*, it would be impossible for a genuine artist not to perceive that it disclosed an extraordinary richness and depth of effect."—p. 8.

Again,—

"The introduction of the arch undermined the Grecian system of entablature, and introduced a double plane of decoration: the ruin of art and taste supervening on this, broke up still further the Roman traditional arrangement; caprice and the love of novelty introduced new forms of members and ornaments into this incoherent mass: arches, of various shapes, were invented or borrowed; the Byzantine dome was added to the previous forms of Roman vaulting. So far, all is a proof of disorganisation. But then comes in a new principle of connexion first, and unity afterwards. The lines of pressure are made prominent features; the compounded arches are distributed to their props; the vaults are supported by ribs; the ribs by vaulting shafts; the upright meeting of the end and side is allowed; the structure is distributed into compartments according to such lines, each of these being symmetrical in itself."—p. 15.

If the admirers of Precedent, those who confound antiquity and excellence as essentially synonomous, feel unwilling to admit the authority of two eminent writers who characterise a large part of Roman architecture, the one as discordant and dishonest, the other as incongruous and inevitably transitional, let them reflect that the Romans were, until the time of their emperors, so constantly engaged in foreign or domestic wars, that they had little opportunity for cultivating the arts of peace, even if they had not lacked the desire and capacity; that they never exhibited that pure love and vivid perception of the Beautiful which essentially characterised the Greek race; and, above all, that the Fine Arts were not indigenous with them, but imported—imported, moreover, as the exotic productions of a tributary province. The previous education of the Romans by no means qualified them for a comprehension of the subtle principles of Greek art; and when we consider that they appropriated its splendid results with no patriotic enthusiasm for them—with no higher feeling, indeed, than the love of luxury and the ostentatious magnificence natural to victorious invaders—it is scarcely to be wondered at that they misunderstood the spirit in which their glorious spoils had been designed. In a word, the Romans not only laid no claim to the artistic feeling of the Greeks, but actually boasted of the opposite tendency of their national genius; and the greatest of their poets so describes them in a noble passage, in which his evident object is to paint the character of his countrymen in its fairest colours:—

"Others, I know, will more skilfully mould the breathing bronze and shape the life-like marble; others will excel in the arts of eloquence; or, by the aid of philosophy, mark out the pathways of heaven and tell the risings of the stars. But, Roman! take thou heed to rule nations by thy might! These shall be *thy* arts—to dictate terms of peace, to spare the submissive, and subjugate the proud."*

In pursuing historically the development of arcuate construction, the next period of its progress is that subsequent to the destruction of the Roman Empire in the West at the close of the fifth century. The change which architecture now experienced was not one of mere individual form, but one which effected a revolution in its fundamental principles, and led ultimately to the most extraordinary results, by entirely destroying the old classic forms and substituting altogether new kinds of architectural composition and detail. The changes which followed the fall of the Roman empire, though essentially similar throughout Europe, assumed two different forms of expression in the North and South. To the Northern class belong the Norman of our own country, the Romanesque of France and Germany; to the Southern, the Lombardic style of Italy and Moresque of Spain. These two classes, though originating in the same type, never amalgamated at any subsequent period of the art. They possess, however, certain grand features in common, which distinguish them from their Roman model, and are especially to be noted as the real causes of the total change of art which ultimately ensued. The grand innovations of the Byzantine period were, then, the ostensible use of buttresses and the employment of columns to support arches springing directly from their capitals. Architecture continued, however, to exhibit the discordance between arcuation and trabeation: the style every where manifests itself as transitional and imperfect—and these evident marks of transition, it may be observed parenthetically, are of themselves sufficient objection to the modern imitation of Norman or Romanesque architecture. The buttresses of buildings of that period never possessed any great solidity; the lateral thrusts of the arch were chiefly resisted by the enormous thickness of the walls, Still a new and fruitful principle had been introduced—that of applying members for the exclusive purpose of resisting horizontal strains. The springing of the arch, also, directly from the pillars, led to greatly increased freedom of construction;—the architect was thereby enabled to get rid of the straight entablature, which had been a source of constant difficulty and restraint by giving to buildings a horizontal regularity, which, combined with the verticality of successive stories, confined the architect to what may be loosely termed a *reticulated* mode of construction. It is obvious, therefore, that until the arch was allowed to spring immediately from the columns, it would be impossible to build edifices possessing the diversity of form exhibited in the Cathedrals of Spires, Mayence, or Peterborough, or the church of St. Martin, at Cologne.

It will be seen, therefore, that the change introduced into the architecture of this period was a great step in the progress of arcuate construction towards its complete development; and although the contest between the arch and entablature was not yet won, the *casus belli*—the real discordance between the two principles—had received practically an accurate definition. The entablature still appeared, but was no longer sustained upon columns. Where it existed, it was either supported by arches or else was purely adscititious—that is, was simply affixed to the building for ornament, without any constructive purpose. Nor was it the only member of the architecture of this period which was treated thus inartistically: arches of decoration, corbel-tables, &c., were frequently introduced, not constructively, but merely as clumsy contrivances for giving variety to the surface of the masonry. It is an important practical observation respecting all mixed styles such as the Roman, Romanesque, and modern Mongrel Classic, that they necessitate the employment of adscititious ornaments to conceal the mechanical structure of the architecture.

Romanesque architecture—taking the term Romanesque in its most extended sense—may be considered to have lasted seven hundred years—that is, to the end of the 12th century. At that time, another great change took place in European architecture—the introduction of the *ogival primitif* of France and the Early English or Lancet style here. The great *formal* distinction between this style and the preceding is undoubtedly the introduction of the Pointed arch. But our present object is to trace not so much the changes of form, as those of construction which characterise successive styles. Restricting ourselves to this branch of the subject, we find the chief importance of the Pointed arch to consist in the lightness and loftiness of the structures in which it is employed. By known mechanical principles it may be shown that, *cœteris paribus*, the lateral thrust of an arch is diminished as the rise, or height of the crown above the springing, is increased. If, for instance, two arches, which sustain equal loads, are of equal span, and resemble each other in all other respects except their rise, be compared, the flattest arch will exert the greatest horizontal thrust. Now, in the semicircular arch the rise could not exceed half the span—in the Pointed arch, the rise was increased frequently three-fold, and occasionally four-fold. It will be seen, therefore, that in the new style the necessity of resisting lateral pressure would be greatly diminished, and accordingly the piers and abutments are found to be much less massive. The facility of sustaining great weights without cumbrous piles of masonry at their bases, lead to the adoption of that glorious characteristic of Christian architecture—the Spire; a member which the perversity of modern debased architecture has applied to buildings in which it necessitates incongruity or concealment of the mechanical construction.

Another important innovation of the Lancet style was the increased breadth of the buttresses. This change may at first seem inconsistent with the diminution of the lateral pressures of the arches; but it is to be remembered that in the preceding style, these pressures were resisted not by buttresses so much as by continuous walls of enormous thickness; and that in this style the thickness of the walls was greatly diminished. So that in the Lancet style, in fact, the appliances for resisting lateral pressures were not increased, but merely rendered more apparent. In the Norman style the whole wall formed one continuous buttress; in the new style this continuity was broken—the buttresses were put just where they were wanted, and no where else. Moreover, the form of this buttress was greatly improved: instead of being of a uniform height from the base to the summit (like the continuous wall) it became *tabulated*—that is, diminished by stages. To refer again to mechanical principles, we see how great an advantage was here gained. The mechanical requisites of a buttress are that the "line of pressure" should fall within the buttress in every part of it; so that provided the base be sufficiently broad and the diminution of the breadth of the buttress from below upwards be not too rapid, all the strength of a uniform structure is attained. The new form of the buttress, therefore, effects a vast saving of superfluous material, and, therefore, a great increase of architectural beauty.

No generic changes of arcuate construction were made subsequently to those described. The succeeding style (the Decorated of this country) introduced great variety and complexity of form, and the traces of the entablature are still fainter than in Early English. Still, considered constructively, the arch and its appliances remained unaltered. In the third style, however, the arch becomes far less acute than before. It is curious to notice in this, as in many other cases, the recurring cycle of variations, which seems to be a law of art. The first innovation of Pointed architecture was the lofty acute arch—now the arch becomes actually flatter than in the old Norman or Roman. As a necessary consequence, the piers and buttresses are increased in magnitude. We have now the piers of the nave of Winchester, the buttresses of King's College Chapel, and the flying buttresses of Westminster Hall.

The later Perpendicular exhibits in form, but not in reality, a return to the Trabeate system. Horizontal lines become more frequent than heretofore: but they are usually confined to surface-panelling, transom-bars, and similar details. They never exhibit themselves in true architraves, or single unjointed blocks. On the contrary, the extraordinary width now

* Excudent alii spirantia mollius æra,
Credo equidem: vivos ducent de marmore vultus;
Orabunt causas melius; cœlique meatus
Describent radio, et surgentia sidera dicent:
Tu regere imperio populos, Romane, memento.
Hæ tibi erunt artes; pacisque imponere morem,
Parcere subjectis et debellare superbos.—*Æn. vi. 847.*

given to arches and vaulting taxed to the utmost the resources of arcuate construction.

Then followed the decline of the arts. Pointed architecture became distinguished by conventionalism and over-refinement—the sure precursor of decay. Artistic feeling grew feebler and at last absolutely perished. A conclusive proof that it *had* perished, and that caprice had succeeded to its place was this—that men lost sight of architectural principles and cared only for architectural forms. There arose a strange classic mania, and, as might be expected in such an age, the classic forms were employed in utter ignorance or defiance of their right application. Every perversion and grotesque absurdity which empericism could invent or ignorance tolerate received sanction during the period styled the Revival. The confusion of arcuate and trabeate construction exhibited in Roman architecture was renewed in an aggravated form. Columns stilted to give them an undue height, their shafts deformed by square dies disposed at regular intervals, or channelled with sinuous lines in extravagant imitation of the natural roughness of unhewn stone were among the minor barbarisms. What shall we say of semblances of huge gables or pediments attached to the *internal* walls of buildings and ridiculous imitations of small gables arranged in rows on the external walls? Sometimes we find double pediments on the outlines of two gables represented in the surface of a wall by triangles set one immediately above the other. And sometimes we find portions of cornices cut away so as to leave a gap in the upper or lower part of the pediment; and at other times the pediment is polygonal or curvilinear, the curves having occasionally a contrary flexure. No amount of precedent would sanction these abuses which seemed to have been perpetrated for the express purpose of bringing the Classic forms into disgrace. Moreover, the weight of Precedent, if in this case it have any weight, is on our side, for it was the Revivalists, not we, who rejected its authority by appropiating the ancient forms to strange and novel uses.

It belongs immediately to the subject to observe that in the history of Art the decadence of constructive arts has generally been coeval with the advancement of the decorative. At the time when architecture has flourished, painting, sculpture, &c., have generally been neglected, and conversely. The noblest, purest, most faithful architecture which the world has seen since the Christian era, belongs undoubtedly to the age of Cologne Cathedral: and yet the uncouth forms of monumental brasses, wood carvings, and painted glass, of that age, are inartistic in the extreme. They are for the most part incorrect in drawing, shadow, or perspective; inaccurate in the anatomical forms and proportion, and manifest that stiffness and uncertainty in the use of the chisel and pencil which infallibly mark the first efforts of rude art. Monumental sculptures did indeed occasionally exhibit great merit, but these works are rare exceptions; and those of them which exist in our country seem to have been the productions of foreign artists. In proportion however as architecture progressed toward decay, the decorative arts established themselves on its ruins. The Chapel of Henry VII. at Westminster is filled with the most beautiful carving; and his tomb is one of the last and noblest productions of mediæval art. The painted windows of King's College Chapel have no parallel throughout the world for magnificence: executed probably after the completion of the building, they exhibit far higher merits than those of gorgeous colouring and minute workmanship. The composition and drawing of the east window in particular are wonderful proofs of the excellence to which the decorative arts had attained.

Of the era of Raphael it does not lie within the compass of our subject to say more than that the magnificence of its sculpture and painting presents a strange contrast to the impurity and incongruity of its architecture. Once, and once only, in the world's history, a Phidias and Ictinus appeared *together.*

The classic Revival affected England more slowly than the rest of Europe. Among a people, whose attachment to particular forms and customs is slowly contracted and long retained, an imported style of architecture would not easily find favour. Even after Pointed Architecture had died of old age, many of its forms were retained. The windows of the Debased Tudor style are mullioned and retain their hood mouldings. The Elizabethan frequently shows a great deal of constructive faithfulness and picturesque effect, and where it is tolerably free from classic details, presents much that is worthy of modern imitation.

There was a trabeate style which reached its greatest perfection in the reign of Elizabeth, which is to be noted as especially remarkable for its character and the time in which it appeared. We mean the timber framed architecture of the halls and manor-houses erected in this reign. This style is frequently exhibited in great magnificence in this country, and in parts of the continent, such as Belgium and Normandy, where timber is abundant. The cities of Ghent, Bruges, Rouen, &c, display beautiful specimens of street architecture, which put to shame our modern system of showy decoration. It seems singular that a style almost purely trabeate should have flourished at a time when great efforts were made to effect an incongrous adaptation of Classic forms to arcuate construction. Nor is it less remarkable that the timber-framed style should be so nearly faithful as it is. The gables are treated constructively as the ends of roofs, and where columns are used, they are generally used as supports. The fashion of affixing columns upon the faces of walls, where they appear as mere protuberances, was of later growth.

The Elizabethan and timber-framed were the last of the original styles. The houses of the period of Queen Anne have indeed a certain degree of character from the conspicuous use of the plate-band or straight arch in doors and windows. Still it may be considered with sufficient accuracy that no new species of construction was introduced subsequently to the reign of Elizabeth. Since that period architecture has consisted in the imitation of ancient styles and the reproduction of ancient forms.

We have therefore arrived at the conclusion of the historical portion of our subject. The application of the principles which distinguish arcuate and trabeate constructio to modern architecture, will be the subject of another paper. These principles have been so systematically violated during the last three centuries that great difference of opiuion will exist respecting their importance in architecture. The historical sketch here given may however be useful in indicating a plan for compiling an altogether new kind of History of Architecture. Numerous writers have already chronicled the successive changes of architectural forms—the history of Architectural Construction remains to be written.

CANDIDUS'S NOTE-BOOK.
FASCICULUS LXXI.

"I must have liberty
Withal, as large a charter as the winds,
To blow on whom I please."

I. Those who have suggested—altogether prematurely, it now seems—the Tudor style, for a new metropolitan royal residence in lieu of Buckingham Palace, have overlooked one or two objections that present themselves. In the first place, the Queen herself might wish for something altogether different from Windsor Castle,—for a "companion" or "*pendant*" to it, but distinct from it in character, and affording opportunity for exhibiting quite another mode of embellishment. In the next, were it to be at all similar in style to the "Palace of Westminster," immediate comparison between the two would be the consequence, and as it is not at all likely that a second palace would at all rival or approach Mr. Barry's edifice, in luxuriant ornateness, the comparison would hardly be to its advantage. Thirdly, domestic Tudor or Elizabethan are now so frequently employed for buildings, which however large they may be, are the reverse of palatial in purpose, that owing to the modern application of them those styles are now in some degree identified with hospitals and other public buildings of that class.

II. Surely it must have been said for Wilkie, since he himself could hardly have uttered such a piece of extravagance as to assert that, "what the tour of Europe is necessary to see elsewhere is now found congregated in the single city of Edinburgh!"—At any rate he could not have uttered any such arrant claptrap in his sober moments, for only the influence of "mountain dew" could have enabled him to find "the bays of Genoa and Naples, the Roman capitol, and the Grecian Acropolis, there realized." Pity! that he could not fancy Venice there also, and take St. George's church for another St. Mark's. If nature has been somewhat liberal towards the Northern capital by affording it a picturesque site, art has been stingy enough. The locality may be called romantic, but the architecture is shockingly prosaic. Scarcely a single edifice in the whole city can be quoted as a monument of art or superior taste, least of all those which have been erected for the nonce as "monuments," to wit, the Nelson one—a thing so truly contemptible that its architect has prudently preserved a strict incognito;—the fragment of the Calton Hill Parthenon that was to have been; and the Scott structure, which, sooth to say, is but a very so-soish specimen of Gothic. Probably some of the more recent buildings may show a little advance in architectural taste, but hitherto it has been at a very low ebb indeed, a good deal of the Edinburgh architecture being truly Pecksniffian, although it has the advantage of being all of genuine stone; yet it would, perhaps, be more correct to call that a disadvantage, since the durability of the material serves to perpetuate and record the poverty of design exhibited in the buildings themselves, and their utter want of æsthetic value. Though the picturesque of filth and wretchedness may be found in many of the "wynds" and lanes in the older part of the city, the modern architecture of the Northern Athens is almost the reverse of pictorial,—chillingly cold, tame, and insipid; which accounts for the picturesque just mentioned being selected by draftsmen and illustrators in preference. The stone edifices of Edinburgh reconcile us to the "lath and plaster" ones of London;—as to the matter of the "lath" it happens to be invariably of brickwork, therefore far more substantial than it has the credit of being; and as to "plaster columns," there is no occasion to rail at what exists only in imagination, unless it has been found that either cast-iron or brickwork becomes transformed as to mere plaster, as soon as it is plastered over.—To skip back to Edinburgh, its buildings *sound* much *better* than they *look*, which accounts for the architects themselves not ever publishing designs of them, notwithstanding the admiration they seem to excite, if we may judge by the vapouring made about them. Drawings are in one respect the best test of architectural design, because design is then judged of by its intrinsic merit and the taste displayed in it, apart from adventitious circumstances, and those of material; the excellence of which last, or the contrary, is not to be imputed to the architect himself. In drawings, while stone buildings show no better than if they were of meaner material, the merit of tasteful design in "lath and plaster," may be enjoyed without any drawback, and we have the satisfaction of knowing that if the structures themselves are of perishable quality, their beauty is rescued from destruction and preserved by the graver, as is the case with many antiquities, and also many far distant buildings which we are acquainted with only by means of the representations of them.

III. The Institute is no Society for the Diffusion of Knowledge either useful or useless. What knowledge it gets it keeps to itself; and truly, knowledge is so valuable a commodity that it ought not to be squandered away in lavish largesses to the public. The Institute is perfectly free from the mania of proselyte-making; it has no notion of encouraging architectural "education for the people," but leaves the people, or people who would fain understand something of architecture, to instruct themselves as well as they can, or else—which is perhaps better still—to remain in ignorance. Nor, indeed, is it by any means certain that a more general diffusion of taste for the art would at all increase the amount of admiration now bestowed on some of its productions and their authors, or the amount of satisfaction derived from them to the public. Great truth is there in the maxim of *omne ignotum pro magnifico*, as there is also in the remark that "familiarity is apt to beget contempt;" and there most assuredly would be danger of its being discovered how very little mind, or talent of any sort there is in many things that have been cried up as wonders. Thanks to their convenient ignorance, there are a good many honest people who have no suspicion whatever that the "fine" and "grand" columns they behold, and whose "hard names" are to them a mystery, are only copied from patterns got out of books. It would be cruel to undeceive them,—to dissipate the dreamy wonder that now fascinates them; and cruel not only to them, but also towards those whose works now pass with the ignorant for marvels of art. If the public is to be liberal with its admiration, it must not be *clairvoyant*. On no account should it be suffered to know enough to be able to criticize fairly and justly; so that it can but find words for praise, that is sufficient, and if they are somewhat ill-applied, they are not, on that account, likely to be the less laudatory, or less magnificent in sound. It is, however, exceedingly difficult to hit the exact mark, and to keep the public at that convenient point of the thermometer of taste, where ignorance of art is so free from indifference towards it, as to be accompanied by a praiseworthy relish for it. While it is proper, it would seem, that persons in general should not be at all instructed in architecture, it is desirable that they should take great interest in it, and be disposed to encourage it very liberally. Architects are apt to complain of the obtuseness and obstinacy of employers—of the stupid whims and caprices which have caused many a fair idea to be marred, but they do not perceive that the only real remedy is to be sought in the better instruction of that class of the community to which architects look for their employers.—But I am interrupted—

IV.—A packet has this very instant been put into my hands; I open it, and find a book, I open that too, and turning over its leaves immediately alight upon the following very free remarks upon the Institute:—

"Their policy, I say, is bad, utterly bad; but I do not say blameable: it is *mistaken*. They have, I doubt not, as sincere and honest a desire for the advancement of the art as I could possibly claim; but their policy is a false one, and in manner as well as in matter. The doctrine of the Institute is false; the constitution of the Institute is false likewise. And when I point out (according to my judgment) the errors in general faith, I would point out also (as equally important), the errors in government of our national school of the art. The Royal Institute of British Architects has not a free liberal constitution. It is beneath the level of other institutions of the country. And this ought not to be. Mistaken doctrine is bad, mistaken policy is perhaps worse. The narrownesses, coldnesses, roughnesses, of much of our social system are expanding, warming, softening, in these days. Year by year the thoughts of men are widening. And the broader basis, the kindlier liberality, the freer liberty, have never failed to be productive of good!

"The curse of the Institute is the constitution of its Council,—an irresponsible and despotic secret government, which, in the circumstances, it would be preposterous to expect to rule otherwise than with narrowness, jealousy, and pique, wanting in ingenuousness, weak in disinterestedness. There are cases in which a committee of the noblest and best could not possibly be otherwise than a clique. The Institute is no representative of the Architects of Great Britain at all. And it is but natural: to become so (as it ought to be) it must change;—and first its government; its doctrine will come secondly in due course. Its gross *exclusiveness* generally is a grand error.—It is too professional, another grand error."—Dr. Verd. "Tell us then, friend, what thou wouldst have it to be."—Mr. Newl. "A *broad-based*, *free*, *disinterested* school of architecture;—*open to all* who love the art,—old and young, professional and non-professional *alike*;—a free theatre of *liberal discourse*,—a society of *artists* and *art-lovers* in architecture, for the ends of architecture *purely*; sly *ballot-boxes* and *secret councils* utterly overthrown, as tyrannical, illiberal, and bad. That is what I would have, and what the public of England, and *architects* especially, are entitled to *demand*.—Let the Institute change its character, and repudiate all close-fisted and selfish policy,—all *professionalism*,—and hoist the banner of *art*, free to all, and to all equally."—*The Newleafe Discourses*.

V. A capital fellow that Newleafe! and a capital book!—one likely to do a great deal of good, by clearly explaining the character of architecture as a fine art, as which it is now scarcely recognised at all, except merely nominally and by courtesy; nor have architects themselves much clearer notions of it than those who are not architects. Not only is its doctrine excellent, and perfectly free from all conventionality, and cant, but the book itself is so clever and entertaining, so full of original thinking—of shrewd remark and caustic pleasantry, as when once opened to be found irresistibly fascinating. Even those who dislike the writer's opinions, and more especially their being uttered to the world, accompanied with so many home-truths—and they will not be a few—will be forced to read on in spite of themselves. Speaking as he has done of the Institute, it argues considerable boldness in the writer to put his real name on the title-page; one which till now has never been before the public, but which is likely to be henceforth more and more distinguished, since it is not to be supposed that one who has made his *début* with so much spirit, will now lay down his pen. Some parts of the book are quite dramatic, and the characters of Mr. Scamozzi-Brunelleschi Brick, Dr. Bluebottle Crape, the antiquary, Mr. Cœur-de-Lion Mwffe (*sic*) the ecclesiologist, and little Smug the travelled architect, are admirably hit off characters, with merely the slightest *soupçon* of caricature. What the Vitruvianists, the archæologists, the Camdenists, and the Ecclesiologists will say of the "Newleafe Discourses," is more doubtful than what they will think. Probably they will, as the wiser course, say little or nothing, but that they will think Newleafe a formidable opponent is an assured certainty;—and all the more formidable because he will have the public on his side, and his example may stir up others to continue the assault upon those inveterate—not, it is to be hoped, invincible prejudices which beset architecture on every side. One commendable trait of spirit in the writer is that he shows himself perfectly free from *flunkyism*; he is not awed by the authority of names, pays no servile deference to professional rank, but censures erroneous opinions in "a Professor," with just as little ceremony as he would in any other individual. Both Professor Cockerell and Professor Willis get a few rubs from him; and if they deserve them, why should they not? At any rate they are game worth aiming at, whereas some others are hardly worth powder and shot.

FENESTRATION AND WINDOWS.

THIRD ARTICLE.

In returning to our subject we shall not pursue any farther our remarks on Fenestration in connection with modern church architecture, because we purpose going into the latter subject generally, and inquiring how far it is adviseable entirely to repudiate for buildings of that class, the Greco-Roman style, instead of taking it up again with a fresh and better spirit, so as to infuse into it renewed vitality. We will, however, just advert here to one unseemly defect which deforms most of our churches in that style—if, indeed, they can be said to belong to it, very few of them possessing what can fairly be called style at all. We allude to the practice of making a row of small mezzanine-looking windows beneath the others, to the great injury of character, composition, and breadth, and of unity likewise, for such little windows seem to express a division of the building into distinct floors within, and appear to belong to low ground-floor rooms intended for inferior purposes. At any rate such apparent division of the structure must be considered an indefensible solecism by those who make it an objection against St. Paul's, that its exterior is divided into two orders. In some cases, indeed, the practice in question is harmless enough, there being neither beauty nor pretension to it, nor any kind of architectural quality to be injured by it; but in St. Pancras' church the small lower windows are glaringly and offensively at variance with the scrupulous—perhaps somewhat over-scrupulous adherence to the original classical pattern, which, unluckily, not going far enough for the occasion was eked out with some "ready cut and dried," but not very classical ideas.

From what we have just been saying the transition will not be very abrupt, if we now proceed to consider one very material point in Fenestration with regard to composition. We have already said that *interfenestral* breadth is one great requisite for good fenestration—almost essential for greatness of manner and dignity of character, and have now to observe that there ought to be "breadth" in both directions—vertically as well as horizontally, for if there be not corresponding largeness of spacing between the several tiers of windows or floors of the building, as well as between the windows on each separate floor, the design will so far partake of littleness and be of the ordinary stamp. Quite contrary to vulgar opinion it may safely be laid down as a maxim that dignity of expression in architecture is in inverse ratio to the number of windows or aggregate superficies of opening compared with the general surface of the building or entire elevation. It is not the frequency, but the paucity of windows that conduces to nobleness of physiognomy in architecture; whereas, on the other hand, that quality—the unquestionable aristocratic mark—can hardly be maintained at all where inflexible necessity demands closely-spaced fenestration. No matter what size a building be, without something like greatness of scale,—nobleness of taste of course included,—its greatness will amount to no more than the vulgar quality of mere bigness. And unfortunately—or rather, fortunately, grandeur of scale is what cannot be mimicked or counterfeited. It is not to be produced by clubbing a number of ordinary-sized houses together into one elevation, for the individual littleness leavens the whole mass, and the larger the latter is, all the more strongly does the littleness which it is attempted to disguise, contrast with the more than ordinary pretension that is made so indiscreetly and so awkwardly.

The two houses facing each other at the Albert Gate, Hyde Park, seem to have been expressly intended to make manifest the striking difference of character produced by closely or widely spaced fenestration; for though they are of the same size, and in other respects alike, while that on the East side is only three windows in breadth, the opposite one is of five, and the very superior appearance of the former must, we think, strike every one who has the slightest tincture of architectural taste.* Yet if so far that East house excels as well as differs from the opposite one, in another it resembles it in regard to fenestration, aud perhaps even to greater disadvantage, it becoming in consequence of unequal character, insomuch as it consists of the same number of stories, therefore the *vertical interfenestration*† is not so good as the *horizontal*, owing to there being too many tiers of windows, and they are put too closely together—or in other words, and to express our meaning by a single term, the interfenestration in that direction is *thickset*, or pycno-fenestration; and, as has been already observed by us, although pycno-style columniation produces richness, pycno-fenestration is generally attended by an air of littleness, if not of meanness. Except in Gothic—the Perpendicular and Tudor styles, also Elizabethan, wherein fenestration may without impropriety be carried to any extent, it being, as we have already said, highly characteristic and expressive also of construction,—crowded fenestration produces confusion, and a great deal more than the space properly admits of, seems to be crammed into a front. As an instance of the kind—an example that forcibly illustrates what we have just said, we may point to the group of three tall stone-fronted houses erected a year or two ago in Grosvenor Place: intended to be more than ordinarily dignified, they are so terribly deficient in amplitude of proportions, as to look compressed and crushed horizontally, while loftiness is obtained not by lofty proportions, but merely by piling up an unusual number of stories. Another example of the *ad evitandum* class is the Atlas Insurance Office, Cheapside, and a remarkable one it is for *mesquinerie* and tastelessness both in regard to fenestration and to columniation also. We will not at present touch upon what some are altogether intolerant of, and peremptorily denounce without further consideration as a barbarous solecism—we mean the application of columns and pediments to the windows themselves,—because that is a matter which we shall have to discuss somewhat fully when we reach that part of our subject, but we certainly have nothing to say in favour of that particular specimen, for besides that the columns to the windows crowd up the intercolumns of the order, in which they are set, too much, the display affected by means of them is so far from being consistently kept up that their entablatures are even more bare than those usually employed for windows, there being instead of architrave and frieze, or moulded architrave only, a mere black surface between the capitals of the columns and the cornice, notwithstanding that the capitals themselves are Corinthian. The division of the building into two distinct orders,—one for each floor above the basement; cuts it up very disadvantageously, causing it to appear upon a contracted scale, whereas had the composition been astylar, it might have possessed a greater degree of ornateness as well as simplicity, for at present the details are very crude and common-place.

We now proceed to consider what is a very important matter in fenestration, whether with or without columniation, namely, the number of windows from the ground upwards, or of tiers of them, that can with good effect be introduced in architectural composition. And here again we find that it is paucity, not number, which contributes to nobleness of manner. A front may be prolonged horizontally to any extent, without the fenestration itself being thereby in the slightest degree affected, but it cannot be extended upwards *ad libitum*, by adding story to story. On the contrary, the maximum is very limited, if good composition is to be observed, it being scarcely possible by any sort of management to introduce more than three rows of windows—that is, two besides the ground-floor—into a well-proportioned elevation. The greater the number of stories, the smaller do the windows become in proportion to the general mass; and though if looked at as a mere pile of building, the structure may be striking enough by its unusual height, and perhaps possess even some degree of grandeur when it comes into view as a distant object, it will be any thing but dignified in regard to architectural physiognomy; and littleness of manner will be aggravated in the same ratio as the number of stories is increased. Therefore whatever pretension be affected for them by means of decoration, many-storied houses—even when combined with others so as to form a general elevation, well proportioned as to relative height and breadth,—are the reverse of aristocratic in appearance, inasmuch as they look more like barracks than palaces—or if not exactly like barracks, like large hotels and lodging houses—buildings erected for the accommodation of a number of families upon a limited ground-site.

If orders are employed—and in combination with windows, pseudo-columniation (or attached columns) is preferable to the genuine—considerable difficulties are apt to arise, both as regards fenestration and the order

* Since it was first erected, however, the front of that house has been most barbarously disfigured by one of the ground-floor windows being enlarged, without the slightest regard to appearance in any one respect. The house seems to have fallen into the hands of some tavern-keeper.

† We make no apology for coining and employing what some will object to as "new-fangled" words: they are sufficiently intelligible and expressive, and being expressive are useful. Well grounded objection there may be to the merely disturbing the terminology of the art by the revival of obsolete terms in lieu of those in general use, or by substituting for the latter, others which if more correct are only equivalent to them; but it is surely rather desirable than the contrary that the deficiencies in our present architectural vocabulary should be filled up, which can be done in no other manner than by inventing sufficiently significant terms for the respective occasions; and of course when they first come up they are liable to be called "new-fangled":—what then?—to stand in awe of the reproach of "new-fangled" is downright "Old Ladyism." The Germans, we find, have begun to adopt from us—at least adopt into their Art-lexicons, the terms Diprostyle, Triprostyle, &c.; yet we have heard them, if not positively objected to, attempted to be depreciated, because—O what an excellent and sagacious "Because"!—because any one acquainted with the Greek numerals might have formed them—and we suppose also becaus tehey are so exceedingly simple, clear, and intelligible, when once explained, that a child may understand them.

itself. Good composition does not admit at the utmost of above two tiers of windows in the intercolumns, and even then it is better if the second range of them are either mezzanine ones, or very little more in height. Therefore, if two stories are required above the ground-floor, the latter must be treated as basement, and the order be elevated upon it,—the course which Barry was forced to adopt in altering the Board of Trade. That done, an additional range of windows can be obtained only in the form of an attic story, because to put a second order over one which comprises more than a single floor, and therefore ought, exclusive of other superstructure than a mere attic, to complete the elevation, is beginning again, and piling up one building on the top of another. Either there ought to be a separate order to every separate floor—no matter how many, —or if the composition be not regulated that way, there ought to be no more lines of windows than will properly come in within a single order. As far, indeed, as precedent to the contrary avails anything, it may easily be found, as it may for a great many other faults of composition, and we have now got precedent for *poly-fenestration*—so to describe it—in conjunction with an order, where three tiers are inserted into the intercolumns, such being the design of the front of the Royal Institution in Albemarle-street, and the wings of the British Museum. In one respect, perhaps, such disposition seems to suit colmumniation exceedingly well, because the intercolumns are kept narrower; yet that single advantage is considerably outweighed by several inconveniences. While, on the one hand, fenestration preponderates too much in the general composition, owing to the multiplicity of windows; so, on the other, does columniation (columns or pilasters, as may be the case,) make the windows appear comparatively insignificant features; nor is it the columns alone that do so, for they being nearly as much in diameter as the width of the windows, the entablature, proportioned to them, seems quite disproportioned to the height of the floors. The consequence is, the order and the building itself are upon different scales; the former has the look of having been originally intended to form an open colonnade, whose intercolumns have been afterwards built up and filled in with windows, as was actually the case with the Temple of Antoninus, at Rome, which Bernini (if we mistake not) converted by such process into the Dogana or Custom-house. Thus the temple and house-front characters, irreconcileable and repugnant to each other as they are, are brought into immediate contact with each other. The Albemarle-street building is evidently *after* the Roman one, and the Museum wings are not much *behind:* all that is not column is window, and *vice-versâ*. If, however, such mode has nothing to recommend it æsthetically, it has the merit of being an exceedingly simple one, and of evading a great deal of trouble.

RUSTIC MASONRY.

We have been compelled by the more immediate urgency of other subjects to defer till now the reply to the paper on Rustication, by Candidus, which appeared in our August number. Free discussion respecting the principles of architecture is by no means to be discouraged, for during the last three centuries mere conventionalism has so completely usurped the place of true art, that we may easily foresee the long and obstinate contest which prejudice will wage against the resumption of correct principles. Still, the discussion, however necessary it is for ultimate success, must be restrained within certain limits; and we therefore feel entitled to protest against the controversial tone assumed by our opponent. The paper to which we are about to reply, commences with the assumption that our profession of willingness "to be set right," was insincere; and though there has been no hesitation in bringing this charge of disingenuousness, not the least attempt is made to support it. Bare assertion can only be met by counter-assertion, and it therefore seems sufficient to assure Candidus that our declaration of readiness to listen to temperate reasoning was made in perfectly good faith, and that we see no reason to repent of having made it.

These preliminary remarks seem the more necessary because the chief object of the present paper will be not so much to defend our original arguments, as to show that the purport of them has been generally misunderstood in the subsequent paper. Passing over, therefore, the first paragraph, in which the writer states, with singular modesty, his intention of exposing the "futility and one-sidedness" of our objections, we come to the first argument properly so called:—it is, that as this country possesses neither the marble nor the climate of Greece, our masonry will not retain perfect uniformity of tint and surface, and that it is an advantage to obtain a different species of regularity by the means of rustication. This, like most apologetic argument, proves too much; for the direct conclusion from it is that rustication should be employed in this country—not occasionally—but always. The rule would stand thus that in Greece and all "sunny climes" rustication should *never* be adopted, but that in all northern or humid countries, the joints of masonry ought on *all* occasions to be bevilled in order to palliate the effect of diversity of "tint and surface." In this case then, unfluted columns, such as those of the portico of the Royal Exchange, should be marked by a series of horizontal annuli at the junction of the blocks composing each shaft. The same argument would apply to Mediæval architecture also, and we must conclude that the walls of our cathedrals would be improved in appearance if covered with a rectangular mesh-work of horizontal and vertical lines.

The next paragraph attributes to us a condemnation of all that has been added to or engrafted upon Grecian architecture—a condemnation of Roman and Italian architecture. This statement is inaccurate—we would indeed reject the combination of the principles of Greek architecture with other discordant principles, and readily avow that many (not all) of the innovations of the Roman and Italian styles were inharmonious. This however does not amount to a total condemnation of those styles, and we have elsewhere attempted to point out in the paper on "Trabeation and Arcuation," the true method of discrimination. We may here notice, out of its course, an assertion in another part of the paper now under discussion, in which we are accused of "fairly damning modern architecture altogether." The charge is as unfair as it is unfounded; if the object of it be to enlist the prejudices of the reader against our arguments, it signally fails of its effect, for we have never condemned any modern building in which the canon of architectural faithfulness is tolerably well observed. We have frequently spoken of the superiority of modern architecture to that of the last age, and have occasionally done even some violence to our opinions, by speaking in terms of partial admiration of buildings which exhibit little regard for principles of constructive decoration.

The objection that our views respecting rustic masonry ought for consistency to be extended to the fluting of columns seems purely factious, since it is obvious that parallel lines of fluting contribute to the principal æsthetic idea of columns—their verticality; whereas our main argument against scoring masonry all over with a vast number of lines running both perpendicularly and horizontally was that they distracted the eye and suggested no æsthetic idea whatever. The remarks respecting the Madeleine, must have been written in total misapprehension of our meaning, or else are the result of a hasty and careless inspection of that building—if indeed there be not an attempt on the part of the writer to criticise the architecture without having *seen* it. We will venture to say that no competent observer, who has actually inspected the Madeleine, will contradict our assertion that the horizontal channels indented in the walls of the cella greatly injure the effect of the periptery. The columns do not stand out with that bold relief, which they would have, were the background left plain, and their vertical character is greatly injured by the horizontal lines running behind them and apparently meeting them at right angles. This is so notoriously a matter of fact—of common observation, that it has never yet been disputed by those who have seen the building. However, we may perhaps facilitate the proper conception of the argument by referring to analogous instances nearer home. If Candidus will examine the two last plates in this Journal, representing the Board of Trade as it was, and as it is, he will find in both façades a number of horizontal lines extending the whole length of them, which distract the eye and almost destroy the vertical character of the columns. In the later edition of the Government offices the rustic lines are not continued quite up to the columns, but stop against a plain panel; still the defect is but little palliated by this contrivance—the mental eye continues the lines, and the natural eye is consequently offended by the incongruity and confusion. The same remark applies to the windows between the columns: the mouldings of the sills and architraves range in horizontal lines, and the effect is nearly the same as if those lines were continued to meet the columns. This seems the true reason for the axiom laid down by many architectural writers that two ranges or stories of windows ought not to be included within one order of columns, and also for the objection laid down in the article on Fenestration (p. 271), that where windows are introduced between a colonnade "the columns seem as much to encumber as to adorn the front behind them, certainly not to belong to it by growing out of the general organization." The horizontal lines of the sills and architraves are mentally united by the observer, and have the effect of being continuous: the eye recognizes the windows, not separately, but collectively as one range; and the general direction of this range being horizontal, and therefore at right angles to the columns produces inevitably the appearance of disconnection among the component members of the architecture.

The paragraph in which the rusticated masonry of the Madeleine is defended, concludes by attributing to us certain opinions on Grecian architecture which the writer justly treats as absurd. As, however, we never expressed these opinions, we are not called upon to defend them.

Of the Architecture of Newgate it is observed, "had it not been rusticated, it would have been comparatively an insipid blank." Why, yes; this is true enough, and it brings us precisely to the very gist of the argument. Our real ground of objection to rustic masonry is not so much that it is intolerably ugly in itself as that it stands in the way of something better—bold and effective composition. Had the architect of Newgate been debarred from the paltry expedient by which he has palliated the nakedness of his design he must have contented himself with this alternative—either to let the poverty of his ideas manifest itself undisguised, or else to substitute a design possessing intrinsic and legitimate merit.

On examination we shall find the same remark applicable to the general employment of rustic masonry. Where the architect possesses real genius and correct principles of taste, the beauty of his architecture will be attained by massive combinations, by effective distribution of light and shadow, by graceful proportions, by strong contrast between the decorated and undecorated parts, and by making the mechanical construction of the building a source of beauty. In proportion as his conceptions are vigorous and effective, he will have the less necessity to resort to rustication and other insipid inexpressive save-trouble expedients. We would deprive architecture of these expedients for the same reason that we would deprive a child of its go-cart—that it may learn to run alone. When these tricks of art are got rid of, good architects will be *forced*, as it were, to trust in their own strength, and bad architects will do as they always have done—follow their betters.

If our opponent could have assigned only one good reason why rustication should be employed in Classic and not in Pointed architecture, we should have been satisfied that he argued on abstract principles, and that his judgment had not been (as we sincerely believe it to have been) perverted by custom. This opinion is not uttered invidiously, for we know how hard it is for those who have been long habituated to technical rules, to look beyond them. It is well enough to tell us that "separate styles have, like separate languages, their respective idioms and peculiarities;" and that Rustication may be considered as a characteristic peculiarity of one kind of Classic architecture—"as being part of its costume, consequently proper to that, though in any other it might show as a decided impropriety." But why—for what reason an impropriety in any other style? The only possible answer to this question is to show that the style with which alone rustication harmonizes, possesses certain distinctive principles which produce this harmony, but which exist in no other style. If there be such principles in Classic architecture, it is surely very easy to point them out. We all know what are the main distinctions between Classic and Pointed architecture: the one is horizontal—the other vertical; the one simple—the other complex; the one rectilineal—the other curvilineal. To which of these or the other distinctions between the two great architectural systems are we to attribute the circumstance that rustication accords with the one, and not with the other? This will, we think, be found on reflection an indisputable position—that either rustication offends against those Catholic principles which apply to all styles alike—or else that Classic architecture has certain principles, possessed by no other style, which render rustication applicable to it alone.

Which member of this alternative is to be adopted? If the first, there is an end of the controversy. If the second, our opponents have still to point out the existence of the principles by which their position is defended. Therefore the whole question may in some sort be said to turn on the causes of the incongruity of rustication with Pointed architecture. Now, as far as we can see, it would be less incongruous with Pointed than with Classic architecture, for the former delights in a multiplicity of lines which is directly antagonistic to the latter.

Our objection that rustication precludes a contrast between the ornamental and plain parts of the structure has not yet been answered. To our view, decorations derive their chief grace and fitness from *contrast*. If *every* part of a building were richly ornamented it cannot be denied that a dazzling and gorgeous effect might be produced. But the most *artistic* architecture is not that which is most ornamented, but that in which the decorations and plain surfaces are balanced against each other—in which some parts are purposely left undecorated in order to enhance the beauty of the rest.

The connection between the subject in dispute and that of mouldings seems also to have been misunderstood. The æsthetic value of mouldings seems to consist in this, that they mark distinctly the mechanical construction of a building. In Classic architecture the cymatium, &c., mark the outline of pediments; the antepagmenta of doorways, the tænia indicates the super-position of the cross—joists on the architrave and the mutule marks the termination of the inclined rafters of the roof: in Pointed architecture the hood mouldings defines the arch of the windows, the corbel table indicates the manner in which a roof or upper floor is supported: in Italian architecture also the division of a building into stories is frequently with the utmost propriety exhibited externally by horizontal mouldings. But without the mouldings have thus a logical fitness, they are adscititious and indefensible. It is clear moreover that their value as indications of construction must be nearly annihilated where the *whole* surface of the walls is marked with lines like those of rustic masonry. In such cases they cease to be *distinctive*.

Another misapprehension of our meaning respecting rustication is the supposition that we have insisted "that it is absolutely intolerable." This is not the case: on the contrary, we think there are many buildings which as they stand are improved by it, or rather would be worse without it. It is not rustication, so much as the necessity for it, which we wish to get rid of. There are many buildings—the Reform Club for instance—of which the architecture is intrinsically too good to need such embellishments.

The true end of art is to produce the greatest effect with simple means. It is easy enough to overload a building with mouldings and sculpture—to do that requires not genius but money; and the vulgar, caught by the glare, will give to the architect the credit which is in fact due to the workman. Architecture, except during its purest periods, has always tended to degenerate into a system of surface-decorations. It is so now, and ornament usurps the place of architecture. Directly the system of polychrome decoration was revived how eagerly was it caught at! It is such an easy method of making a building look showy! Fresco-painting also, encaustic tiles, and cheap imitations of costly woods will often save the architect a world of trouble—the trouble of thinking. And yet these things are not intrinsically worthless, or to be despised; unlike Rustication, they are valuable accessories of art, but no more than accessories—excellent servants, but bad masters.

THE NEW PLANET.

The discovery of a planet of which the existence, distance, orbit, and mass had been *predicted* by mathematical computation long before its presence in the heavens had been recognised by the telescope, may justly be considered, as Mr. Hind observes, "one of the greatest triumphs of theoretical astronomy." It cannot but be a matter of regret to find the new planet called Le Verrier's, whereas in fact the first theoretical discovery of it is due to Mr. Adams, who to our certain knowledge completed his investigation, as far as the approximations of the first order, two years ago. Sir John Herschel has addressed the following letter on the subject to the *Athenæum*.

Collingwood, Oct. 1.

"In my address to the British Association assembled at Southampton, on the occasion of my resigning the chair to Sir R. Murchison, I stated, among the remarkable astronomical events of the last twelvemonth, that it had added a new planet to our list,—adding, "it has done more,—it has given us the probable prospect of the discovery of another. We see it as Columbus saw America from the shores of Spain. Its movements have been felt, trembling along the far-reaching line of our analysis, with a certainty hardly inferior to that of ocular demonstration."—These expressions are not reported in any of the papers which profess to give an account of the proceedings, but I appeal to all present whether they were not used.

"Give me leave to state my reasons for this confidence; and, in so doing, to call attention to some facts which deserve to be put on record in the history of this noble discovery. On the 12th of July, 1842, the late illustrious astronomer, Bessel, honoured me with a visit at my present residence. On the evening of that day, conversing on the great work of the planetary reductions undertaken by the Astronomer-Royal—then in progress, and since published,*—M. Bessel remarked that the motions of Uranus, as he had

* The expense of this magnificent work was defrayed by Government grants, obtained at the instance of the British Association, in 1833.

satisfied himself by careful examination of the recorded observations, could not be accounted for by the perturbations of the known planets; and that the deviations far exceeded any possible limits of error of observation. In reply to the question, Whether the deviations in question might not be due to the action of an unknown planet?—he stated that he considered it highly probable that such was the case,—being systematic, and such as might be produced by an exterior planet. I then inquired whether he had attempted, from the indications afforded by these perturbations, to discover the position of the unknown body,—in order that 'a hue and cry' might be raised for it. From his reply, the words of which I do not call to mind, I collected that he had not then gone into that inquiry; but proposed to do so, having now completed certain works which had occupied too much of his time. And, accordingly, in a letter which I received from him after his return to Königsberg, dated November 14, 1842, he says,—'In reference to our conversation at Collingwood, I *announce* to you (*melde* ich Ihnen) that Uranus is not forgotten.' Doubtless, therefore, among his papers will be found some researches on the subject.

The remarkable calculations of M. Le Verrier—which have pointed out, as now appears, nearly the true situation of the new planet, by resolving the inverse problem of the perturbations—if uncorroborated by repetition of the numerical calculations by another hand, or by independent investigation from another quarter, would hardly justify so strong an assurance as that conveyed by my expressions above alluded to. But it was known to me, at that time (I will take the liberty to cite the Astronomer-Royal as my authority), that a similar investigation had been independently entered into, and a conclusion as to the situation of the new planet very nearly coincident with M. Le Verrier's arrived at (in entire ignorance of his conclusions), by a young Cambridge mathematician, Mr. Adams;—who will, I hope, pardon this mention of his name (the matter being one of great historical moment),—and who will, doubtless, in his own good time and manner, place his calculations before the public.

J. F. W. Herschel.

Sir John Herschel compares the discovery of the new planet to the discovery of the Western World: he might have added that America did not take its name from Columbus, but from a later navigator.

Professor Challis, of the Cambridge Observatory, has published a statement in the *Cambridge Chronicle*, that, in September and October, 1845, Mr. Adams deposited in the two principal observatories of England, those of Greenwich and Cambridge, calculations of the heliocentric longitude, mass, longitude of perihelion, and eccentricity of the orbit, of the supposed planet. M. Le Verrier published a calculation of the heliocentric longitude of the planet last June (eight months later).

To the personal friends of Mr. Adams the dispute must appear a ridiculous one: seeing that his discoveries have been a subject of common conversation among them for the last two years. And they very well know that modesty, which characterises profound science, alone prevented Mr. Adams from making his investigations known in a more public manner than by depositing them in the observatories of Greenwich and Cambridge. His original intention was, we believe, not to take any active steps for the publication of his investigations till the planet had been observed by the telescope.

The question seems likely to be made the subject of as "pretty" a quarrel as any in which the *savans* have ever been engaged. At a recent meeting of the Paris Academy, the announcement that the English astronomers meant to claim for their countryman the honour of first predicting the place, &c., of the new planet was received with manifestations of the utmost indignation. It is stated that in the excess of their wrath, they did not refrain from designating Airey and Herschell—impostors! In a letter in the *National*, which a correspondent of the *Literary Gazette* attributes to Arago, Sir J. Herschell and Professors Airey and Challis are said to have entered into a conspiracy to rob M. Le Verrier of his discovery. Herschell in particular is reviled with ingratitude because he is the son of one *whose fame M. Arago made known to Europe*." This exceeds the usual limits of even French bombast.

Our own journals take up the question very coldly. Surely this cannot arise from ignorance of the importance of the subject. However, "the truth is great, and will prevail," and as we happen to know personally that Mr. Adams's claims are indisputable, we do not for an instant doubt that they will soon be established to the perfect satisfaction of the public.

The planet is said to have a ring and a satellite: its distance from the sun is three thousand two hundred millions of miles—upwards of thirty times that of the earth. The distance of Uranus from the newly discovered source of its perturbations is one hundred and fifty millions of miles. The new planet is the largest in our system, except Jupiter and Saturn: its cubic bulk being 250 times that of the earth.

The *Athenæum*, speaking of M. Le Verrier, says incidentally, that "he worked out the problem first"! A more heedless admission was never made in a scientific journal: if it be, as it appears to be, a mere *obiter dictum*, the result of sheer carelessness, it ought, for truth's sake, to be withdrawn immediately. We repeat emphatically, that it is notorious to ourselves and to all Mr. Adams's scientific friends, that his discoveries were made long before M. Le Verrier's name was heard of in connection with the subject.

INSTRUMENT FOR TRACING RAILWAY CURVES.

Sir—The accompanying sketch and description of an instrument which I have found extremely useful for setting out railway curves is well adapted for all situations, and is very portable and simple.

A B C′ (fig. 1) is a permanent frame or square B C′ being perpendicular to A B, and B C is a moveable limb with a vernier to read off the degrees on the quadrant. Instead of making the offsets as heretofore perpendicular to the tangents, they are made by this instrument in the direction of the secants as *b c*, *d f*, and *h g*, &c. (fig. 2.)

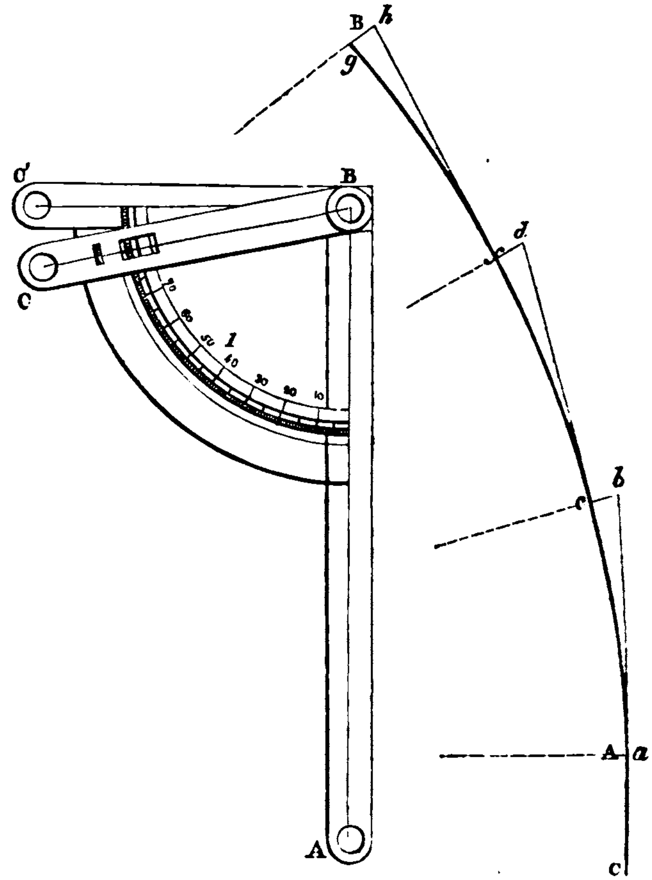


Fig. 1. Fig. 2.

In order to use this instrument, it is necessary to calculate by trigonometry the angle *a b c* fig. 2, and the length of the secant, for the purpose of finding the length of the effect *a b*, the latter is equal to the difference of the radius of the curve and the secant; in all cases it is requisite first to determine what length of tangent is most suitable to the ground, on which the curve is to be set out.

After this the moveable limb B C, is fixed on the quadrant at the angle so found for *a b c*, and the tangent *a b* being traced and measured on the ground, the instrument is placed with B of fig. 1, corresponding to *b* of fig. 2, and B A in the direction of *b a*, being so placed the moveable limb B C, fig. 1, will be in the direction of the required offset *b c*, fig. 2, which is to be measured off accordingly, giving the point *c* (fig. 2) as the first point in the curve A B.

For the second and other points *d f*, and *h g*, and *a*, the instrument is reversed, laying the fixed limb B C′, fig. 1, on the offset *b c*. B of the instrument corresponding with *c*, fig. 2, the line A B of the instrument being perpendicular to *b c*, will consequently point on the ground in the direction of the second tangent *c d*, and at *d* the second operation is to be performed as at *b*, for the offset *d f*, and so on.

The circular openings at A B C′, and *c*, are for the purpose of receiving nicely fitted rods to keep the instrument in its proper positions on the ground until the necessary prolongations *a b*, and *b c*, and *a* have been made.

Wm. Tait.

EARTHWORK ON SIDE-LONG GROUND.

By John Hughes, C.E., A.I.C.E.

The corrections to quantity arising from an inclination of the ground surface, in cross sections, are most frequently neglected, when estimating the cuttings and embankments of a railway or canal. This omission is in general expressly mentioned in the engineer's specification, so as to avoid all question upon the terms of the contract; it gives rise, therefore, to no positive injustice to any party, whilst a statement of the number of cubic yards to be removed, as ascertained from the heights taken along the centre line, is considered sufficiently near the truth to enable a contractor to appreciate the means he is required to supply. This practice obtains, because the corrections for excess and defect are assumed as balancing each other, and because the process of calculating them has been considered a tedious and troublesome labour. My purpose is to show that neither of these grounds should be acted upon;—the first is mathematically unsound, and the strength of the second may be materially abated.

If the ground surface is supposed to be generated by the motion of a straight line, which is always at right angles with the centre line, its ends resting on the outer edges of the slopes, the direction of such motion being coincident with the centre line, and all positions of the generatrix being parallel, then the correction to the area of a cross section of any cutting or embankment first computed on the assumption that this line is horizontal, and that the height or depth is measured on the centre, will, when it has any inclination with the horizontal, always be *additive*. The corrections to widths due to this inclination I will designate by $+x$ on one side, and by $-x'$ on the other; the correction to area will then be represented by the expression $\frac{xx'}{r}$; r being the ratio of the slopes.

If the ground surface is supposed to be generated by the motion of *two* lines, situated in the same vertical plane, having their ends resting on the centre line and on the outer edges of the slopes, all other circumstances being the same as already described, then the correction to area will be on one side, as an addition, supposing the ground to rise $(B+rC)\frac{x}{2r}$; and on the other side, as a deduction, supposing the ground to fall $(B+rC)\frac{x'}{2r}$. Consequently, the whole correction to the area of the cross section, calculated to the height C, in the ordinary way, is $\frac{B+rC}{2r}(x-x')$.

I take leave, at this point, to refer to the diagrams and characters employed in a paper on "Setting out Railways," in the Journal for September last (p. 277), as explanatory of these I now adopt. Moreover, let $+z$ and $-z$ represent the corrections to widths in a cross section parallel to the first at a distance from it $=$ L.

Then, in the case first named, where the cross sections all exhibit the ground surface as a right line, the solid, which is *constantly* to be *added*, has for its value

$$\frac{L}{6r}\left[x(2x'+z')+z(2z'+x')\right]\ldots\ldots\ldots\ldots\ldots\ldots\ldots A$$

And in the second case

$$\frac{L}{6}\left(\frac{B+rC}{r}\right)\overline{(x-x')+\tfrac{1}{2}(z-z')}+\frac{L}{6}\left(\frac{B+rC'}{r}\right)\overline{(z-z')+\tfrac{1}{2}(x-x')}\ldots\ldots B.$$

However complicated these formulæ may appear as algebraic expressions, their numerical application is perfectly simple and easy. To compare the two, let us first consider the increment to the area of one cross section only, which is $\frac{xx'}{r}$, and also $\left(\frac{B+rC}{2r}\right)(x-x')$; by assigning the following values:—

$$B+rC=31;\ r=2;\ x=5;\ x'=3\cdot78.$$

Then, $\frac{xx'}{r}=\frac{5\times 3\cdot78}{2}=9\cdot45$ .... Square feet;

and, $\frac{B+rC}{2r}(x-x')=\frac{31\times 1\cdot22}{2\times 2}=9\cdot45$ .... Square feet.

Also, in the other cross section,

if $B+rC'=35,\ r=2,\ z=7\cdot241,\ z'=5\cdot122$,

we have, $\frac{zz'}{r}=\frac{7\cdot241\times 5\cdot122}{2}=18\cdot54$ .... Square feet;

and, $\frac{B+rC}{2r}(z-z')=\frac{35}{4}\times 2\cdot119=18\cdot54$ .... Square feet.

Upon the choice between these two formulæ, it is proper to remark that although the process according to $\frac{xx'}{r}$ is the shortest, perfect accuracy requires that the values of x and x' should be nicely calculated, even to a third place of decimals, to ensure exact coincidence with the result by the formula $\frac{B+rC}{2r}(x-x')$; and more especially when $\frac{B+rC}{2r}$ is large.

In the next place, let us compare the facilities of the two formulæ for the increment to the solid due to the side-long inclination of the ground with the values above given, the cross sections being 50 feet asunder $=$ L.

First,	$x'=3\cdot78$		$5\cdot122$
	$x=3\cdot78$		$5\cdot122$
	$z'=5\cdot122$		$3\cdot780$
$(2x'+z')=$	$12\cdot682$	$(2z'+x')$ ...	$14\cdot024$
Multiplied by	5		$7\cdot241$
	$63\cdot41$		$101\cdot548$
			$63\cdot41$
			$2)164\cdot958=82\cdot5.$

With this number enter Table No. 1 of my Tables* for calculating earthwork, where I find, on the first line of figures,

opposite 82.	1·0123
" ·5	·0062
For 82·5	1·0185

and multiplying this by $\frac{50}{2}=\frac{100}{4}$ we get ... 25·46 cubic yards.

By the second formula for the increment to the solid, the process will be—

$x-x'$ .... $5-3\cdot78=1\cdot22$ .... this $\div 2=$ .... $0\cdot61$

$\frac{1}{2}(z-z')$ .... $\frac{7\cdot241-5\cdot122}{2}=1\cdot059$ .... this $\times 2=$ .... $2\cdot119$

$(x-x')+\frac{1}{2}(z-z')$	$2\cdot279$	$(z-z')+\frac{1}{2}(x-x)$	$2\cdot729$
$\frac{B+rC}{r}=\frac{31}{2}=$	$15\frac{1}{2}$	$\frac{B+rC'}{2}=\frac{35}{2}$	$17\frac{1}{2}$
	$35\cdot324$		$46\cdot393$
			$1\cdot364$
			$47\cdot757$
			$35\cdot324$
	$1\cdot0247$	.... from Table No. 1	$83\cdot081$
	$\cdot0009$		
	$1\cdot0256$		

and multiplying by $\frac{50}{2}$ .... 25·64 cubic yards.

A slight examination will enable us to perceive that the last is the preferable process to be adopted in practice; for as an algebraic expression it involves less trouble, although apparently the contrary; and avoiding the extreme nicety necessary in the values of x, x', z, and z' in the first is, even in the hypothesis of the generatrix of the ground surface being one straight line, the most accurate of the two.

This hypothesis will never be satisfied over the most uniform ground, and in this sense also the second formula claims the superiority. Expressed in words, it may be stated as follows:—

1. Take the difference between the additive and subtractive corrections to the widths at each cross section terminating the length of cutting or of embankment under calculation.

2. Add together half the width of the railway previously divided by the ratio of the slopes to the height at the centre of each cross section; and call these the multipliers.

3. To the difference of the corrections to widths in each cross section add half the difference of the corrections in the adjoining cross section, and multiply these sums by their respective multipliers.

4. The last two results added together and multiplied by one-sixth of the distance between the cross sections gives the solid content sought.

The rule thus expressed requires modification according to the signs attaching to x, x', z, z', as will be evident to every one familiar with the first principles of algebra, and needs no further remark here.

* "Concise Tables to facilitate the Calculation of Earthwork and Land required in the Construction of Railways, Canals, and other Public Works; adapted to the Practice of the Engineer, Architect, and Surveyor." By John Hughes, engineer. London: Effingham Wilson, Royal Exchange.

The elements for calculating the corrections to cubic quantity which have been previously employed, require that the corrections to widths, due to the inclination of the ground surface, should be determined; that is, that the values of x, x', z, and z', should be known; and this process may appear to involve as much trouble when preparing a preliminary estimate for ordinary parliamentary purposes, as when the position of the line is absolutely final: and when the more careful and accurate calculations are undertaken. They would appear, in fact, to require that the field-work should embrace every level and measurement necessary for setting out the earthwork on the ground. It is desirable, therefore, to present a form of calculation which should dispense with so much detail, and which should at the same time enable us to make an estimate that cannot be attacked before a committee of the House of Commons for insufficiency, on the score of a neglect to take into account the addition to be made to quantities derived from the central heights, on the supposition that the ground in cross section does not differ materially from a horizontal plane; an addition which is due to the fact that this supposition cannot be maintained in a mountainous or rough country, such as occurred on the various lines projected through Wales in the session of 1845-6.

Under such circumstances, after the usual deposit of the plans and sections have been made, in accordance with the standing orders, it should be included amongst the various additional particulars sought by the engineer preparatory to his estimate, to obtain a number of cross sections, over the length of each projected cutting or embankment, sufficient for determining the increase in earthwork which may arise from a material inclination of the ground to the horizon. And, *now*, the first formula (A) is, on the whole, the most concise in application. Such cross sections can do no more than exhibit the *rate* at which the ground inclines; in other words, to what extent it falls or rises in any given horizontal distance, as of 100 feet, or 1000 feet, &c.

Table for Corrections to Widths of Railways, &c., due to Sidelong Ground.

To facilitate the calculation of the corrections to widths, and therefore of the increments to quality, I have arranged a table, available as well when the ground surface is examined in the approximate manner just described, as when the more detailed levels are taken for setting out the earthworks of the line. This table is annexed, and its use will become familiar from following the steps of an example:—

Taking the measurements from the form of level book attached to the paper on "Setting out Railways," already referred to (see the Journal for September, p. 277), we find at the beginning of the first chain's length,

$$B + r\,C = 30{\cdot}75\,;\ H = 1{\cdot}9\,;\ -H' = 2{\cdot}2\,;\ r = 1{\cdot}5.$$

Then 1·5 × 1·9 = 2·85 ; and 1·5 × 2·5 = 3·3.

Entering the table with 2·85, I find opposite 285 the tabular number ·903509; from which, as there are two decimal places in the number 2·85, I cut off two decimals and have for rH ...... 2·85 ...... ·3509.
And in the same way, entering the table with $B + rC$ = 30·8, I obtain 30·8 .... .0324 ; and taking the difference of these two tabular numbers, ·3509 — ·3324 = ·3086, which, found in the table, corresponds to 3·14, the value of x, additive.

On the other side, for the value of $-x'$.

rH' = 3·3 tabular number 3030
x ...... 30·8 .... ·0324

·3354, which corresponds to 2·98.

At the other end of the first chain, $B + rC'$ = 24·45 ; H = 3 ; H' = 1·9.

3 × 1½ = 4·5 .. Tab. No. ..	·2222	1·9 × 1½ Tab. No. for 2·85 ..	·3509
deduct for, 24·5 .... do.	·0408	add ..	·0409
x, additive = 5·51	·1814	x' subtractive = 2·55	·3917

These examples show the use of the table in setting out the earthwork.

For values of x, x', &c., as elements of calculation for correcting the quantity, when the *rate* of inclination of the ground surface simply is taken in the field, this rate of inclination should be expressed so as to indicate a vertical height in terms of 1000 parts horizontal:—Thus, if in a chain's length of 50 feet, the inclination of the ground amounts to 1·25 feet, the ratio expressing the vertical height in terms of 1000 parts horizontal is 25. Also, if in the length of a Gunter's chain = 66 feet, the rise or fall measured 2·2 feet, the ratio in 1000 parts would be 33·3. This is a common Rule of Three question, thus:—

50 : 1·25 :: 1000 : 25

which, when using a Gunter's chain, and a level-staff divided into feet and decimals, is abbreviated by converting the height or difference of level, read off on the latter, into links, and multiplying that equivalent by 10. Let us call this ratio of the inclination of the ground b ; — r the ratio of slopes of cutting and embankment, as before, as likewise the other characters which follow.

The table should be entered with a number, the result of the formula $\frac{r \times b \times (B + rC)}{1000}$, from the tabular number of which we must *subtract* the tabular number corresponding to the value $(B + rC)$, to obtain the value of x; and, on the other hand, we must *add* to get the value of x'

Thus, suppose b = 33·3 ; and $B + rC$ = 30.8 ; r = 1·5 ;

$$\frac{rb(B + rC)}{1000} = \frac{33{\cdot}3 \times 1{\cdot}5 \times 30{\cdot}8}{1000} = 1{\cdot}54 \ldots \text{Tab. No.} \ldots\ {\cdot}6494$$

30·8 ....deduct ·0335

x = ... 1·03 .... ·6169

x' = ... 1·47 .... ·6819

Again, if b = 7·64 ; r = 2 ; $B + rC$ = 35·2 ;

$$\frac{7{\cdot}64 \times 2 \times 35{\cdot}2}{1000} = {\cdot}538 \ldots \text{Tab. No.} \ldots\ {\cdot}1859$$

35·2 ....deduct ·0284

x additive 6·35 .... ·1575

x' subtractive 4·67 .... ·2143

It is not altogether foreign to the subject of this paper to present some applications of the prismoidal formula, which, as cases of frequent occurrence, are deserving of being noted for their simplicity, and for the brevity of their solution in numbers; especially as they are seldom, if ever, met with in works on mensuration.

1. In a triangular prismoid, of which the area of the base is called B, and the three heights perpendicular to the plane of that base h, h', and h'',

$$\text{the solidity} = B\,\frac{(h + h' + h'')}{3}.$$

2. In a prismoid with a trapezoidal base; divide this base into two triangles, and call one of the parallel sides of the trapezoid as the base of each triangle; then add together twice the heights above the base of one triangle, to once the height above the base of the other triangle, and multiply this sum by one-sixth the area of the base of the triangle; this done for each triangle, and the results added together will give the solidity of the prismoid. Thus, if h, h', are the heights above the base at the ends of one of the parallel sides of the trapezoid; and h'', h''', the heights at the ends of the opposite parallel side; B, and B', being the areas of the triangles, having those sides for their bases respectively; then

$$\text{the solidity} = B\,\frac{(2h + 2h' + h'' + h''')}{6} + B'\,\frac{(2h'' + 2h''' + h + h')}{6}.$$

This solid may have one, two, three, or four heights, and the formula admits of further simplication according to the relation of the heights to each other.

3. When the four heights, being unequal, the base of the prismoid becomes a parallelogram of which the area = B,

$$\text{the solidity} = B\,\frac{(h + h' + h'' + h''')}{4}.$$

This last formula furnishes the means of determining the solidity of a body of any extent whatever, terminated by an irregular surface, but of which the base is a parallelogram. With this view, we must suppose it divided by two systems of equidistant vertical planes, parallel respectively to each other and to the sides of the parallelogram; and if l = one of the equal parts, into which one of the sides of the parallelogram is divided,

h, h_1, h_2, h_3, h_4, &c., the series of vertical dimensions taken through points at the distances l, in the first vertical plane;

$h', h'_1, h'_2, h_3', h'_4$, &c., the corresponding vertical dimensions in the second vertical plane; and so on.

Then the area of each plane is,

$$A = \frac{l}{2}\left(h + 2h_1 + 2h_2 + 2h_3 + \ldots \frac{h}{n}\right)$$

$$A' = \frac{l}{2}\left(h' + 2h'_1 + 2h'_2 + 2h'_3 + \ldots \frac{h'}{n}\right);$$

and so on. Then if L represent the perpendicular distance between the vertical parallel planes,

$$\text{the solidity} = \frac{L}{2}\left(A + 2A' + 2A'' + 2A''' + \ldots\ldots\ldots\ldots A^n\right).$$

These theorems may readily be deduced as corollaries from the prismoidal theorem, but they are also capable of an independent elementary proof.—See *Puissant Traité de Topographie.*

4. If a line of slope (of a single slope) turns at right angles to its original direction, the solidity of the angular portion, when h = height at the angle, and r the ratio of the slope, is

$$rh \times \frac{rh^2}{3}$$

5. If the direction of a double slope and bottom, as a ditch or trench, turns off at right angles, then b being the width of the bottom, the solidity of the angular portion is $(3b + 6rh)\,\frac{bh + rh^2}{3}$.

Example.

In erecting some Iron Works, it became necessary to provide a proper foundation for a quantity of ponderous machinery, by removing a considerable depth of cinders, rubbish, and loose ground over the whole site of the proposed buildings, which covered a rectangular space of 150 feet × 80 feet.

To calculate the quantity of earthwork to be executed:—The parallelogram being set out, each of its long sides was divided into six equal parts of 25 feet, and each of the short sides into four equal parts of 20 feet. Note,—*the calculation is much shortened by dividing each side into an* EVEN *number of equal parts.* This is shown on the figure.

The necessary depth was then ascertained by boring, and a series of levels over the surface of the ground were taken, as shown by the dotted lines, which being reduced to the plane at the intended depth, as a datum, in the usual way, gave the dimensions as figured in the diagram. The sides of the excavation were to be finished with slopes of 1 to 1.

* Since the tables are calculated to give 'both' slopes of a cutting, the mult'plier must be divided by 2, to obtain the contents of 'one' slope.

It is to be observed that a more rigorous calculation, with the use of Table 3, which would involve just double the number of figures, gives, as the content of the slopes along the sides, a smaller quantity by 6¼ cube yards, and of the slopes along the ends a smaller quantity by 42 cube yards and if extreme accuracy is desired, such form of calculation must be followed, as explained p. 17-19 of the introduction to my tables. It is only, however, when each height differs from being an aritmethical mean between the two adjacent heights, that this more lengthened operation can be required; and such a difference may be estimated by inspection, to enable the calculator to judge whether it is desirable to incur the trouble.

JOHN HUGHES, A. I. C. E.

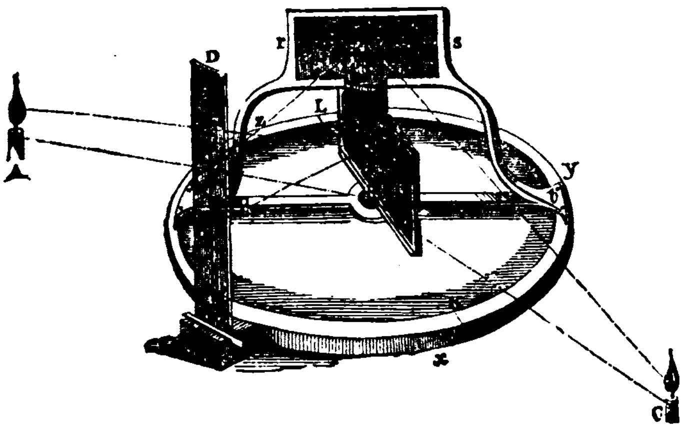
1, *Lancaster Place.*

A NEW MINING SURVEYING INSTRUMENT.

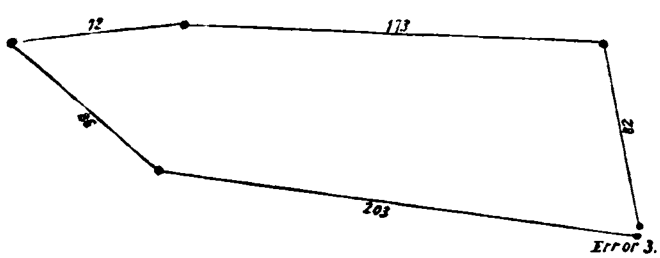
SIR—I beg to offer to your notice, and through your valuable Journal to that of practical surveyors and engineers, a sketch of a model instrument for taking horizontal angles, which I think is new, and likely to become exceedingly useful, although it is but a modification of the principle upon which the quadrant and sextant are constructed. I have been led to the construction of the model, by constant experience for the last 20 years, of the difficulty and uncertainty of the use of the dial or compass for underground surveying. Practical men need no mention of these, but for the information of those not actually conversant with subterraneous surveying, I may mention briefly the principal difficulties,—there is first the attraction of the needle by the tram rails (now generally composed of wrought iron) which renders it necessary at each station of the instrument, to take them up for a distance (to make sure work) of 5 to 7 yards on each side of it—a laborious operation, and much impeding the mining operations by obstructing the wagon-way, besides occupying much of the time of the surveyor, who has to await the pulling up and removal of the rails. The next difficulty is the slow but progressive variation of the needle rendering a colliery plan of 9 or 10 years old altogether inaccurate, and therefore making it necessary to alter the meridians (generally numerous on a working colliery plan) or to make allowances in the observations taking during every survey made after the lapse of such a period of time. Then follow local attractions in the stratum of the coal itself or in the strata above or below it, often causing a difference of 2° to 3° between a fore and a back observation on the same line. Another is the gradual weakening of a needle in constant use, and its consequent sluggish working causing great loss of time, and great uncertainty—these are formidable evils, and other minor ones might be adduced if necessary.

It may be said with perfect truth that horizontal angles may be readily taken by a common circumferentor, or by a theodolite,—but of these the latter is too bulky, heavy, and complicated an instrument to be admissible into or usable in a coal mine, under ordinary circumstances, and there is a radical defect in the former which completely destroys its efficiency in mine surveying. It consists in the instability of the instrument and its consequent uncertainty during the movement of the upper upon the lower limb,—and if by way of correcting this, the instrument be furnished with a double set of sights, one for the back and the other for the fore observation, in the manner of those of early construction—this difficulty occurs, that the surveyor having fixed one pair of sights, must go to the other side of the instrument in a gallery very often less than three feet high, and than five feet in width (and this width occupied by the legs and other parts of the instrument itself) to take the other observation, and afterwards he must go back again to take the first observation again to assure himself that the instrument has not shifted during the adjustment of the moveable sights for the second observation. If he find, as is most probable, that it has stirred, the observation must be repeated perhaps several times, and this in a space where it is next to impossible to move without disturbing the instrument. Even two operators, one on each side of it, would be useless, as they would be in the way in nine cases out of ten of each others observation, and would obstruct it by intercepting the view of the object.

By the instrument of which the above is a sketch, both objects are brought to the eye, as by a quadrant, at the same vertical line, and seen at the same time, and the angle indicated by the vernier, without any of the uncertainty and difficulty I have mentioned as besetting the use of the common dial and that of the circumferentor.



Briefly to illustrate its use, permit me to refer you to the sketch, supposing it requisite to take the angle formed by the two lines joining respectively A B, B C, the instrument is placed at the angle, and the limb *x y z*, which is flat, circular, and divided on the outer edge into 720 or half degrees, each indicating in an observation a whole degree—this limb is then turned on a joint below, admitting horizontal motion, until the candle A is reflected from the mirror B, to the eye of the observer placed anywhere opposite the vertical line D E—this mirror B is fixed vertically on the lower limb, with the silvered surface exactly in the centre. Then the upper limb is so adjusted that the candle C is also reflected from the mirror G (which is fixed vertically to this limb, and whose centre of motion is in the plane of the mirror B.) to the eye of the observer on the line *d e*, of the sight D E, during this adjustment if any movement occurs in the instrument, it is instantly detected and adjusted by the observer without change of place, without difficulty, and in the least imaginable time. The angle required is then indicated by the vernier at either end of the limb *q, r, s, t*, at *q* or *t*. To test the efficiency of the instrument, I made the subjoined survey with it, of a small but very hilly sloping piece of ground, of which I subjoin the plotting showing the error, which considering the imperfection of the model, will be considered, I think, very small.



The model is constructed, the lower limb of wood and divided by the hand, and the upper one of brass, and with the whole fitting constructed by a workman unaccustomed to instrument making. I propose in the perfect instrument to place two levels at right angles on the lower limb, to fix it upon a ball and socket joint or parallel plates to facilitate the levelling thereof, and to apply rack-work capable of being easily thrown in and out of geer to the upper limb, and similar racks and a champ screw to the sight D E, which is moveable round the lower limb, and which in the model is a slip of glass—for this I propose to substitute an ordinary sight with a vertical thin wire in lieu of the line on the glass. I should mention that the mirrors are marked by vertical lines on the silvered surfaces, and that these lines are in the axis of motion of the upper mirror. I should mention that in the graduation of the lower limb, there are two opposite points marked zero, situated in the line of the silvered surface of mirror B, and marked in the sketch K L respectively.

I remain, Sir, your most obedient servant,

William Peace.

Haigh Colliery, Wigan, October 9, 1846.

ENCAUSTIC-PAINTING, WITH WAX, RESIN, AND OIL.

By Mr. Linton.

(Communicated to the Commissioners of Fine Arts.)

Wax was the most important ingredient in the vehicles for painting employed by the ancients. Its use is traceable from the early ages of Egypt,[1] and throughout those of Greek and Roman art. It was extensively and almost exclusively used by the early Christian painters, and continued to be commonly employed till a late period in the middle ages. There is also abundant evidence of the use of resins by the ancients, and the employment of such substances among the ingredients for painting, as well as for varnishes, was continued after the invention and improvement of oil-painting. The process which has been found most satisfactory is that which excludes the fixed oils as much as possible, substituting for them wax, resin, and an essential oil. As a first condition affecting the durability and brilliancy of the work, a ground of pure white is recommended. In this, the practice of remote antiquity has been confirmed by the best modern authorities. The Egyptians, in the preparation of the surface for painting on walls and on mummy cases, have left proofs of the estimation in which white grounds were held in the earliest times. The practice of the Greeks and Romans is exemplified by the prepared white tablet which was found among the ruins of Herculaneum. Aristotle among the ancients, and Leonardo da Vinci and Armenini among modern writers, speak of white grounds as essential to the brightness and durability of pictures. Caravaggio and others of the "Tenebrosi," on the contrary, who were instrumental to the decline of art by employing dark grounds, have proved that the effects of time are accelerated by that practice. Many of the works of Tintoret have suffered from the same cause.

In the method about to be described, wax with resin may be considered, as a substitute for a portion of the oil usually employed; "the object being," as a French chemist observes, "to replace an alterable recipient for the colours, such as oil is, by one whose nature it is to resist the action of time and the agents of destruction."[2]

The Process.—Secure a stout and well-pumiced canvas, free from size and gummy matter. Fasten it slightly on the stretcher, with the smooth surface undermost. Dissolve any quantity of bleached wax in double its weight of oil of turpentine, and saturate the canvas with the solution while hot, and near the fire. Then take the canvas off the frame and stretch and fix it properly, the smooth side being now in front for the reception of the ground.

The Vehicle.—Prepare the vehicle, which is to be exclusively employed throughout both ground and picture, in the following proportions:—

3 ounces of essential oil (of turpentine, lavender, or rosemary, &c.)
2 „ resin (mastic, Copal, or Damara, &c.)
1 „ bleached bees' wax.

Place them in a glazed pot near the fire, occasionally stirring them with a stick, until the solution is completed. When cool it will be a magylp ready for use.

Procure a quantity of white-lead ground in oil; that of the shops may answer the purpose for the two first coats, but flake white is preferable, and is indispensable in the two last layers. Mix a portion of the vehicle with the lead, and reduce to a creamy consistence by the addition of turpentine essence.

Ground.—Spread, with a large flat knife or trowel, four coats of this white-lead cream over the canvas as smoothly as possible, allowing several hours to intervene between the layers.

Picture.—In proceeding with the picture, the usual tube[3] or bladder-colours of colourmen, ground in oil, may be employed (unless the painter have this labour performed at home), while the vehicle may be placed on the palette near the colours, in the usual way, to be ready as a diluent. If a rapidly obtained *impasto* be desired, a portion of the vehicle must be mixed with the colour, which in a very short time will be found to have obtained a consistence almost fit for modelling.[4] The vehicle can also be thinned at pleasure by additional oil of turpentine, which will enable it to work more freely; or it may be softened and retarded in drying by a slight addition of plain oil; or stiffened by replacing it near the fire to diminish the essence. The most careless or lavish use of it cannot be followed by any injurious results, since, after the essential oil has evaporated, the ingredients subside into a firm and unchangeable mass among the colours, without either shrinking or losing the forms into which they have been wrought by the hand of the painter. The essential oil has free egress, by the agency of the wax, through the back of the canvas, as well as through the front of the picture.

---

[1] See, among other examples, No. 31 in the British Museum—a small funereal group of painted sculpture.

[2] Durosiez, ib. p. 12.—I took a quantity of the best flake white ground in oil, and thinning it with nut oil, I put several layers on a prepared millboard. From the same parcel of oil white lead I took another portion, and diluting it to a working consistence with wax cream (wax and oil of turpentine) I put the same number of layers on another part of the millboard. In a few weeks the portion which was diluted with additional oil, had become of a decidedly yellow tint, while that which was mixed with the wax cream remained as purely white as at first.

[3] Bladder-colours become fat and rancid from the access of air in the course of time, and many of the colours in tubes oxidize or blacken in a few months; among the latter I have found white lead, Naples yellow, yellow ochre, raw sienna, &c., so affected.

[4] It may be as well to remark that an excessive application of essential oil in painting has a tendency to injure the tenacity of the paint, as may be seen in what house-painters term bad "flatting." The rapid evaporation of the essence from the more substantial materials with which it is combined breaks up, in some degree, their cohesiveness.

Pictures painted with oil only, or with common magylp, consist of a succession of skins or layers of paint, more or less cut off from mutual intercourse; but the cero-resinous medium keeps the whole substance in a constant state of intercommunicative moisture during the progress of the work. The painter can pursue his operations, without delay, to any stage he may think proper; he may also return to them at pleasure; and he will find himself relieved from the necessity of such a preparative as "oiling out," an injurious and disagreeable practice, often called for by the greasy oozings through the surface or outer skin of the oil picture. It may also be remarked that the scrapings, glazings in, and rubbings off for texture, which are so often resorted to where oil alone has been used, are wholly unnecessary in this system, which, by humouring the vehicle to the required consistence, yields all the means for a varied manipulation that can be desired.[5]

Encaustic.—When the picture is completed, a short time being allowed for the evaporation of any excess of essential oil which may remain in those portions of the work which have been recently loaded with colour, it should be gradually moved towards and held in front of a fire until the surface has obtained an equal gloss, care being taken that it does not fry by too sudden or close an approximation; it must then be withdrawn to set and cool; after which it must be rubbed with fine linen cloths or with silk until a polish is produced. If the picture be large, a *cauterium*, or chafing-dish, may be moved in front of it at a careful distance (from 2 feet to 18 inches or a foot, but not nearer), in order to obtain the required gloss. Should the picture have been painted upon millboard or panel, the evaporation of the essential oil must necessarily take place from the surface only; the capacity of the picture for retaining heat being thus greatly increased, the latter will act, if the encaustic or "burning in" process, be performed gradually and slowly upon the resin, as well as the wax and oil, and effect a thorough fusion of the whole medium, which will result in a most brilliant and durable enamel, more resembling a vitrified than a waxed surface. The more perfect the desiccation, the more perfect and durable will be the gloss. The reason why encaustic surfaces frequently become dull is, that the gloss is produced before the essence has entirely evaporated, the after-evaporation through the wax enamel reproducing the flat and porous surface. "Its lustre," says Professor Tingry, "is equal to that of varnish, without having any of its inconveniences. A wax surface stands shocks, a varnished one does not. If any accident alters the polish of wax, rub it with a piece of fine cork." To clean an encaustic picture, M. Durosiez gives the following directions:—"Remove the dust, wash it well with alcohol and water, then with pure water, dry it, expose it to heat (in the mode described), and polish with cloths as at first." The encaustic surface has more atmosphere than very new varnish,[6] and is sufficiently transparent to display the deepest shadows to advantage; it does not require periodical additions, like fresh varnishings; and it is not subject to chill, like most of the essential oil solutions of the resins. "Encaustic pictures," says Montabert,[7] "never alter; they can be retouched; they are luminous and transparent, and possess all the excellencies of oil-painting, combined with greater durability."[8]

As an addendum to the description of the process, a few remarks on the materials of which it consists may not, perhaps, be thought unnecessary. *Oil of Turpentine* being the most available essence in this country, and answering the requisite artistic purposes quite as well as either rosemary or lavender, it may not be amiss to retain it for the process. The best bleached bees-wax that can be procured is another required ingredient. Pure wax from the comb, bleached by exposure to the light,[9] is to be preferred to the shop white wax, as the latter is usually adulterated with tallow. Wax is said by many to run when used in pictures, and by others to be subject to crack. Professor Brande, however, informs us in his "Chemistry" that this substance will not melt under 154½° Fahrenheit, a degree of heat scarcely ever attained by the sun in this country: this statement, which differs but slightly from that of other eminent chemists, ought to satisfy the most suspicious that the confidence placed in wax by the Greeks, Romans, and Egyptians, denizens of far hotter climates than ours, was not that of ignorance. Besides, when in combination with other matters, wax is so notorious for its powers of adhesion, that a vastly increased degree of heat would be required to fuse it when so circumstanced. I have several times exposed sketches, painted with this cero-resinous vehicle united to colours ground in oil, to a stove heat of 160° Fahrenheit after the essential oil had entirely evaporated, without the slightest running of the surfaces. And in forcing the heat still higher upon a layer of white-lead ground in oil added to the vehicle, the white became very slightly tinged with yellow (from the partial combustion of the oil, as I afterwards proved) without any other change whatever.[10] As to the disposition of wax to crack in pictures, it may be observed that unless it be employed in some layers and excluded from others, cracking cannot possibly ensue. Since, however, there are no two substances in the painter's *matériel* which are characterized by similar dispositions to contract and expand, extreme caution should be adopted in the juxta-position of differently constituted vehicles in the several layers of a picture. Varnish over unhardened oil, drying oil over the same, or wax over any of the three, would be very likely to produce cracking. Dr. Roux says that "wax does not contract like the unctuous oils;"[11] and the Italians consider that new tempera as well as oil-paintings are subject to crack in extremely dry seasons, but that wax rests undisturbed. Among the resins suitable to this process there is abundant choice. Damara is a favourite on the continent. It is very clear and bright, and does not crack when spread alone as an essence varnish over a wax picture. Mastic, which has a little more colour, has long been a favourite with painters, but it is very subject to chill (a failing which has been attributed to unsound watery tears[12]) when made with volatile only. Correggio and the Lombard painters are said by Armenini to have dissolved it in fixed oil for a glazing vehicle or varnish. Sandrac was a favourite with the old masters; but I found it work very harshly without fixed oil. Elemi is another continental favourite. It is slightly coloured, but is said to be tough in varnish. (Aiken.) Anime is difficult to dissolve; "it is more brittle and less solid than copal. (Tingry.) The fluid resins, Venice and Chio turpentines, with Canada and Capivi balsams, may any of them be used to advantage in this process, due consideration being had to the excess of essential oil which they contain.[13] The solution of the harder resins seems to have been better understood in former times. To dissolve copal effectually has ever been considered a difficult task; and perhaps a greater value has been placed on the resin on that account. The power of wax in consolidating the feeblest resins seems to place every requisite means at our command without undue labour or difficulty. And yet the superior qualities of copal, its toughness, its brilliancy, its consistence, and its durability, single it out as the most desirable of all resins to bring into subjection. Bonanni, Tingry, &c., &c., have devoted much time and skill to its solution, and have succeeded variously. Oil of turpentine, which Tingry pronounces (because it is a resinous essence) the most perfect solvent for resinous substances, and especially for copal, requires several months exposure to light in order to imbue it with the requisite powers. The essence having attained these qualities, will, when made hot, and in a warm room, take up the powdered resin, if carefully sprinkled into it and stirred up at the same time. If the essence be new, the solution is almost impracticable. When copal has been fused and thrown into cold water before levigation, it dissolves more readily. It has sometimes been fused a second time before solution, but this is an operation which must have a powerful effect on its best qualities, and it is to be hoped that the least injurious mode may be generally adopted. The oils of rosemary and lavender have often been successful where oil of turpentine of a sufficient age has not been available. If the caoutchouc portion (so called) of the resin continue to float in transparent masses after the essence has cooled, time and light only can perfect the union. The fluid resins readily take up an eighth of their weight of copal. I could never effect a stronger solution with them; but with three ounces of turpentine oil alone I have completely dissolved an ounce of the pale copal unfused; a proportion which is quite strong enough for any useful purpose. One ounce of copal in eight ounces of essence is the usual proportion in Tingry; but one in three or four is necessary to make a good cero-resinous magylp. I may observe that the above solution of one to three dried very rapidly; and that it possessed such a degree of toughness and flexibility that five stout coats of it spread on a broad strip of letter paper, and hardened, exhibited not the slightest symptom of cracking when closely wrapped round so small an object as a common lead pencil. If every painter desirous of possessing real copal varnish would place a quart of oil of turpentine in his window, every three or four months, in a clear glass bottle, leaving an interval of one or two inches between the cork and the essence, removing each bottle as it became fit for use (in eight or twelve months as it might happen), he would have every chance of continued supplies of the varnish for his studio; since a pestle and mortar, a common brown mug to hold the essence, and an Argand chemist's lamp to receive the mug, constitute all the apparatus requisite to perform the operation both with precision and safety.

William Linton.

7, Lodge-place, Regent's Park, August, 1846.

---

5 If the add'tion of a little oil or extra turpentine essence be required, and the magylping property be overpowered, recourse must be had to the palette tina.

Dr. Bachoffner, in allusion to Sir Humphry Davy's having found the colours of the ancients (at Pompeii) to be similar to those now in use, thinks "that modern vehicles are at fault."—'Chemistry applied to the Arts."

8 For a wax varnish: "Take three parts white wax and one part resin; melt together; apply over the picture, and polish with cloths."—'Antologia Romana.'

9 The blocks of yellow wax may be bleached as follows: Cut them into shavings upon a carpenter's plane inverted; and then expose them to the sun in an unsmoky atmosphere, occasionally turning over and moistening them with clean water. In the steady and potent light of Italy, the bleaching operation is completed in three or four days, as I have many times witnessed; but in our variable climate it cannot be effected without more time and trouble. The brown wax of commerce is frequently adulterated with common resin. The dark-coloured old combs are almost unbleachable, and their substance is of a less tenacious or waxy character, as it is mixed with bee bread and other impurities. Fine bees-wax may always be obtained of Mr. Milton, the eminent apiarian, in Weymouth-street, Portland-place.

10 Cennini and Baldinucci give recipes for cements of wax and resin only for broken marbles, in which the wax is proportioned to the resin as three to one.

11 See the Third Report.

12 J. Scheffer's "Graphice," Norimbergo, 1669.

13 In applying these balsams and turpentines to pictures it has been advised to evaporate by heat the excess of essential oil which renders them fluid at the common temperature of the air, and to re-dissolve them in some more evaporable essence. An undrying principle may be productive of as much mischief in a resinous as in an oleaginous vehicle.

CANAL OF THE ISTHMUS OF PANAMA.

The following translation of extracts from the report of Napoleon Gafella, an engineer appointed by the French Government to survey the Isthmus of Panama, is taken from the *Journal of the Franklin Institute*:—

The remarkable isthmus which unites the two Americas and extends between the Gulf of Mexico and the Pacific Ocean, to a length of 1430 miles, in a direction from W.N.W. to E.S.E., presents along this enormous length a variable width. From the mouth of the Guazacoalco, its point of junction with North America, where it has a width of 137 miles, it continues narrowing regularly enough, with the exception of the two large promontories of Yutacan and Central America, to its other extremity, towards the Gulf of Darien, where it is united to South America. It is towards this latter portion, where it is called more particularly the Isthmus of Panama, that it attains its minimum width. From the mouth of the Caimito, on the Pacific Ocean, to the embouchure of the Chagres on the Atlantic, the distance is but 36 miles; but the minimum width appears to be a little more to the eastward, between the bay of Mandingo or San Blas, on the Caribbean sea, and the shore of the Pacific Ocean, near the embouchure of the Rio Chepo, where the distance, according to the map, is but 31 miles. The chain of mountains which extends in a direction nearly north and south, the whole length of the two Americas, from the icy seas of the north pole to Cape Horn, presents along nearly its whole length a considerable elevation. Its peaks are only surpassed in height by the summits of the highest of the Himalayas, and even its vast plateaux have an elevation superior to that of the highest mountains of the interior of France. This chain extends, without any discontinuity, the whole length of the isthmus, but then as the breadth of the land diminishes, so the ridge of the chain sinks considerably, and presents some depressions, of which the height above the ocean is less than that overcome by some of the European canals already constructed. One of these remarkable depressions exists in the neighbourhood of Panama—not at the point where the isthmus is narrowest, but a little to the westward, where, however, it is narrower than at Panama. In examining the configuration of the isthmus from west to east, it will be remarked that, passing from the state of Costa Rica (Central America) into the province of Veraqua (New Granada), under the 85th degree of west longitude, 8 degrees to the westward central ridge dividing the waters flowing into the two oceans, appears to break off suddenly at the steep and precipitous peaks of the Trinity (Cerro de la Trinidad). There commences the depression of which I have spoken, and which extends a distance of 25 miles, to the hills of Ormigueros. The ridge then rises by degrees, and attains, opposite Porto Bello, and near the Gulf of San Blas, its previous height. Along this distance there are a number of points whose elevation varies from 425 to 525 feet, between which the ridge rises but little, and forms hillocks, and not peaks or elevated masses. This depression of the central chain is, then, one of the first and most evident observations which the explorer makes; and it has been noticed by nearly all those who have surveyed the isthmus; Mr. Lloyd points it out for the line of a canal; and it is there, also, that Mr. Morel, the agent of the Salomon Company, has laid down his route. It is evidently there that the summit level of the maritime communication to be opened between the two oceans, should be placed. Unfortunately, those who have hitherto visited the isthmus, have only judged approximatively of the height of this portion of the chain, and that by a simple visual observation, made without employing any instrument, and mostly at long distances; and taking, without doubt, as points of comparison, the elevated mountains of the Trinity, and other masses of a considerable elevation, situated more to the eastward; those of the Cerro Cabra, which are 1614 feet high, and those of the Cerro Grande of Gorgona, which rise to a height of 1017 feet. Thence, doubtlessly, comes the erroneous opinion spread abroad, on the faith of some navigators, that the central chain uniting the elevated table land of Mexico with the Andes of Peru, ceases entirely in the portion of the country of which we are now speaking; and is cut by a transversal valley, where man will have almost nothing to do to establish a navigable communication between the two oceans. Thence, also, without doubt, the extraordinary assertion advanced by the Salomon Company, that this depression of the chain offers a point of passage situated only 37 feet above the mean height of the sea at Panama, a point which the company naturally chose for carrying across the summit level of the canal which they projected. From the sides of the Cerra de la Trinidad flow three principal streams, of which the most important, the Caimito, empties itself into the Pacific 14 miles west of Panama. The two other streams, which flow towards the Atlantic, are the Cano Quebrado and the Rio Trinidad—rising at nearly the same point, they separate as they advance. In the triangular space comprised between them, the laws of nature, which, throughout America, have placed the ridge of separation of the waters flowing into the two oceans, nearer the western side, appears to have been maintained. The wide space which separates the bed of the Trinidad from the base of the spur, is occupied by vast and, for the most part, unbroken plains, from the middle of which rise some isolated hillocks. One does not there meet with the water-courses which might be expected from their extent, but many swamps, and even deep lakes, communicating with the Rio Trinidad by small natural canals, called *esteros*. In these plains is found the large lake of *Vino tinto*, observed by Mr. Morel, which is upwards of a league in diameter. Here also are found, near the mouth of the river, the swamps of *Agua Clara*, which have in some places, as I have been assured, a depth of water of 42 feet.

Besides these streams, there is another on the western slope, flowing directly into the Pacific; it is the Rio Grande, situated between the Caimito and Panama, and having its mouth 1½ miles west of that city. It is indeed a stream of no great magnitude, the upper portions of which are completely dry during some months of the year; but it presents a characteristic which it has in common with other affluents of the Pacific Ocean, which is, that the lower portion of its bed has but a slight descent and great width, so that the tide mounts it to a considerable distance, and thus forms an arm of the sea (*estero*) intruding into the land, with a depth varying from 25 to 33 feet, and sometimes even more, which offers facilities for navigation, though only during high water, and as far as the tide flows. It is to this characteristic that the Rio Grande owes its name, though in fact it is but a brook. Alongside of the Rio Grande is another little ravine, pouring its waters directly into the sea. This is the Rio Farvan, having, towards its mouth, a wide and deep bed, which, at this point, is only separated from the Rio Grande by a hill, around which its waters are forced by high tides, flowing into the Alvine marshes, through which the road from Panama to Chorera passes, thus mingling the waters of the two creeks.

This feature of a great diminution of fall near the embouchure of the stream, is still more perceptible on the Atlantic slope. The Chagres, which is undoubtedly the most important and most voluminous stream of water of this portion of the isthmus, presents it in a very striking manner. The tide of the Atlantic, which rises but from 13 to 15 inches, ascends the river a distance of 17 miles; and is navigable, but with some difficulty, beyond a distance of 18 miles from its mouth. Thence it can be ascended only by poling, on account of the rapidity of the current and the irregularity of the bottom. Laden boats ascend it as far as Gorgona and Crucés, but in the dry season (from December to June) they are obliged to unload the larger barques on a beach near the mouth of the Cano Quebrado, and to load again in smaller boats; and even with these they have great difficulty in reaching Crucés. With the exception of the Rio Chagres, the other rivers of the isthmus can hardly be said to be navigable, and none of them can be made useful for the purposes of navigation.

The waters flowing from the central chain, at its point of depression, are divided, as we have seen, between two basons: that of the Caimito upon the Pacific slope, and that of the Rio Chagres, or rather of the Cano Quebrado, upon the Atlantic slope. It is then between these two basins, that the point for the passage of a canal of communication between the two oceans, is to be sought. It is along their tributaries that we must look for the valleys where the canal should pass; and finally, it is in the neighbourhood of the localities where their waters empty into the sea—that is, near the mouths of the rivers Caimito and the Chagres—that we must seek the points of communication of the canal itself with the two oceans; the bars which always form at the points where the running waters of rivers meet the still waters of the ocean, rendering it necessary, as a general rule, to avoid carrying a great line of navigation to those points.

The Rio Chagres has, in fact, at its mouth, a bar with a depth of water of but 18 feet. Under these circumstances, the insufficiency of such an entrance for an oceanic canal like that of which we are treating, may be easily comprehended; a canal which should admit ships of the greatest tonnage, and demanding at the least a draft of 23 feet of water. Doubtlessly it would not be impossible to remedy, at least temporarily, this defect; but the uncertainty, proved by experience, of the results of operations carried on at the mouths of rivers even larger than the Chagres, especially when they are for the purpose of opposing the accumulation of sand, should induce us to employ such means only in case it should be impossible to find another suitable entrance; here, however, nature herself appears to have provided one. Five miles to the eastward of the Rio Chagres, is the large and capacious bay of Limon, 2½ miles in width, and 3¾ miles long. It has a great depth of water, which, in the centre, reaches 32 feet. This bay is separated from the river by a tract of land in general of but slight elevation, and offering some low portions, which afford facilities for excavating a canal of communication with the river; works simple and easily constructed, will suffice for the establishment of a vast and sure port at the entrance of the canal, in the bay, which, opening to the north, is at present exposed directly to the action of the north, north-east, and north-west winds, which reign almost constantly in these latitudes.

These disadvantages found at the embouchure of Rio Chagres in the Atlantic, are still more apparent at that of the Rio Caimito in the Pacific. This embouchure is situated in the middle of a vast beach, which low water leaves uncovered; it thus unites a want of depth of water and the inconvenience of sand banks. The coast does not offer in this neighbourhood a favourable locality for a good port, with a sufficient depth of water, for to the depth of water necessary for vessels must be added the height of the tide. But, fortunately, the neighbourhood of the port of Taboga, and the almost constant tranquility of the Gulf of Panama, at the bottom of which is the mouth of the Caimito, permit us, in establishing the entrance of the canal, to take into consideration only the depth of water at high tide.

The place on the coast which appears to me the best to correspond with the required conditions in this respect, is a little bay with an opening of 382 yards, situated 2½ miles to the eastward of the mouth of the Caimito. At its entrance the mean depth was found to be at least 26¼ feet at high tide. There would be but little to do at this point to establish the entrance lock of the canal with such a depth of water that ships might enter, at least at high water, during the neap tides, about the first and last quarters of the moon.

TANNED CANVAS.

Communications from Mr. Hamlet Millett *respecting a mode of rendering Canvas durable by means of Tan, to the Commissioners on the Fine Arts.*

It may be necessary first to state that the process of tanning canvas, although easy and expeditious, is altogether different from that which is employed by tanners for converting the skins and hides of animals into leather: it varies also from that mode in common use among the Yarmouth herring-fishermen and others for tanning their nets to protect them from premature rottenness, although the process of extracting the tan from the oak bark is nearly the same as that which is used by the fishermen for the above purpose, namely, by decoction. It will be seen from the following statement that every possible care and attention has been paid to render the results of the experiments as decisive as could be desired.

Four unprimed ¾ canvases were tacked with copper nails to four stretching frames. The four canvases were cut from off the same roll of cloth, and the stretchers were all manufactured from the same plank of wood. Two of the four canvases, after being stretched on their frames, were immersed for three days and nights in a vat of strong tan, made expressly for the occasion; the tanning liquor being kept, during the whole process, at a temperature of 150°. The two canvases, after being taken from the vat and well dried in the open air, were hung on the side of an underground cellar, the walls of which were never free from damp; the floor was often flooded in wet seasons for months together, and the water, long before it disappeared, never failed to become putrid. This circumstance rendered the situation in which the tanned canvases were hung for trial peculiarly well adapted for ascertaining the power of the antiseptic properties of tan. The two untanned canvases, after being tacked with copper nails to their stretchers, were hung up near the two tanned ones. Care being taken to exclude all circulation of air, the cellar door was locked, and the four canvases were entombed without once seeing the light for no less a period than ten years.

Mr. Millett proceeds to state that when, after the trial, the four canvases were removed from the cellar into the light for examination, the two tanned canvases were found to have completely resisted putrefaction, no symptom of decomposition appearing in any part of them. Pliers were forcibly applied to the edges, but the cloths were found to be as strong as they were on the day when they were first placed in the cellar. The stretchers also, which were tanned with the canvases, were found to be no less sound; they were pierced with a gimlet in several parts, both back and front, and were found to have undergone no change. Not so with the untanned canvases and their stretchers; in them decomposition had made very considerable progress; they were found to be in a half state of decay. On using the pliers the canvas proved to be extremely tender, rending with little exertion. The stretchers also were in a state of decay; on piercing them with a gimlet they were observed to be very unsound; and the growth of fungi, one of the evidences of decomposition, showed itself, particularly about the joints of the stretchers. The same two tanned canvases were again placed in the cellar, together with one of the two untanned canvases; the other, after having been cleansed (as well as its stretcher) from the mould that covered it, I caused to be tanned precisely in the same way in which the other canvases had been treated. After being taken from the vat and dried in the open air, this canvas was also placed in the cellar with the other three, and the door was again closed on them.

These experiments, Mr. Millett adds, were continued with the same canvases during a considerable lapse of time, in all about twenty years. When finally examined, the two tanned canvasses, together, with their stretchers, continued, notwithstanding the severe trial they had experienced, sound in every part; not the smallest symptom of decay could be discovered; proving, far beyond my anticipations, that the antiseptic properties of tan are sufficiently potent to resist putrefaction and decomposition in canvas, and even in wood; hence, rendering them durable even when placed in the most trying situations.

The untanned canvas and its stretching-frame were found, on their final inspection, to be completely decomposed; the canvas dropped from the frame, and the frame itself was a mass of touchwood. The half decomposed canvas and stretcher which I had caused to be tanned before the second trial took place, as above stated, had suffered no further decomposition; a strong proof that tan has not only the power to prevent but to arrest the progress of decomposition. This latter experiment was expressly on a supposition that, if the result should prove successful, the process might be rendered available in prolonging the existence of the valuable works of the old masters.

Process for extracting tan from oak bark for tanning canvas.—One hundred weight of good, sound, and coarsely-ground oak bark, will make one hundred gallons of proper tanning liquor, which is sufficient to tan about sixty square yards of canvas.

To make a vat of tan of any required size.—Take any quantity of good coarsely-ground oak bark, according to the number of square yards of canvas about to be tanned, and water agreeably to the foregoing proportions; boil them together for twelve successive hours in a copper vessel (not in an iron one, as the oxide of iron has a tendency to decompose tan), taking care to supply the decoction with fresh water from time to time to make up the loss occasioned by evaporation. When sufficiently boiled, strain off the tanning liquor from the bark through a hair-sieve, and put it by for use. The tanning liquor thus made is at least three times as strong as that made made use of by the herring fishermen, to render their nets durable, and still stronger than that employed by the Dutch shipowners for tanning the sails of their vessels with the same view.

The copper in which the oak bark has been boiled, will serve every required purpose as a vat, with one trifling addition, namely, a small piece of flat oak board, about nine inches in diameter, and one inch thick, cut into a circular shape, to be placed at the bottom of the inside of the copper. Its use is to prevent the canvas, whilst undergoing the process of tanning, from touching the bottom of the vessel.

Process for tanning the canvas.—Take any quantity of canvas, say 15 yards, to tan which 25 gallons of tanning liquor, made as above are required. Pour the tanning liquor into your vat or copper, and heat it by means of a gentle fire under it, to the temperature of 150°, then immerse the canvas therein, and continue the immersion at the same degree of temperature, day and night, for 48 hours. A longer period would do the canvas no harm; a shorter is by no means recommended. The canvas during the process of the tanning should now and then be moved in the vat, in order that every part of it may be equally tanned. The tanned canvas, on being taken from the vat, must be neither wrung nor squeezed, but hung up or laid out on a grass-plot to dry, allowing the air alone to take up the remaining moisture.

The process for tanning canvas, when strained on stretching frames, is dissimilar to the foregoing, both as to the construction of the vat, and the mode for regulating and keeping up the necessary temperature required for carrying on the process of tanning the canvas already strained. The process about to be described might indeed be dispensed with, as canvas can be as readily strained on the stretching-frames after as before it has undergone the process of tanning, and much labour and expense would be saved thereby; but it has been thought that the stretching-frames on which the canvas is strained, ought to receive from the tan the same protecting advantages as the canvas itself, they being equally subject to the causes of decomposition. Stretching-frames intended to undergo the tanning process, ought to be completely made and fitted, but not put together before they undergo the process of tanning. It is scarcely necessary to observe that the stretching-frames here mentioned are those to which canvas is not yet attached.

To construct a vat for tanning canvas when stretched on its frame, together with the apparatus for heating the tanning liquor, and keeping it at a proper temperature during the operation of tanning.—A case made of oak planking, about an inch in thickness, and somewhat resembling a picture packing-case, was provided, with one side left open to admit the strained canvases; this served as a vat. The case or vat being placed edgewise, a lead worm of a 20-gallon still was wound round the inside of it, and steam from water, constantly kept in a boiling state in the still, and forced through the worm in the vat, kept the tanning liquor at a proper temperature. This was the sort of vat which was used for tanning the two ¾ canvases and their stretching frames, before mentioned; it was expressly made for carrying into effect those experiments.

Mr. Millett proceeds to offer some observations *on the mode of lining pictures*:—A picture requiring to be new lined, being spread out for that purpose, take a basin of strong tanning liquor, prepared according to the foregoing process, and in a moderately warm state; wash the back of the picture therewith, using a soft sponge; when the tanning liquor so applied shall have become dry, the same process should be repeated, and so continued for three or four times. The use of the tanning liquor so employed, is to arrest, by the antiseptic properties of tan, the further progress of the decomposition which may have taken place in the original canvas on which the picture is painted. The second precaution to be observed is to apply a well-tanned canvas as a lining to the picture; and lastly, as a still further protection to it, it would be well to use a stretching-frame that has undergone the process of tanning also.

A vat or apparatus constructed as follows, will be found well adapted for the purpose of tanning stretching-frames:—A square trough of any required length, and about a foot in height and breadth, formed of zinc and lined inside with oak planking, with a lid made to open and shut, is all that is necessary as regards the vat itself. To heat the tanning liquor therein and keep it at a proper temperature, during the operation of tanning, a lead-pipe leading from a steam-boiler, and passing through the tanning liquor in the vat, is also required. The heating process should be regularly kept up for at least 48 hours. The stretching-frames should be regularly made and fitted previously to their being tanned, and they should be tanned before they are finally put together.

The writer further remarks that few things are so destructive to canvas as oil, and expresses his opinion that, in priming canvas for painting, care should be taken to have it well sized, so that it may fully resist the oil in the priming colour.

BRITISH ASSOCIATION.

Session 16*th*, *held at Southampton, September*, 1846.

Section A.—Mathematics.

Self-Registering Instruments.

Mr. Brooke stated that he had applied to the barometer, thermometer, and psychrometer, a new apparatus, by which also he had obtained a register of variations of the declination magnet, a description of which he had transmitted to the Royal Society. This may be briefly explained to consist of two concentric glass cylinders, which enclose between them a piece of photographic paper, and are carried round by clockwork once in twelve hours. These are covered by a blackened case having a narrow slit parallel to the axis of the cylinders, through which a small point of light, reflected from a spherical concave mirror attached to the magnet, and then refracted through a cylindrical lens, passes and impresses the paper. Some photographs were exhibited, and were much approved of by the president, by Dr. Whewell, and other leading members of the committee who were present: from these the position of the magnet at any given time might generally be determined within ten seconds, and frequently within five. The self-registering barometer was described as a syphon barometer, the extremities of which were nearly an inch in diameter, and exactly the same size, being adjacent portions of the same tube. A glass bulb having a tubular stem rests on the surface of the mercury in the lower end of the tube, and is maintained in a vertical position by small friction-rollers. On this stem rests the short arm of a balanced lever, and the barometer is so placed that the long arm of the lever carries a black paper screen between a lamp and the slit in the apparatus above described; the light of the lamp being condensed by a cylindrical lens placed in front of and parallel to the slit in the apparatus. This screen has a narrow slit in it, at right angles to the former; and the small portion of light, transmitted through the point at which the two slits cross each other, produces a trace upon the photographic paper. The ratio of the arms of the lever may be determined at pleasure, so as to magnify the variations from two to ten times; and as the line is very sharply defined, when magnified five times the variations may be readily determined to the thousandth part of an inch. The author stated that he had not had the opportunity of determining the errors of the instrument, arising from friction and other causes, but he believed them to be very small. In the self-registering thermometer and psychrometer the mercury in a wide flat bore of the tube intercepts a portion of the focal line of light formed by refraction through a cylindrical lens placed as above. This does not require more particular description, as it differs only in details from similar apparatus, of which a description is in print.

Mr. F. Ronalds, on presenting his third annual volume of observations and experiments made at the Kew Observatory, described his experiments on the photographic self-registration of the electrometer, the barometer, the thermometer, and the declination magnetometer, explained his existing apparatus for these purposes, and exhibited the resulting photographs—but first briefly adverted to his previous proposals in 1840 and 1841, and experiments in 1844 relative to the subject. The principal characteristic of his improved system is a peculiar adaptation of the lucernal microscope. An instrument of this kind was employed in July 1845 to register the variations of Volta's atmospheric electrometer. The pair of straws were properly insulated and suspended within the body of the microscope, and towards its object end. A condensing lens was placed at the end itself, and a good lamp stood beyond it; a strong light was therefore projected upon those sides of the straws which were turned towards the condensing lens, and the other sides were in deep shade. The light also impinged upon a little screen fitted into the back of a case about two feet long fixed to the eye end of the microscope, at right angles with it, and vertically; through this screen was cut a very narrow curved slit, whose chord was horizontal, and radius equal to the length of the straws. Between the electrometer and the screen an excellent combination of achrometer lenses by Ross was accurately adjusted, to produce a good chemical focus of the electrometer at a distance as much beyond the external surface of the screen as the thickness of one of the plates of glass to be presently mentioned. In the long vertical case was suspended a frame about half the length of the case, provided with a rabbet, into which two pieces of plate glass could be dropped, and these brought into close contact by means of six little bolts and nuts. The frame could be removed at pleasure from the line by which it was suspended, and the line, after passing through a small hole stopped with grease at the top of the long case, was attached to a pulley about four inches in diameter, on the hour arbor of a clock. Lastly, counterpoises, rollers, and springs were used for insuring accurate sliding of the frame, &c. A piece of photographic paper was now placed between the two plates of glass in the movable frame, the long case was closed so as to prevent the possibility of daylight entering it, the clock was started, and the time of starting was noted. All that part of the paper which was made to pass over the slit in the screen by the motion of the clock, became now therefore successively exposed to a strong light, and was consequently brought into a state which fitted it to receive a dark colour on being again washed with the usual solution, excepting those small portions upon which dark images of the lower parts of the straws were projected through the slit; these parts of course retained the light colour, and formed long curved lines or bands, whose distances from each other at any given part of the photograph, *i. e.* at any given time, indicated the electric tension of that time. Sometimes daylight was used instead of the light from a lamp, and in that case, during the process some appearances of the sky were occasionally noted, by which it was evident that in serene weather, when the sun's light and heat varied, and the paper became consequently either more or less darkened, the electric tension as shown in the photograph varied also, increasing with the increase of light, &c. This fact has not perhaps before been observed; but as the darkening effect on the paper could not always be depended upon, separate notes were taken of the intensities of light and the same results obtained. At the suggestion of the astronomer royal a distinguishing electrometer formed on the day pile system was afterwards employed, which exhibited in the photograph not only the tension but the kind of electricity possessed by the electrometer at any given time.

The *dry thermometer* was next tried; it was of the horizontal kind, had a flat bore, and its tube was introduced through the side of the microscope; the tube had a diaphram of very narrow aperture fixed upon it, and the slit in the screen at the eye end of the microscope was now of course straight and horizontal. The image was a little magnified, and the breadth of the dark band or line in the photograph became the measure of temperature inversely at any time.* The barometer employed was of the syphon kind; the microscope was turned, in order to bring the long case and its sliding frame into an horizontal position; the clock was placed at one end, and a little weight sufficient to keep the frame steady was suspended by a line passing over a pulley at the other end. The lower leg of the barometer was introduced through the now bottom of the microscope, it was provided with a similar kind of diaphram to that on the thermometer, and of course the slit in the screen was now vertical. A very light blackened pith-ball rested on the surface of the mercury, and its image was slightly magnified, but will in future be much more so. The *declination magnet* was one of two feet, provided with a damper, and its mode of suspension was essentially similar to that of the Greenwich declinometer. In order to adapt it for self-registration, a very light conical brass tube, projecting six inches beyond its north end, was affixed to the lower side of the spur which carried it, and to the north end of that tube a small wire, called the index, was attached at right angles; this index descended through little slits in the bottoms of the two cases, enclosed the magnet, &c., and took the place of the electrometer described above in the lucernal miscroscope, which was placed below the cases, and was now required to be much longer than before, in order that the image and motion might be sufficiently magnified, yet retaining a flat field. Everything was very firmly fixed upon the two pillars which formerly carried the transit instrument of George III.

A great many photographs were obtained and sent for inspection to Greenwich. Of some termday impressions, Mr. Glaisher, the magnetical and meteorological superintendent of the Greenwich Observatory, says, in an official note, that "the beautiful agreement of those results with these at Greenwich is highly satisfactory." This must be gratifying to Mr. Ronalds, who has from the first so ably devised and conducted the experiments and observations at Kew.

Mr. Dollond's *atmospheric recorder* registers simultaneously and continuously on the same sheet of paper every variety of change in the barometer, thermometer, hygrometer, electrometer, pluviometer, and evaporator: it also records the force and direction of the wind.

The *barometer* is upon the siphon principle, of a large bore. Upon the surface of the mercury in the shortest leg is placed a float, very accurately counterpoised, leaving only sufficient weight to compel it to follow the mercury, and is correctly adjusted to that part of the apparatus which moves the indicator, when the pressure of the atmosphere is at thirty inches. The connexion of the float with the indicator is so arranged as to give a scale of three to one.

The *thermometrical* arrangement consists of ten mercurial thermometers of a peculiar form. These are suspended upon an extremely delicate and accurate balance. They are placed at the north end of the frame, and are screened from the effects of the wind and rain by perforated plates of zinc.

The *hygrometer* consists of a slip of mahogany cut across the grain. This was placed in a cylinder filled with water, and suspended from the upper end with a weight of two pounds at the other end, until it was found by repeated examination to be completely saturated, and no longer to increase in length. The length was then referred to an accurate scale, and the slip of mahogany placed alongside the pipe of a stove, under the same suspension and weight, until its shortest length was obtained. The difference of the two results being carefully taken, the scale was formed accordingly. It is placed in a tube, open at both ends for a free passage of air, outside the observatory. It is suspended and weighted as before, with full power to act upon the arm of the indicator, quite free from the action of the sun or rain, and is found to be extremely active and firm in its operation, showing upon an open scale every hundredth of its extremes in dryness and moisture.

The *electrometer* for thunder-storms and electric changes is constructed by placing a well insulated conductor upon the highest convenient place, from which a wire is brought down to an insulation on the top of the observatory, and from thence to a standard through another insulation to a metal disc, between which and another fixed disc there is a movable disc attached

* In order to convert this into the wet-bulb 'hygrometer' nothing of course is necessary but the application of the usual cup of water and the capillary threads.

to a glass or insulating arm, for the purpose of connecting it with an accurate support upon which it can move with the greatest facility. In connexion with this arm and disc there is a pencil carried forward to the line of indication. The third disc before stated is fixed to a standard at about three inches from the first: to this a wire is attached and carried into the earth. By this arrangement the electricity put in motion by a thunder-cloud is received and registered. The effect during a thunder-storm is extremely interesting. When a cloud charged with the electric fluid comes within the range of the conductor, the movable disc begins slowly to pass from the first to the third disc, discharging each time a proportion of the electricity, and increasing in rapidity of motion until the discharge of the cloud by lightning takes place. It then falls back to the first disc, and remains perfectly quiet until the next electric cloud approaches. If, in the interim, a cloud charged with rain only should descend or pass over, no movement of the disc takes place.

For the pluviometer, at a distance from the outside of the observatory, there is a receiver of one foot square, clear from all surrounding matter that might interfere with the direct fall of the rain upon its surface. From this receiver a pipe conducts the rain into another receiver inside the observatory, directly under the registering apparatus; in this there is an air-float connected with a set of inclined planes, each inclined plane being equal to one inch of rain. These inclined planes, as they pass up, move the indicator across the destined proportion of the paper; showing, as it proceeds, the result of each drop to the hundredth part of an inch in superficies, and continues to advance until it arrives at one inch. It is then instantly discharged, and returns to the zero of the scale, or commencement of another inch. The internal receiver is calculated to contain six inches of rain.

The evaporator is supplied with water from a vessel which is, in form, an open cube of one foot square, placed by the side of the receiver for rain, and filled from a correct gauge to a given number of inches; it is covered with a plate of glass, elevated sufficiently above the edge of the vessel to prevent rain from falling into it, but not so close as to prevent the air from freely acting upon the surface of the water. A receiver inside the observatory is placed under the arm of the indicator upon the same level as that outside, connected by a pipe. In this receiver there is a float, governed by the evaporation from the external vessel, which moves the pencil of indication until an inch of the water has evaporated; it then, as in the rain-gauge, returns to the zero. This is repeated for several inches until the receivers are nearly empty, when they must be refilled from the external vessel.

The power or force of the wind is registered by a combination of suspended weights, acted upon by inclined planes or edges in connexion with a board of one foot square to receive the impression; this board is kept in opposition to the direction of the wind by a powerful vane, its motion being as free from friction as possible, every part being correctly counterpoised. When the board is acted upon by the wind, it raises the suspended weights by a chain passing over a pulley in a line with the direction of the wind, and well secured from the weather. The suspended weights in connexion with an inclined lever carries the pencil of indication along the scale, and registers the weight lifted in oz. and lb. avoirdupois. The scale having been found, by repeated trials, to be correctly equal to the weights recorded upon it. The direction of the wind is also registered at the same time by another pencil, which marks the course upon the paper, throughout the whole circle of the horizon, or that proportion through which it passes.

Section B.—Chemistry and Mineralogy.

"*On the Decomposition of Water into its constituent Gases by Heat.*" by W. R. Grove.—Prof. Grove, in the first place, called attention to the fact, proved by Cavendish and the French philosophers, that oxygen and hydrogen being exposed to a high temperature, or the electric spark, immediately combined to form water. He then announced his discovery that all the processes by which water may be formed are capable of decomposing water. He believed that the explosion of the mixed gases by the electric spark was due only to the heat of the spark, and not at all to electrolysis. Priestley's method for decomposing gases by passing them through heated tubes was described, and the advantages of using a form of Volta's eudiometer, in which incandescent platina was employed, to effect decomposition, pointed out. By an apparatus of this kind, ammonia, camphor, the prot- and per- oxides of nitrogen were readily decomposed. It was stated that hydrogen gas exposed to the ignited wire always shows the presence of oxygen; and that it is impossible to pass hydrogen gas through water without its taking up so much oxygen, as to acquire the power of giving luminosity to phosphorus in the dark. It was found that if hydrogen and carbonic acid were exposed to the action of the ignited wire, there was a contraction of one volume, leaving a residue of carbonic oxide. If, instead of carbonic acid, carbonic oxide was employed, the mixed gases expanded in volume; and the carbonic oxide, taking oxygen from the water, was converted into carbonic acid. Here we have two dissimilar results produced by the same cause—by means of hydrogen we take oxygen from carbonic acid, and by means of hydrogen we take oxygen from water. If steam is formed in the eudiometric tube and acted on by the ignited wire on cooling, a small bubble of gas is formed, which is found to be oxygen and hydrogen in the exact proportions in which they form water. This is the result of the first action of the heated wire:—in a few seconds a small bubble of gas is formed, but if the action be continued for a week, it does not increase in quantity. It is, however, easy to remove the bubble as it is formed, and bring a fresh quantity of steam under the influence of the heated wire, and thus collect a quantity of gas which should be quite sufficient for any eudiometric examination. Numerous forms of apparatus were described by which this experiment can be performed. It might be objected that, as the wire was ignited by a voltaic battery, the decomposition was not due to the heat of the wire, but to an electrolytic action. This objection would not, however, be maintained by those who were acquainted with electrical phenomena. With the view, however, of removing all doubt, the use of the battery was entirely done away with, and all the results were obtained by the agency of heat alone, in the following manner. Into a silver tube a capillary tube of platina is soldered, and this is again connected with a bent tube, which admits of the removal of any gas formed. The tubes being filled with distilled water, their ends being immersed in vessels of oil or water, the flame of a spirit lamp, urged by the blow-pipe, is brought to bear upon the capillary tube of platina, by which it is almost immediately brought to a white heat. The water is, of course, instantly converted into steam; and this steam is decomposed by the agency of the heat alone. By boiling, we thus convert steam into mixed oxygen and hydrogen gases; and this operation may be continued for any length of time by removing the bubble of gas formed, and bringing a fresh supply of steam under the influence of the heated platina. If fused globules of platina are dropped into water, there is immediately formed a bubble of oxy-hydrogen gas, which may be collected in an inverted tube. Prof. Grove went on to show the probable connexion between this phenomenon of decomposition and the spheroidal state of fluids when they are projected on capsules of heated platina, which had been referred to a repulsive action of a coating of steam enveloping the spheroid of fluid; but in all probability the revolving drop was undergoing decomposition by the agency of the heat to which it was exposed.

Dr. L. Playfair remarked that the facts which Mr. Grove had announced might possibly be regarded as due to a catalytic action of the platina, such as had been observed by Dr. Faraday, and such as was evidenced in the action of oxide of copper on the hypochlorites. Many bodies at high temperatures exhibited a great affinity for oxygen, which they did not possess at lower temperatures, as, for instance, silver, gold, and even platina itself, which metals absorbed oxygen when intensely heated, and gave it out again on cooling. If the experiments had been tried in tubes of quartz or silica, they would not have been open to the objection which the use of so peculiar a metal as platina appeared to involve.

Dr. Leeson made some remarks, which went to show that in all probability the bursting of steam boilers might be explained by the discovery of Prof. Grove.

Mr. Hunt explained some experiments of Woolfe on the boilers of some Cornish steam-engines, which appeared to prove the conversion of steam into gas under the influence of the heat to which the water and steam were exposed in the experiments.

Prof. Faraday thought Mr. Grove's discovery would not explain the bursting of steam boilers, which might be easily done by Prof. Boutigny's experiments on the spheroidal condition of fluids. He did not agree with Prof. Grove that the repulsion of the steam was insufficient to explain the spheroidal state. He would rather desire, in the present stage of the inquiry, to discuss the philosophy of the question than the applications of Mr. Grove's discovery. Was it a decomposition of water by the agency of heat, or was it the action of certain substances when heated? It appeared to him that the investigation was a great step onwards and towards a knowledge of the corpuscular action of bodies, and he did not doubt that some remarkable developments as to the influence of caloric in overcoming the force of aggregation would ensue.

On the changes which mercury suffers in glass vessels hermetically sealed.

Prof. Oersted read a paper on this subject. He said that the progress of these changes is so exceedingly slow, that it seldom becomes sensible for years. He had observed them twenty years ago in a glass bulb of mercury. At first a yellow powder was formed in the bulb, and after some years a black one. He took up the subject in 1838, experimenting with four bulbs, two of white and two of green glass, carefully weighed, in order to detect any portion of air that may be admitted through the pores or fissures of the glass. The weight, however, remained unaltered. In July 1839, a small change was visible. At first a feeble ring of yellow powder adhering to the glass was observed, where the mercury had been a long time in contact with the glass. And again in a new place, under similar circumstances, a new ring was formed, and so on. The surface itself upon which the mercury had rested some time had a thin covering of yellow adherent powder. In the course of years the yellow powder became black. The mercury had lost a great deal of its fluidity, and it adhered slightly to the glass. The order in which the two colours follow each other indicate that they are not produced by oxidation. In the green bulbs no change was visible. In 1845, Prof. Oersted procured twelve bulbs, six of which should contain besides the mercury, atmospheric air, the air of the other six being expelled by boiling the mercury; three of each series being white, and three green glass. In July last there was no sensible change in the first series (namely, mercury mixed with air), but in the second (from which the air had been expelled), change had taken place at all but one. Rarefaction of the air had no connexion with the phenomena, but the boiling of the mercury seemed to have some influence upon them. The Professor intends to continue the investigation of these phenomena, which, however, appear to him to depend upon a reaction between the glass and the mercury. Analysing the two powders, sulphur was detected. But as a yellow compound of mercury and sulphur contains oxygen, and as no oxygen was found in the black powder, it may be questioned whether the first compound takes oxygen from the air of the bulb and returns it in passing to the state of the black one, or that some hitherto unknown exchange takes place between the elements of the glass and the mercury.

"*On the Corrosion of Iron Rails in and out of use.*" By R. Mallett.—The researches on this subject are still in progress, experiments are being made upon six different lines of railway. The principal facts already ascertained are:—1st. That there is a real difference in the rate of corrosion between the rails in use and out of use:—that this appears to be connected with their peculiar molecular condition so induced. 2nd. The determination of the complex conditions as to magnetism, which affect rails some time in use, producing both induced and permanent magnetism in the rails, each rail being magnetic with polarity, and having from four to eight separate poles each.

Mr. Hunt stated his confirmation of the experiments of Ritter—that magnetism had the power of protecting iron from corrosion;—to which he referred the protecting influence exerted on the rails in use on railways.

"*Notice of a Gas Furnace for Organic Analysis.*" By Dr. Percy.—This was an ingenious arrangement, by which gas, burnt, mixed with air, through wire gauze, was substituted for charcoal. Its advantages are its extreme cleanliness, and the power which the operator possesses of regulating, at will, the heat,—which is not practicable in the ordinary furnace for organic analysis with charcoal.

Section C.—Geology.

"*On the Northwich Salt-Field,*" by G. W. Ormerod.—The rock-salt of Northwich is part of the New Red Sandstone series: it forms two strata, the uppermost of which is 75 feet thick, and the lower 105 feet; they are separated by 30 feet of stone, containing veins of salt. Throughout the district, the brine is reached at the same level, about 87 feet below the river Weaver; and varies uniformly in all the shafts when any change takes place. In this district there are three faults, which have displaced the strata to a considerable amount. The first fault is a throw-down to the east of 400 yards; it intersects the South Lancashire coal-field, and passes into Cheshire, along the valley to the west of Bellefield and Hill Cliff, a range of New Red Sandstone (*bunter sandstein*), capped by the ripple-marked beds denominated "water-stones," in which the foot-marks of the *Cheirotherium* occur; the summit is 352 feet above the level of the sea. Near Northwich this fault appears to pass into another, which is an *upthrow* to the east of 460 feet, and passes also through the South Lancashire coal field, by Wigan Churd, and east of Warrington into Cheshire, when it continues along the valley east of the Bellefield range. Through the coal district this line is proved by numerous workings; and in the salt district, by the extent to which the workings and the sinking of the land have gone. The third great fault, passing by Northwich, ranges by south-west to north-east, passing near Holt, and running up the valley between the Peckforton Hills and the low range occupying the east side of the Dee. This valley is occupied by marl, in which saline springs are frequent. At Northwich the line runs in a north-easterly direction, forming the north-west boundary of the rock-salt. The subsidences already mentioned as taking place in the salt district are either sudden or gradual, and have been noticed for many years. At the yard of the Weaver Navigation Office the sinking is at least six feet; and on the road from that place to Winnington the depressions are shown by cracks in houses and visible subsidences in the land. From the same cause, a lock and a factory have required to be removed, meadows are laid under water, and the towing-path by the river has had to be raised. The Whitton Brook has also been made six feet deeper, to enable the navigation to proceed as formerly.

Mr. Phillips observed, that one of these faults laid down in Mr. Ormerod's map was 50 miles long, and one was in the direction of the magnetic meridian. In the south of England, the New Red Sandstone became much thinner, less complicated, and was deficient in salt.

Sir H. De La Beche stated that the variegated tints of the water-stones were due to a difference in the amount of oxydation of the ores they contained. The decomposition of vegetable matter had, in some places, reduced the per-oxide to the condition, comparatively, of a prot-oxide,—changing the red colour of the rock to a pale blue.

Mr. Greenough remarked, that salt existed below the coal-measures in Durham, as well as in the New Red Sandstone, whilst the salt beds at the base of the Carpathians were of tertiary age.

"*On certain Deviations of the Plumb-line from its Mean Direction, as observed in the neighbourhood of Shanklin Down, in the Isle of Wight, during the progress of the Ordnance Survey,*" by Mr. W. Hopkins.—The difference of latitude between Greenwich and the station of the Ordnance surveyors at Dunnose, on the *north* side of Shanklin Down, as determined by triangulation, was *greater* by 2·22 seconds, than as determined by zenith sector observations. When, however, a new station was chosen on the *south* side of Shanklin Down, the difference of latitude, as determined by triangulation, was *less* by 3·99 seconds than it appeared to be when determined by the zenith sector. These discrepancies would be accounted for, if the mass intervening between the stations at Shanklin Down were sufficient to produce, by its attraction on the plumb-line, the observed deviations. The requisite calculations for proving the adequacy of this cause had not been made; the tendency, however, would necessarily be to produce effects of the same nature as those observed; and the author thought it probable that the intensity of the attraction of the hill would be found sufficient to account for the phenomena.

Coal of India.

Mr. Ansted read an analysis of a report to the Indian Government on the coal of India.—The subject of coal in reference to our Indian territories has for a long time been looked upon as of great practical importance; and the increase of steam navigation, as well as the proposed introduction of railroads into that country, renders every matter connected with the subject in the highest degree interesting. I have received, since my arrival at Southampton, through the kindness of Colonel Sykes, a copy of a report recently made to the Indian Government, giving an *aperçu* of the information at present obtained concerning the various beds of coal chiefly in Northern India, and I cannot help thinking that an account of the information thus communicated may be generally useful, especially as much of it is new, and a very large proportion of the remainder, although known to those who have been long accumulating matter that bore reference to this subject, is little familiar to the great body even of those most interested in Indian affairs.

The coal-districts of India, as determined in this report, may be considered as five in number,—three of these are in Northern India, and one in Cutch, while the fifth includes the province of Arracan and the coast of the Burman empire near Tennasserim. Of these the Cutch coal is certainly not of the carboniferous epoch, and it appears to be of little importance at present, and unpromising. It has also been described by Captain Grant, in the Transactions of the Geological Society, and therefore I will not now allude to it. I shall endeavour to describe, first, the chief points of importance with reference to the great and continued series of the North Indian coal-fields, and then allude shortly to the prospects of success in the attempt to obtain coal from the coasts of the Bay of Bengal.

The whole district, extending from the neighbourhood of Hoosungabad on the Nerbudda river (lat. 23 n. long. 78 e.), on the left or south bank of the river, and extending in a north-easterly direction for a distance of about 400 miles to Palamon, thence eastward for 250 miles to Burdwan near Calcutta, and running northward for 150 miles to Rajmahal, exhibits, it would appear, at intervals by no means distant, a continually repeated outcrop of rocks, consisting of sandstones and shales, with occasional limestone; while at intervals a number of beds of coal have been recognised, of variable thickness and value, but all appearing to exhibit evidence of the existence there of a great coal-district.

Commencing again on the flanks of the Garrow mountains, near the Burhampooter, and on both banks of that vast river, we find another, or perhaps a continued, outcrop of similar beds also containing coal, and reaching in a north-easterly direction for nearly 400 miles. The intermediate plains, whose breadth between Rajmahal and Jumalpore is about 100 miles, are chiefly alluvial, and thus it is possible that there exists a vast range of carboniferous strata, reaching for upwards of 1000 miles along the flanks of the Himalaya mountains,—the distance from the mountain chain gradually increasing as we advance westward, the mountains tending northwards and the outcrop of the carboniferous bed southwards, until finally, the distance between them being upwards of 500 miles, the relation is not easily recognised. The whole of the drainage of the Ganges and the Burhampooter occurring, however, in this interspace, we are enabled to connect the geological phenomena in a very interesting manner. Before, however, considering the relation of the discovery thus made to Indian geology generally, it will be necessary to give some account of the nature of the coal in the various places where it has been worked, and the present state of our knowledge on the subject.

Neighbourhood of Calcutta.

I. Commencing with the neighbourhood of Calcutta, we have first to consider the Burdwan coal-district, and with this I shall group the Adji and the Rajmahal fields; all these are on the banks of either the Hooghley or Ganges, or on the tributaries of these rivers. The Burdwan district has been long known, and a good deal worked. The workable beds of coal are nine and seven feet thick respectively. They are associated with sandstone, shale, and a little clay, ironstone, and about six other thinner seams of coal, while other thick beds are mentioned, but their real existence as separate beds is doubtful. There are now thirteen spots at which this coal is worked, but most of them are surface working. The deepest sinking is 190 feet. The distance to Calcutta is about 90 miles, but the actual transit of coal is nearly 200 miles. There would seem to be a continuous outcrop of the same kind of rocks from Burdwan up the Adji river, and northwards to Rajmahal. On the Adji river the coal has been worked in more than one spot, and is found to be of about the same quality as that of Burdwan; but neither of them is considered of nearly so good quality as the English coal. Farther on, at Rajmahal, coal is known to exist, but has not yet been much worked. The quality of that which has been obtained does not appear good.

Palamon Coal Field.

II. The Burdwan coal-field appears to be connected, by a continuous outcrop, with a district at Palamon, in which coal has been worked in no fewer than four places. The coal here is apparently immediately reposing in a valley enclosed by hills of granite, and is associated with a good deal of iron. There are several beds that are of workable size, but a good deal of the coal is heavy and of inferior quality, and some of it appears to be anthracitic. These coal-beds are not far from the Soane river, a n about 100 miles from its confluence with the Ganges, a little above Dinapoor and Patna; but the Soane is not at present navigable. To the west of Palamon the carboniferous beds are described as appearing along two irregular lines, the one towards the south-west for 150 miles, reaching beyond Koorbah, and the other more westward, by Sohagepoor, to the Nerbudda. These beds appear to connect themselves with the Burdwan coal-field; and near Ramgurh, coal has been obtained in two or three places. This coal is said to be of very good quality and of considerable thickness; but there can be little doubt that a statement made in the report, of the bed of coal being 200 yards in thickness, must be owing to some misunderstanding of the account and sketch originally communicated. It seems certain, however, from the extent of the outcrop, that the seam must be one of considerable magnitude. Westwards, again, from Palamon, and at a distance of about 50 miles, coal has been found in several places in Singrowli, but the beds at present known are thin; and again, to the south-west, the same mineral occurs at Sirgoojah, where fine coal has been seen, but is not used at present. Between the Singrowli coal and Jubbulpore excellent coal has been found in several places, indicating an extensive coal-field; but the nature and thickness of the beds is not stated.

The Nerbudda district, although from the drainage of the country it belongs to the Bombay side of India, is manifestly more related, so far as the old rocks are concerned, with the Bengal territory. The coal is about 350 miles from Bombay, and the Nerbudda river is at present not navigable. There seem to be three districts in the Nerbudda valley in which coal is found, but the most important of them is that near Gurrawarra, about midway between Hoosungabad and Jubbulpore. The coal here, indeed, appears to be perhaps the best hitherto found in India, and exists in beds three in number, whose thickness respectively is said to be 20 feet, 40 feet, and 25½ feet. There are also other beds, one of which is four feet.

The discovery of this, the Benar coal-field, promises to be of great importance. It is also very near another basin, where there are beds also of excellent quality, one of them 6 feet in thickness. At Jubbulpore itself coal has been found at a depth of 70 feet, one bed being nearly 12 feet thick.

Coal Fields East of Calcutta.

III. Let us consider now the district east of Calcutta. We there find true carboniferous rocks on both flanks of the Garrow Mountains, commencing near Jumelpore, and thence continuing north-eastwards for a distance amounting on the whole to nearly 400 miles through Lower and Upper Assam. The district nearest Calcutta is Silhet, on the south flanks of the Garrow, where eleven beds of coal have been determined, whose total thickness as already ascertained is said to amount to 85 feet. This coal is of excellent quality, and can as readily be conveyed to the Upper Ganges as the Burdwan coal. The most remarkable beds occur at Cherra Ponji; but these appear irregular, although they are undoubtedly of great thickness in several spots, amounting sometimes to nearly 30 feet. There are also other important beds. They have been known for more than ten years, but have not been worked; and since their first discovery large quantities of iron have been smelted with charcoal.

After passing the districts in which the coal has been thus clearly exhibited, we proceed next to the Assam districts, also more or less continuous, and extending for about 350 miles chiefly along the south side of the Burhampooter; the whole being divided into the two groups of Lower and Upper Assam, separated at Bishenath, 170 miles above Calcutta. Six coal-fields are enumerated in the Upper district, and three in the Lower; but the latter, although it would seem not so promising, are looked on as scarcely less important in consequence of their greater accessibility.

So far as details are concerned, however, the Lower Assam coal offers but little that is in any way positive; the indications consisting rather of rolled fragments drifted, than of distinct and well-marked beds. It is called lignite in a report from Lieut. Vetch; but both coal and lignite are terms frequently used without reference to any peculiar character of the mineral, or any geological position. Similar beds of coal or lignite to those found in Lower Assam, south of the Burhampooter, are also mentioned as occurring on the north in three of the streams flowing into that river from the Bootan range. The Upper Assam coal is manifestly of great interest, and likely to prove very important. It is associated with abundance of clay ironstone.

About eighty miles above Bishenath other beds, stated to be 6 feet thick, have been worked for the sake of trying the economic value of the coal. It is described by the commander of one of the Assam Company's steamers, in a letter dated 24th January, 1845, as far the best he ever had on board a steamer, and far superior to any coal in Calcutta. From the growing importance of the tea-trade from Assam, this is likely, therefore, to be of great value. Still farther up the country there are several important beds, dipping, it would appear, at so high an angle, and placed so unfavourably with regard to present means of transport, that it would be difficult to work them. The other beds that appear in this district are exposed to the same difficulty; and the coal throughout northern India appears to be in this respect unfavourably placed.

Passing on now to the other districts in India, and the East, in which carboniferous rocks and beds of coal have been met with, I have to enumerate two, the Tenasserim and the Arracan districts, which, from their near vicinity to India and their geographical position, are of considerable importance. The former has been known for some years, and there are said to be four spots at which coal appears; but of these one only seems likely to prove of economic value. From the accounts given of this coal there is every reason to conclude, that one of the beds is not of the carboniferous period; and although another (on the Thian Khan) has been the subject of a far more favourable report, being called cannel coal, and stated by Mr. Prinsep to be an admirable coal for gas, there is yet much probability of the whole being of the tertiary period. These beds have been described in the *Journal of the Asiatic Society* for 1838.

In Arracan there are eleven beds of coal, but all of them are thin, and their position nearly vertical. They are said to be associated with sandstones, limestones, and shales; but it is clear that they can at present be looked at only as indications, and not of any practical importance.

Such is a general account of the coal-districts of India, so far as I have been able to glean evidence from the report of the committee for the investigation of the coal and mineral resources of India for May 1845. This report manifestly contains much detailed information that is of practical importance; but one can hardly help being struck by the absence of that definite information with regard to associated beds, and the general position of the coal, which could alone, under the peculiar circumstances, have given to geologists satisfactory evidence as to the age of this widely-extended deposit. Speaking now to geologists, and to many who are fully alive to the vast importance of accurate and detailed knowledge of the structure of a country before great mining operations are commenced in it, I need not do more than allude to the absence of this kind of information; but, having stated its absence, I may perhaps be permitted to offer my own views of the subject as obtained from the perusal of the documents laid before me.

Geological Position.

Connecting, as I think we cannot help doing, the general geology of Asia with that of Europe, and looking at the wide extension of true coal-bearing rocks in the northern hemisphere,—tracing these rocks, as we are able to do at intervals, from our own country eastward through Belgium, Northern Germany, Bohemia, and Silesia, thence across to the valley of the Donetz, watching the development of the older beds of the Devonian period in Armenia, and thence on the northern side of the great Himalayan range,—discovering them in their most characteristic form in the Altai mountains, and finding them also on the south flanks of these lofty mountains in the neighbourhood of Calcutta, where the Burdwan beds have long been known, giving satisfactory evidence of their age; there is certainly no reason for wonder if these carboniferous beds, in their most typical and valuable form, should be traceable also throughout Northern India. For what is the geological structure of that country? The Himalayas themselves, the great back-bone of Asia, are probably to be looked on as a mountain chain much more recent than the Alps. In India, the great Sewalik tertiaries, where fossils are now being figured and described by Major Cautley and Dr. Falconer in a monograph, the most magnificent that has yet been attempted, are lifted into hills which elsewhere might well deserve the name of mountains; and whatever the conditions may have been subsequently to original deposition of the beds, there is no reason why, in a country where the scale is in everything so vast, there should not be a continuous outcrop of carboniferous rocks for hundreds of miles together. In consequence of movements of very recent date, wide tracts of India, occupying tens and almost hundreds of thousands of square miles to the south, are covered with basalt, and other large tracts of still greater extent by modern and almost alluvial formations, providing by their decomposition the most prolific soil in the world. Between and amongst this extent of modern eruptive movement, and forming, perhaps, a barrier to some of the beds, comes in, it would seem, the great range of carboniferous beds, exhibited at intervals through the country, nearly parallel with the great range of disturbance, and also greatly disturbed and elevated, and broken into small basins. So far as the evidence goes, it is certainly probable that the coal found near Burdwan to the north and west, and apparently continuous with it, is of the same age. If so, analogy would suggest that the similar and similarly situated beds much farther to the west but still nearly continuous, are of the same age; and the districts to the east contain, it would seem, at least some coal so like the other in quality, that here also we should expect it. But analogy goes yet farther, and running down the coast of the Birman empire towards the great island of Borneo, recent investigations seem to show that there also beds of coal of great value, and of the carboniferous epoch, exist. I will not cross the great line of elevation in the tropic of Capricorn, and cross to the eastern coast of Australia, for a farther illustration; but the idea cannot fail to strike every geologist that so singular an association of similar beds over so large a part of the existing land on the earth must, if true, have its origin in some general cause, the result of a law of far greater universality than any we now recognise.

But, on the other hand, it is by no means impossible, when we consider the extent to which the tertiaries are developed in the great range of conglomerates on the flanks of the Himalayas, and the similar and almost equally fossiliferous deposits on the banks of the Irawaddi on the east and in the Gulf of Cambey on the west, that, after all, these beds are not carboniferous, but merely occasional and irregular bands of modern or tertiary lignite. Should this be the case, it will be necessary and interesting to determine the point, and recognise, if possible, the actual extension of the Burdwan field, concerning whose age the fossils collected by Dr. Royle leave no doubt. The relation also of these beds with those of the Altai, mountains by a comparison of fossils is an important and most interesting point.

Economic Value of the Coal Fields.

Speculations of this nature cannot fail to be suggested by the present communication. A vast and most important subject is presented for our consideration, but, unfortunately, the evidenee is imperfect in a most important point. These beds of coal, occurring as they do chiefly in granitic basins, and often detached, like the coal of France, may be, as I believe they are, of the carboniferous age; they may also be oolitic, like the imperfect coal of Cutch, and of some parts of our own country, or they may be tertiary lignites. Now it may seem of little importance to the mere surveyor what the geological position of these beds may be, provided there is the material he needs; but experience renders it probable that on the mere question of age does, in fact, depend much of their true economic value. Could it be satisfactorily shown that throughout the wide district of northern India there is a true outcrop of carboniferous beds, such as occur in England, in America, or even in eastern Australia, there can be no question that the value of a very large part of the possessions of England in the East might be considered much increased; for the beds would then probably be steady and permanent, and the application of the resources in knowledge and wealth of a great, a rich, and an enterprising people, would very soon bring into operation, in all those districts, manufactures and commerce on the grandest scale. The navigation of the rivers, the state of the roads, the means of communication by railroads, would be immediately established or permanently improved; and the result must be improvement in the condition of the country.

Should it, on the other hand, appear that these so called coal-fields are merely detached basins of lignite, whether tertiary or oolitic, they would, in all probability, be of variable and local thickness: their value might appear considerable at the first glance; but it might even not repay the expense of working: the quantity would be much less than was calculated, the quality would not improve in deep workings, and the real and important uses of mineral fuel would not be recognised in it. A small amount of strict geological knowledge and a few fossils would have tended to set at rest, if it did not completely settle, this question, which I think it will be at once seen is of great importance. I ought, perhaps, to apologise for taking up the time of the meeting by such remarks as these; but the absence generally of distinct knowledge of the principles of our science amongst gentlemen who on every other account are so admirably adapted for the work they undertake is too well illustrated in the present case and too generally important not to excuse my introducing the subject. My own position, too, as one of those employed in the education of a large number of practical men in geological science; and the fact that I have interrupted a course of geological lectures to the cadets, who will in future years form the great body of the officers of our Indian army, is a satisfactory proof that this view is now beginning to be understood by those who are, perhaps, most interested in its application. Much yet remains to be done in the application of science to art, and possibly the result of the present investigation may give additional reason, if any were wanted, for commencing some general system of scientific education.

The result of the present inquiry will be seen at once to be unsatisfactory, although highly suggestive for future investigation. No value can be attached to mere statements of the existence of carbonaceous matter in beds, because many of the important practical conditions are independent of mere appearance and experiments on detached fragments.

Col. Sykes observed that it was of importance to obtain coal for the proposed railways in India, especially as wood was beginning to be scarce in many parts. The report mentioned the occurrence of coal at 90 localities,—most of them in a bed between the Nerbudda and Calcutta. With a trifling exception the whole of India south of this line was destitute of coal.

Mr. Lyell stated that he had lately examined the coal-field of Richmond, in Virginia,—one of the most valuable in the United States. He had obtained fishes from that coal-field, which M. Agassiz referred to the *Oolitic period;* and the plants, which had been examined by Mr. Bunbury, presented an assemblage agreeing with those found at Whitby, in Yorkshire. The coal-field was known to be newer than the carboniferous period; and it contained one bed of coal, 30 feet thick, from which gas had been made,—and it was now becoming of great value. No estimate of the probable value of Indian coal could be formed by comparing it with coal of the same age in Europe.

Sir H. De la Beche observed that it was incorrect to suppose that, in other countries, the most valuable coal would be found in rocks agreeing in age with our own coal-measures. The *Burdwan* coal appeared to be of the same age with the Australian coal, as there were plants common to both.

Mr. Jukes pointed out the identity in direction of the granitic hills of North-Eastern Australia with those of the Malay Peninsula; and the occurrence of coal, at an intermediate point, in Borneo.

Dr. Falconer considered the Burdwan coal-field peculiar:—its plants were all unlike those of Europe; and it contained neither dicoyledonous nor coniferous wood. He thought it might be older than any of our coal-fields.

Mr. W. Sanders exhibited Sections made on the line of the Great Western Railway, between Bristol and Taunton.—The general section represented a distance of 45 miles, on a scale of 33 inches to the mile. It passed first through the junction beds of red marl and lias; then for 6 or 7 miles through new red sandstone, touching once upon the upper beds of the carboniferous limestone. For the next 12 miles there are alluvial tracts, separated by cuttings of new red sandstone. At 21 miles, the Uphill cutting passes through the new red sandstone and lias and then the carboniferous limestone, at the base of which are some masses of trappean rock. The railway then proceeds for 17 miles over an alluvial plain, interrupted only by a cutting through the new red marl and lias at Puriton. From this point to Taunton the course is over a moderately level country of new red sandstone. Four enlarged drawings represented the details of the Ashton, Uphill, and other cuttings. In the section at Pylle, Mr. Sanders discovered remains of Cypris, and a plant (*Naiadites lanceolata*), in the lower lias marls; and in the Uphill and Puriton sections the representatives of the bone bed occurs. Since there are usually several calcareous beds in the lower marls, containing the same fish-scales, shells, &c., Mr. Sanders prefers the classification of Mr. Conybeare, who considered these beds the lowest member of the lias to the separation of the bone bed,—which is only a part of this series, into the Triassic system, as proposed by M. Agassiz, on account of the nature of its fishes.

"*On the Muschet Band, commonly called the Black-band Ironstone of the Coal-field of Scotland.*" By Mr. Bald.—This band of ironstone was discovered about forty years ago, by Mr. David Muschet, of the Calder Iron-works, near Glasgow. It had been frequently passed through; but was thrown away as rubbish till Mr. Muschet ascertained its value,—when extensive mines were opened for working it. Two bands of this ironstone are found in the great coal-fields of Lanark,—one 14 inches thick; the other, which is 73 fathoms lower, is 16 inches thick. The ironstone of the Muschet band is much more easily reducible than the ordinary dry ironstone,—and requires less fuel. In Scotland it appears to be co-extensive with the coal formation. In South Wales, also, it is found; but there is little of it in England or Ireland. Fifty years ago there were only five iron-works in Scotland, comprising about fifteen blast furnaces which, together, produced 540 tons of iron per week. There are now 100 blast furnaces in action, which produce 12,000 tons per week, or 624,000 tons in the year,—the value of which, at 3*l.* per ton, is 1,872,000*l.* This great increase Mr. Bald attributed to the discovery of the Muschet ironstone, and to the introduction of the hot-blast. He also mentioned that Mr. Muschet, who is now in his eighty-sixth year, has published a volume on the manufacture of iron, containing an analysis of every ironstone and ore he could obtain; and he trusted his labours would, at least, be recognized in scientific societies, although the pecuniary advantage arising from his discoveries had fallen into other hands.

Section G—Mechanics.

"*On the Sailing Powers of two Yachts, built on the Wave Principle.*" By Dr. Phipps.—The first was built for Dr. Corrigan, of Dublin, in 1844; a small open boat 24 feet by 6, of 3⅔ tons, which did so well that she was able to beat everything near her own size, and to sail with those which exceed it in some instances as far as four times. She was dry in seas where they were wet, was very stiff, sure in stays, and steered well at all times. The second is a yacht of 45 tons, O.M., for Samuel Hodder, Esq., of Ringabella; built from the drawing by Mr. Peasley, of Passage West, in Cork. She appears to have the following qualities: a first rate performance, attained without sacrifice of any good quality, large accommodation, high stability. She is weatherly, steady and easy, dry in the worst weather, and pitches and ascends less than any vessel I was ever in. She turns so sharply that no 10 ton yacht can do it quicker, and steers so well, scudding in a gale of wind, that notwithstanding an unbalanced state, from an injudicious shift of mast, she neither broaches to, nor is compelled to lay to—which a companion of larger size (60 tons), and of tried sea qualities, was forced to do, and, in consequence, arrived from Cork to Dublin 14 hours after the wave-built yacht. In a race at Kingstown for the Railway Cup of 100 guineas, in which she was matched against the best boats of the three countries, in a time race, including one fine yacht of 100 tons, she won—and did the course exactly in 4h. 22m. 58s.—it being 46 nautic miles. Making no allowance for tacking or starting from absolute rest, the rate of this is 10½ knots per hour. This is a great result for a principle yet in its infancy. The same vessel left Holyhead in a gale of wind, with storm-sails, main-sail stowed, and everything made snug; with a reefed try-sail, a double-reefed fore-sail,, and third jib. She lay in one stretch to the Irish coast, where she tacked to the southward, beating down to the Arklow light in 11 hours. Six persons on board, being separately questioned, agreed that the time from Holyhead to the Irish coast was 4½ hours. Making every reasonable allowance, less than 50 nautic miles could not have been done; and this gives a velocity of 11 nautic miles per hour,—an unrecorded speed for ships of any size, close hauled, but surprising for a vessel of 45 tons, and in a very rough sea. It was, in fact, remarked on board that, as the wind freshened, her pace increased without limit. This agrees with the fact stated by Capt. Fishbourne, of the Flambeau steamer, on wave lines, that she had a speed greatest in the worst weather, as compared with her rival.—It is perhaps possible to improve sailing vessels greatly, as compared with steamers. When so improved, they might be used where sailing vessels nearly compete with steamers at present. This may be further helped by the diminution of insurance and of the present unneccssary waste of human life.

Mr. Scott Russell, after expressing his gratitude to the Association for directing its attention to so important a subject, proceeded to explain the theory of what was known as the wave principle in ship building. He was first induced to direct his attention to this subject when the canal companies proposed some years ago to establish swift boats that might compete with the mail coaches. On being applied to by them, his first attempt was to build one with a spheroidal bow, produced by the revolution of an ellipse; but the result was not as successful as was to be wished. The favourite shape of bow among seamen at the time was that called a duck's breast, but the effect was to raise a large wave immediately in front of the vessel, which of course considerably retarded its velocity. He then directed his attention to the motion of the water itself. When a vessel passed through the water at a great velocity a high wave was raised at the head, as high in the old steamers as four feet; and this wave on falling back formed a hollow by its pressure immediately behind it, and the water was afterwards sent out with great force on both sides of the bow. All this was a costly and useless expenditure of force. He thought that, in removing the particles of water to allow the vessel to pass, it was necessary to expend the least force on the whole; and, therefore, the first impulse should be given gently. This force should increase to a certain point, and then decrease as gradually, leaving the particles to rest quietly at the greatest breadth. In endeavouring to ascertain the least resistance necessary to bring the particles of water out of a state of rest he conceived that there ought to be a similarity between the motion of water and that of a pendulum revolving in a circle according to the curve of the vessel's size; and this led him to adopt the form known as the wave principle. This is different from a bow formed of two straight lines meeting at an acute angle, in being gently hollower than such a bow towards the cut-water, and a little rounder towards the greater breadth. The object to be attained was, he conceived, to remove the particles of water rapidly, and at the same time not to throw them farther aside than the breadth of the vessel amidships. That this object was effected by the wave principle he ascertained in the following manner:—He got his model boat, 75 feet long, to be carried along by high-bred horses at a speed of 17 miles an hour, and made the head pass between two oranges floating on the water, and which he intended to represent two particles of the water to be removed. The oranges merely touched the side of the vessel until they got amidships, and there remained; thus showing that no greater force had been applied to them than was necessary to remove them out of the way of the vessel. Another phenomenon observed was, that, instead of the high wave at the bow, which sailors thought was a sign of a ship sailing well, or what they called carrying a bone in her teeth, the elevation and subsequent depressson of the water were entirely got rid of. In their place there was a gentle, long elevation, just under the shoulder of the vessel, where all sailors would like her to be supported. For the closing of the water at the stern he at first thought it would be better to have the same shape behind; and this had the effect of bringing the oranges together again behind in an horizontal direction; but he found it did not answer at all. It occasioned too high a resistance, and had a multitude of bad qualities. He discovered, in fact, that the fuller she was behind, and the flatter she lay upon the surface of the water, the quicker she sailed: and that this should be the case is clear, when it is considered that the water, returning to its level, is governed by an entirely different law from that by which it is first separated. The power which sends the water into the wake has nothing to do with that which displaces it before. It is forced upwards by the greatest pressure from below in vertical lines of the cycloidal family. A run fine below and full above was attained by many experiments, as the best for good steering and other qualities. This full water-line above should never exceed a cycloid. The vertical lines, in which the water rises in the secondary wave (which really replaces the displaced water) may be cut off, at any convenient height, close to the stern. These two considerations united led him to the adoption of what is known as the wave principle. In the wave formation the greatest breadth of the ship is not at the bows, or even amidships, but a great way aft, in the ratio of three to two. In the shear plan the bow of this form has one main cycloid, and all the other bow lines are parts of cycloids. In this form the particles ascend and descend without shock.

Mr. Vignolles asked if the Admiralty had got vessels built on this principle,—*and if not, why not?*

Mr. Scott Russell replied, that he had been much more desirous for the adoption of the system in other ships than in the Admiralty, because he had been informed that the Admiralty did not like the introduction of scientific principles into ship-building, and preferred remaining as they were. He had, therefore, been averse to obtrude the subject on them. He might state, however, that the best informed men at the Admiralty were aware of the existence of the wave principle; and it was not improbable they might adopt it, although he could not say how soon, nor to what extent.

Professor Owen's Geological Lecture.

Extinct Animals of Great Britain.

In one of the evening lectures the Professor commenced by stating that he proposed to submit to the learned and distinguished assembly which he had the honour of addressing some of the general conclusions which he had deduced from a study of the fossil remains of the class mammalia discovered in the soil of Great Britain; and he deemed it fortunate to have this opportunity of showing what enlarged and unexpected views of ancient nature might be obtained from dry comparisons and descriptions of processes of bone and tubercles of teeth, and he hoped to make those views intelligible to all, without the obscuration of technical anatomical terms. He proposed, first, briefly to notice the principal forms or kinds of mammalian quadrupeds that had been successively introduced into the portion of earth which now constituted our island; secondly, to consider the mode of their introduction here, and their relations to existing species at present localised in Europe and Asia; and, finally, to point out the correspondence between the existing and extinct groups of mammalia peculiar to other great natural divisions of dry land.

Animals Preceding the Oolitic Period.

We discern, he said, the earliest trace of the warm-blooded, air-breathing, viviparous quadrupeds at that remote period which immediately preceded the deposition of the oolitic group of limestones. The massive evidence of the operation of the old ocean, from which those rocks were gradually precipitated, extends across England, from Yorkshire on the north-east, to Dorsetshire on the south-west, with an average breadth of nearly thirty miles; and from some land which formed the southern shore of this arm of sea, were washed down the remains of small insectivorous, and probably marsupial quadrupeds, distinct in genus and species from any now known in the world. With these small mammals there occur elytra of beetles, and debris of cycadeæ and other terrestrial plants. The character of some of these vegetable fossils and of the associated shells, as the trigoniæ, and the great abundance, in the oolitic ocean, of fishes whose nearest living analogue is the cestracion, recall many of the characteristic features of actual organic life in Australia. From the remote period in which the remains of mammals first make their appearance to that in which we again get indubitable evidence of their existence, a lapse of time incalculably vast has occurred. We trace it, though inadequately, by the successive deposition from seas and estuaries of enormous masses of rocks of various kinds, the graveyards of as various extinct forms of animal and vegetable life. The shelly limestone slate, which contains the bones of the amphitheria and phascolotheria, lies at the base of the inferior oolite. Upon it have been accumulated the enormous masses of the great oolite, the cornbrash, and the forest marble; and upon these have been successively piled the Oxford clay and coral rag, the Kimmeridge clay and Portland stone. In the still more enormous masses of Wealden rocks, rising to the height of eight hundred feet, and deposited after the formation of the Portland sands by the water of an immense estuary, no true indications of warm-blooded animals have been hitherto discovered. Four hundred feet deep of gault and greensand rest upon the Wealden, but reveal no trace of cetacean or other form of mammalian life. Over these foundations of the present south-eastern part of our island the ocean continued to roll, but under influences of heat and light favourable to the development of corals and microscopic calcareous shells, during a period of time which has permitted the successive accumulation of layers of these skeletons, in a more or less decomposed state, with probable additions from submarine calcareous and siliceous springs, to the height of one thousand feet. But although amongst the remains of higher organised animals that have become enveloped in the cretaceous deposits there have been recognised birds, pterodactyles, and a land-lizard, probably washed down from some neighbouring shore, no trace of a mammalian quadruped has yet been discovered in them. The surface of the chalk, after it had become consolidated was long exposed to the eroding action of waves and currents. Into deep indentations so formed have been rolled fragments of chalk and flint, with much sand. The perforations of marine animals on that surface have been filled with fine sand; and there are many other proofs of the lapse of a long interval of time between the completion of the chalk deposits of Britain and the commencement of the next or tertiary era. Of this era our present island gives the first indication in traces of mighty rivers, which defiled the fair surface of the rising chalk by pouring over it the debris of the great continent which they drained,—a continent which has again sunk, and probably now lies beneath the Atlantic. The masses of clay and sand that have been thus deposited upon the chalk are accumulated chiefly in two tracts, called the London and Hampshire basins, which seem to have been two estuaries or mouths of the great river; the one extends from Cambridgeshire through Hertfordshire and Suffolk to the North Downs, the other from the South Downs into Dorsetshire.

At the time when these vast but gradual operations were taking place, an arm of sea extended from the north to the area called the basin of Paris, which received the overflow of a chain of lakes extending thither from the highest part of the central mountain-group of France. An enormous mass of mixed or alternating marine and fresh-water deposits was accumulated in this basin, coeval, if we may judge from the identity of the species of shells, with the outpouring of eocene, London, and plastic clays upon the English chalk.

Eocene Animals.

The proofs of the abundant mammalian inhabitants of the eocene continent were first obtained by Cuvier from the fossilised remains in the deposits that fill the enormous excavation in the chalk called the Paris basin. But the forms which that great anatomist restored were all new and strange; specifically, and for the most part generically, distinct from all known existing quadrupeds. Long before any discovery had been made of remains of terrestrial mammals in the contemporary London and plastic clays, the existence of neighbouring dry land had been inferred from the occurrence in those deposits of bones of crocodiles and turtles, and from the immense number of fossil seeds and fruits, resembling those of tropical trees, as pandani, cocoa-nuts, &c.

Scanty as are the eocene mammalia hitherto discovered in the London clay, they are highly interesting from their identity or close affinity with some of the peculiar extinct genera of the Paris basin. In the fresh water and marine beds at the north side of the Isle of Wight, and at the opposite coast of Hampshire, the united thickness of which beds is about 400 feet, remains of the very same peculiar quadrupeds of the contemporaneous Parisian formations have been found.

One of the rarest and most remarkable of the pachyderms, whose peculiar characters were obscurely indicated by Cuvier from scanty fossils yielded by the Montmartre gypsum, has had its claims to generic distinction established, and its nature and affinities fully illustrated, by more perfect specimens from the eocene marls of the Isle of Wight: in no other part of Great Britain has any portion of the chæropotamus been found, except in the above limited locality, which alone corresponds with the formations of the Paris basin in mineral character as well as in date and origin. This discovery becomes, therefore, peculiarly interesting and suggestive. For were the common notion true, that all the fossil remains of quadrupeds not now existing in our island had been brought hither during a single catastrophe, and strewed with the detritus of a general deluge over its surface, what would have been the chance of finding the lower jaw of a chæropotamus in the very spot and in the very limited locality where alone in all England the same kind of deposits existed as those in which the unique upper jaw of a chæropotamus had been found in France? With the chæropotamus are associated, in the Binstead and Seafield quarries, remains of anoplotherium, dichobunes, palæotherium, and lophiodon, showing, with the fossils from the London clay, that the same peculiar generic forms of the class mammalia prevailed during the eocene epoch in England as in France.

With the last layer of the eocene deposits, we lose in this island every trace of the mammalia of that remote period. What length of time elapsed before the foundations of England were again sufficiently settled to serve as the theatre of life to another race of warm-blooded quadrupeds, the imagination strives in vain to form an idea of, commensurate with the evidence of the intervening operations which continental geology teaches to have gradually and successively taken place. Our own island yields us but a dim and confused indication of the geological operations that took place between the eocene and pliocene periods, in the wreck of strata that constitute part of the so-called crag formations on its eastern coast. When the eocene and other foundations of our present island begin to rise from the deep and become the seat of fresh-water lakes, receiving their tranquil deposits, with the abundant shells of their testaceous colonies, and during the long progress of that slow and unequal elevation which converted chains of lakes into river courses, an extensive and varied mammalian fauna ranged the banks or swam the waters of those ancient lakes and rivers: of this we have abundant evidence in the bones and teeth of successive generations which have been accumulated in the undisturbed stratified lacustrine and fluviatile formations. The like evidence is given by the existence of similar remains in unstratified coral drifts, composed of gravel exclusively derived from rocks in the immediate vicinity of such drift, without a single intermixture of any far transported fragment; equally conclusive and more readily appreciable proof that the now extinct pliocene and pleistocene mammalia actually lived and died in the country where their remains occur, has been brought to light from the dark recesses of the caves which served as lurking places for the predaceous species, and as charnel houses to their prey.

Gigantic Pliocene Animals.

At the period indicated by these superficial stratified and unstratified deposits the mastodon had probably disappeared from England, but gigantic elephants of twice the bulk of the largest individuals that now exist in Ceylon and Africa roamed here in herds, if we may judge from the abundance of their remains. Two-horned rhinoceroses, of at least two species, forced their way through the ancient forests or wallowed in the swamps. Deer, as gigantic in proportion to existing species, were the contemporaries of the old uri and bisontes, and may have disputed with them the pasturage of that ancient land. The carnivora, organised to enjoy a life of rapine at the expense of the vegetable-feeders, to restrain their undue increase and abridge the pangs of the maimed and sickly, were duly adjusted in members, size, and ferocity, to the fell task assigned to them in the organic economy. Besides a British tiger, of larger size, and with proportionally lager paws than that of Bengal, there existed a stranger feline animal of equal size, which, from the great length and sharpness of its sabre-shaped canines, was probably the most ferocious and destructive of its peculiarly carnivorous family. Of the smaller felines, we recognise the remains of a leopard or large lynx, and of a wild cat. Troops of savage hyenas, larger than the fierce crocuta of South Africa, which they most resembled, devoured what the nobler beasts of prey had left. A species of bear, surpassing the ursus ferox of the Rocky Mountains, found its hiding place in many of the existing limestone caverns of England. With it was associated a somewhat smaller kind, more like the common European bear, but larger than the present individuals of the ursus arctos. Wolves and foxes, the badger, the otter, the foumart, and the stoat, complete the category of the known pliocene carnivora of Britain.

These animals native in Great Britain.

The first idea which commonly suggests itself on the discovery at some depth in the soil of the fossil remains of a large quadruped, now strange to our island, is, that the carcase of such animal had been drifted hither from some distant region. Prof. Owen alluded, in refutation of this idea, to the evidence which Dr. Buckland had brought forward of the long-continued habitation by hyenas of the Kirkdale cave in Yorkshire; of the remains of young mammoths, rhinoceroses, and hippopotamuses, that had been dragged into the cave, and their devoured, or their bones knawed, by the hyenas. Amongst other phenomena he particularly adduced the following: it is well known that the antlers of deer are shed and renewed annually, and a male may be reckoned to leave about eight pairs of antlers besides its bones to testify its former existence upon the earth; but as the female has usually no antlers, we may expect to find four times as many pairs of antlers as skeletons in the superficial deposits of the countries in which such deer have lived and died. The proportion of the fossil antlers of the great extinct species of British pliocene deer, which antlers are proved by the form of their base to have been shed by the living animals, is somewhat greater than in the above calculation. Although, therefore, the swollen carcase of a great exotic might be borne along a diluvial wave to a considerable distance, and its bones ultimately deposited far from its native soil, it is not likely that the solid shed antlers of such species of deer should be carried by the same cause to the same distance, or rolled for any distance, with other heavy debris of a mighty torrent, without fracture and signs of friction. But the shed antlers of the large extinct species of deer found in this island and in Ireland have commonly their points or branches entire, as when they fell; and the fractured specimens are generally found in caves, and show marks of the teeth of the hyenas, by which they have been knawed; thus at the same time revealing the mode in which they have become introduced into those caves, and proving the contemporaneous existence of both kinds of mammalia. The perfect condition, and the sharply defined processes, often in high relief, of many of the bones of the elephants, rhinoceroses, and hippopotamuses, from our tranquil fresh-water deposits, concur with the nature of their bed to refute the hypothesis of their having been borne hither by a diluvial current from regions of the earth where the same genera of quadrupeds are now limited. The very abundance of their fossil remains in our island is incompatible with the notion of their forming its share of one generation of tropical beasts drowned and dispersed by a single catastrophe of waters. This abundance indicates, on the contrary, that the deposits containing them formed the grave-yard, as it were, of many successive generations. With regard to the mode of introduction of this latest and most extensive series of quadrupeds, it could hardly be supposed that the ponderous rhinoceroses, the hyenas, wolves, foxes, badgers, oxen, horses, hogs, and goats, the smaller deer, hares, rabbits, pikas, or even the aquatic rodents, could have reached this island from the continent, if the present oceanic barrier had interposed. The idea of a separate creation of the same series of mammalia which existed on the continent in and for a small contiguous island will hardly be accepted. The zoologist Desmarest deduced an argument in proof that France and England were once united, from the correspondence of their wolves, bears, and other species known to have existed in this island within the period of history. Prof. Owen deemed the conclusion irresistible when the same correspondence was found to extend through the entire series of proboscidian, pachydermal, equine, bovine, cervine, carnivorous, and rodent mammalia, which characterised the two countries during the pliocene and post-pliocene periods of geology. Thus, observed the lecturer, the science of anatomy having revealed the great fact of the former existence in our present island of the same species of quadrupeds, most of which are now extinct, that co-existed on the continent, has become in an unexpected degree auxiliary to geographical science, and throws light upon the former physical configuration of Europe, and on the changes which it has since undergone.

Geographic Union of England and France.

Prof. Owen then briefly touched upon the purely geological evidence of the former union of England with the continent, and to the comparatively modern period of some remarkable changes which have taken place on our southern coast, and to which may be attributed the final establishment of the British Channel. But in referring to that event as comparatively recent, the term, he said, must not be judged of in relation to any such insignificant fraction of the world's time as has been marked down in the records of the present infancy of the human race: we shall better appreciate it, perhaps, by recalling the ideas of perpetuity which we attach to our ocean barrier, when, gazing on its waves, we sum up the known changes which they have produced on the coast line within the period of history or tradition. The indications of such changes, mighty in comparison with any of which human history takes cognisance, prepare us to view with less surprise the corresponding changes which have taken place in the mammalian fauna; but we are still ignorant of the cause of the extirpation of so large a proportion of it as has become extinct. It is an important fact, however, that a part, and not the whole, has thus perished, and that the cause has not been a violent and universal catastrophe, from which none could escape but by miraculous intervention. There is no small analogy, indeed, between the course of the extirpation of the pliocene mammals and that which history shews to have affected the wild animals of continents and islands in connexion with the progress of man's dominion. The largest, most ferocious, and the least useful of the pliocene species have perished; but the horse, the hog, probably the smaller species of wild ox, the goat, and many of the diminutive quadrupeds, remain. There is not, however, any satisfactory evidence that the human species existed when the mammoth, the tichorine and leptorhine rhinoceros, and the great northern hippopotamus, became extinct. It is probable that the horse and ass are descendants of species of pliocene antiquity in Europe:

there is no anatomical character by which the present wild boar can be distinguished specifically from that which was contemporary with the mammoth. The reindeer has, relatively to Britain, been exterminated, nor will our present climate permit its existence here. With the diminution of the great herbivora, which would naturally follow the limitation of their range when England became an island, that of the carnivora, dependent on them for food, would inevitably follow. And not here only, but likewise on the great continent over which they ranged, which would indicate that the extirpating cause, if it were extrinsic to their own constitution, had been due to changes of the earth's configuration and climate much more extensive than could be connected with the insulation of so small a portion of Europe as Britain.

Thus, continued the Professor, in the endeavour to trace the origin of our existing mammalia, I have been led, by long researches on the fossils of this island, to view them as descendants of a fraction of a peculiar and extensive mammalian fauna which overspread Europe and Asia at a period geologically recent, yet incalculably remote and long anterior to any evidence on record of the human race. It would appear, indeed, from the comparisons which the present state of palæontology permits to be instituted between the recent and extinct mammalian faunæ of other great natural divisions of the dry land, that these divisions also severally possessed a series of mammalia as distinct and peculiar in each during the pliocene period as at the present day.

Comparison with the Extinct Animals of other Countries.

When such a comparison is restricted to the fauna of a limited locality, especially an insular one like Great Britain, the discrepancy between the pliocene extinct and the existing groups of mammalia appears to be extreme. But if we regard Great Britain in connexion with the rest of Europe, and if we extend our view of the geographical distribution of extinct mammals beyond the limits of technical geography,—and it needs but a glance at the map to detect the artificial character of the line which divides Europe from Asia,—we shall then find a close and interesting correspondence between the extinct Europæo-Asiatic mammalian fauna of the pliocene period and that of the present day. The very fact of the pliocene fossil mammalia of England being almost as rich in generic and specific forms as those of Europe leads, as already stated, to the inference that the intersecting branch of the ocean which now divides this island from the continent did not then exist as a barrier to the migration of the mastodons, hippopotamuses, bisons, bears, &c., which have left such abundant traces of their former existence in the superficial deposits and caves of Great Britain. Now it is a most interesting fact, that in the Europæo-Asiatic expanse of dry land species continue to exist of nearly all those genera which are represented by pliocene and post-pliocene mammalian fossils of the same natural continent and of the immediately adjacent island of Great Britain.

America.

If we turn our attention to a more distant natural continent—South America, for example—we shall find that at the present day South America alone, is inhabited by species of which no fossil remains have yet been discovered in Europe, Asia, or Africa. In South America not a single fossil is referable to a true old world *mus*, though numbers of the common rat and mouse have been imported into South America since its discovery by Europeans.

In North America the most abundant mammalian fossils of the corresponding recent geological epoch belong to a species of mastodon (*M. giganteus*) peculiar to that continent. Since, however, North America borders closely upon Asia at its northern basis, and is connected by its opposite apex with South America, it perfectly accords with the analogies of the geographical relations of the last-extirpated series of mammals of the old world that the Asiatic mammoth and the South American megatherium should have migrated from opposite extremes, and have met in the temperate latitudes of North America, where, however, their remains are much more scanty than in their own proper provinces.

Australia.

Australia, in like manner, yields evidence of an analogous correspondence between its last extinct and its present aboriginal mammalian fauna, which is the more interesting on account of the very peculiar organisation of most of the native quadrupeds of that division of the globe. The first collection of mammalian fossils from the ossiferous caves of Australia brought to light the former existence on that continent of larger species of the same peculiar marsupial genera; some, as the thylacine, and the dasyurine sub-genus represented by the *Das. ursinus*, are now extinct on the Australian continent; but one species of each still exists on the adjacent island of Tasmania; the rest of the fossils were extinct wombats, phalangers, potoroos, and kangaroos—some of the latter being of gigantic stature. Subsequently, and after a brief interval, we obtain a knowledge of the former existence of a type of the marsupial group, exemplified by the genera *Diprotodon* and *Nototherium*, which represented the pachyderms of the larger continent, and which seems now to have disappeared from the face of the Australasian earth.

The most remarkable local existing fauna, in regard to terrestrial vertebrated animals, is that of the islands of New Zealand, with which geologists have been made familiar by Mr. Lyell's indication of its close analogy with the state of animal life during the period of the Wealden formation. The only terrestrial mammalian quadruped hitherto discovered in New Zealand, whose recent introduction into that island is at all doubtful, is a small rat. The unequivocally indigenous representatives of the warm-blooded vertebrata are birds, of which the apteryx is the most peculiar. It is the smallest known species of the struthious or wingless order, has the feeblest rudiments of the anterior members, and not any of its bones are permeated by air-cells. This bird forms the most striking and characteristic type of the proper or primitive fauna of New Zealand.

Not a trace of a fossil quadruped has been found in New Zealand; but our present knowledge of the living and the last-exterminated faunæ of the warm-blooded animals of that small but far-distant and isolated portion of earth, shows that the same close analogy existed betwen them as has been exemplified in the corresponding faunæ of larger natural divisions of the dry land on the present surface of this planet.

These Animals cannot have been derived from a common Asiatic centre.

Thus the facts obtained from a study of the fossil remains of mammalian quadrupeds, applied to a scientific consideration of the present distribution of the highest organised and last-created class of animals, demonstrate that, with extinct as with existing mammalia, particular forms were assigned to particular provinces, or natural divisions of the dry land of this globe; and what is still more interesting and suggestive, that the same forms were restricted to the same provinces at the pliocene period as they are at the present day. In pursuing the retrospective comparison of recent mammals to those of the eocene and oolitic strata, in relation to their local distribution, we obtain indications of extensive changes in the relative position of sea and land during those epochs, in the degree of incongruity between the generic forms of the mammalia which then existed in Europe, and any that are now found on the great natural continent of which Europe forms part. It would appear, indeed, from our present knowledge, that the further we penetrate into time for the recovery of extinct mammalia, the further we must go into space to find their existing analogues. To match the eocene palæotheres and lophiodons, we must bring tapirs from Sumatra or South America,—we must travel to the antipodes for myrmecobians and dasyures, the nearest living analogues to the amphitheres and phascolotheres of the ancient oolites. From what ancient centre, if any, the first types of the primary groups of the class mammalia may have radiated, we seem ever destined to remain ignorant, by reason of the enormous alterations of land and sea that have come to pass since the class was first introduced into our planet. We find, however, that from the period when the great masses of dry land assumed the general form and position that they now present, the same peculiar forms of mammalia characterised their respective faunæ. If we carry our retrospect no further back than the pliocene tertiary period, the evidence of the distribution of the recent and extinct mammalia would justify the conclusion that New Zealand, Australia, South America, and the old world or the geographers, had been as many distinct centres of creation. The difficulties that beset the commonly received view are insurmountable. According to the hypothesis that all existing land-animals radiated from a common Asiatic centre within the historical period, we must be prepared to admit that the nocturnal apteryx, which can neither fly nor swim, migrated across wide seas, and found its sole resting-place in the island of New Zealand, where alone the remains of similar wingless birds have been found fossil;—that the wombats, dasyures, and kangaroos should have as exclusively travelled to Australia, where only have been found, in pliocene strata and bone caves, the remains of extinct and gigantic species of the same genera or families of marsupialia; and that the modern sloths, armadillos, and anteaters, should have chosen the route to South America, where only, and in the warmer parts of North America, are to be found the fossil remains of extinct species of those very peculiar edentate genera. It is not less striking and suggestive, though at first sight less subversive of the recent-dispersion theory, to find the elephant, rhinoceros, hippopotamus, hyena, beaver, pika, hare and rabbit, vole and mole, still restricted to that great natural division of dry land to which the fossil remains of the same genera or species appear to be peculiar.

Mr. Lyell's Lecture on the Mississippi Delta.

Mr. Lyell delivered an evening discourse on the delta and alluvial deposits of the Mississippi, and other points in the geology of North America, observed in the years 1845-6. The delta of the Mississippi may be defined as that part of the great alluvial plain which lies below or to the south of the branching off of the highest arm of the river, called the Atchafalaya. This delta is about 13,600 square miles in arrear, and elevated from a few inches to ten feet above the level of the sea. The greater part of it protrudes into the Gulf of Mexico, beyond the general coast line. The level plain to the north, as far as Cape Girardeau, in Missouri, above the junction of the Ohio, is of the same character, including, according to Mr. Forshay, an area of about 16,000 square miles, and is therefore larger than the delta. It is very variable in width from east to west, being near its northern extremity, or at the mouth of the Ohio, 50 miles wide, at Memphis 30, at the mouth of the White River 80, and contracting again farther south, at Grand Gulf, to 33 miles. The delta and alluvial plain rise by so gradual a slope from the sea as to attain, at the junction of the Ohio, a distance of 800 miles by the river, an elevation of only 200 feet above the Gulf of Mexico.

Mr. Lyell first described the low mud-banks covered with reeds at the mouths of the Mississippi, and the pilot-station called the Balize, then passed to the quantity of drift-wood choking up some of the bayous, or channels,

intersecting the banks, and lastly enlarged on the long narrow promontory formed by the great river and its banks between New Orleans and the Balize. The advance of this singular tongue of land has been generally supposed to have been very rapid; but Mr. Lyell and Dr. Carpenter, who accompanied him, arrived at an opposite conclusion. After comparing the present state of this region with the map published by Charlevoix 120 years ago, they doubt whether the land has, on the whole, gained more than a mile in the course of a century. A large excavation, eighteen feet deep, made for the gas-works at New Orleans, and still in progress in March 1846, shows that much of the soil there consists of fine clay or mud, containing innumerable stools of trees, buried at various levels, in an erect position, with their roots attached, implying the former existence there of fresh-water swamps, covered with trees, over which the sediment of the Mississippi was spread during inundations, so as slowly to raise the level of the ground. As the site of the excavation is now about nine feet above the sea, the lowest of these upright trees imply that the region where they grew has sunk down about nine feet below the sea-level. The exposure also in the vertical banks of the Mississippi at low water, for hundreds of miles above the head of the delta, of the stumps of trees buried with their roots in their natural position, three tiers being occasionally seen one above the other, shews that the river in its wanderings has opened a channel through ancient morasses, where trees once grew, and where alluvial matter gradually accumulated. The old deserted bed also of the river, with its banks raised fifteen feet above the adjoining low grounds, bears testimony to the frequent shifting of the place of the main stream; and the like inference may be drawn from the occurrence here and there of crescent-shaped lakes, each many miles in length, and half a mile or more in breadth, which have once constituted great curves or bends of the river, but are now often far distant from it. The Mississippi, by the constant undermining of its banks, checks the rise of large commercial towns on its borders, and causes a singular contrast between the wealth and splendour of 800 or more fine steamers, some of which may truly be called floating palaces, and the flat monotonous wilderness of uncleared land which extends for hundreds of miles on both sides of the great navigable stream.

Mr. Lyell visited, in March 1846, the region shaken for three months in 1811-12 by the earthquake of New Madrid. One portion of it, situated in the states of Missouri and Arkansas, is now called the sunk country. It extends about seventy miles north and south, and thirty east and west, and is, for the most part, submerged. Many dead trees are still standing erect in the swamps, and a far greater number lie prostrate. Even on the dry ground in the vicinity all the forest trees which are of prior date to 1811 are leafless; they are supposed to have been killed by the loosening of their roots by the repeated shocks of 1811-12. Numerous rents are also observable in the ground where it opened in 1811, and many "sink holes," or cavities, from ten to thirty yards wide, and twenty feet or more in depth, interrupt the general level of the plain, which were formed by the spouting out of large quantities of sand and mud during the earthquake.

Formation of the Delta occupied 67,000 years.

In attempting to compute the minimum of time required for the accumulation of the alluvial matter in the delta and valley of the Mississippi, Mr. Lyell referred to a series of experiments made by Dr. Riddell at New Orleans, showing that the mean annual proportion of sediment in the river was to the water $\frac{1}{1245}$ in weight, or about $\frac{1}{3000}$ in volume. From the observations of the same gentleman, and those of Dr. Carpenter, and of Mr. Forshay, an eminent engineer of Louisiana, the average width, depth, and velocity of the Mississippi, and thence the mean annual discharge of water were deduced. In assuming 528 feet, or the 10th of a mile, as the probable thickness of the deposit of mud and sand in the delta, Mr. Lyell founds his conjecture on the depth of the Gulf of Mexico between the southern point of Florida and the Balize, which equals on an average 100 fathoms. The area of the delta being about 13,600 square statute miles, and the quantity of solid matter annually brought down by the river, 3,702,758,400 cubic feet, it must have taken 67,000 years for the formation of the whole; and if the alluvial matter of the plain above be 264 feet deep, or half that of the delta, it has required 33,500 more years for its accumulation, even if its area be estimated as only equal to that of the delta, whereas it is in fact larger. If some deduction be made from the time here stated in consequence of the effect of the drift-wood which must have aided in filling up more rapidly the space above alluded to, a far more important allowance must be made, on the other hand, for the loss of matter, owing to the finer particles of mud not settling at the months of the river, but being swept out far to sea, and even conveyed into the Atlantic by the Gulf stream. Yet the whole period during which the Mississippi has transported its earthy burden to the ocean, though perhaps far exceeding 100,000 years, must be insignificant in a geological point of view, since the bluffs, or cliffs, bounding the great valley, and therefore older in date, and which are from 50 to 250 feet in perpendicular height, consist in great parts of loam containing land, fluviatile, and lacustrine shells, or species still inhabiting the same country. These fossil shells, occuring in a deposit resembling the loess of the Rhine, are associated with the bones of the mastodon, elephant, tapir, mylodon, and other megathoid animals; also a species of horse, ox, and other mammalia, most of them extinct species. The loam rests at Vicksburg and other places on eocene or lower tertiary strata, which in their turn repose on cretaceous rocks. A section from Vicksburg to Darien, through the states of Mississippi, Alabama, and Georgia, exhibits this superposition, as well as that of the cretaceous strata on carboniferous rocks at Tuscaloosa. Mr. Lyell ascertained that the huge fossil cetacean named Zeuglodon by Owen is confined to the cocene deposits. In the cretaceous strata the remains of the mosasaurus and other reptiles occur without any cetecea. The coal-fields of Alabama were next alluded to, from which fossil plants have been procurred by Professor Brumby and Mr. Lyell, of the genera sphenopteris, neuropteris, calamities, lepidodendron, sigillaria, stigmaria, and others, most of them identical in species, as determined by Mr. C. Bunbury, with fossils of Northumberland. This fact is the more worthy of notice, because the coal of Tuscaloosa, situated in latitude 33° 10′ north, is farther south than any region in which this ancient fossil flora had previously been studied, whether in Europe or North America; and it affords, therefore, a new proof of the wide extension of a uniform flora in the carboniferous epoch. Mr. Lyell, adverting to the opinion recently adopted by several idle botanists, that the climate of the coal period was remarkable for its moisture, equability, and freedom from cold, rather than the intensity of its tropical heat, stated that this conclusion, as well as the oscillations of temperature implied by the glacial period, is confirmatory of the theory first advanced by him in 1830, to explain the ancient geological changes of climate by geographical revolutions in the position of land and sea.

The lapse of ages implied by the distinctness of the fossils of the eocene, cretaceous, carboniferous, and other strata is such, that were we to endeavour to give an idea of it, we must estimate its duration not by years, as in the case of the delta, but by such units as would be constituted by the interval between the beginning of the delta and our own times.

Doctrine of the earth's antiquity not to be refuted by prejudice.

"It is now fifty years," said Mr. Lyell, "since Playfair, after studying the rocks in the neighbourhood of Edinburgh in company with Dr. Hutton and Sir James Hall, was so struck with the evidences they afforded of the immensity of past time, that he observed, 'How much farther reason may go than imagination can venture to follow!' These views were common to the most illustrious of his contemporaries, and since that time have been adopted by all geologists, whether their minds have been formed by the literature of France or of Germany, or of Italy, or Scandinavia, or England; all have arrived at the same conclusion respecting the great antiquity of the globe, and that, too, in opposition to their earlier prepossessions, and to the popular belief of their age. It must be confessed that while this unanimity is satisfactory as a remarkable test of truth, it is somewhat melancholy to reflect that at the end of half a century, when so many millions have passed through our schools and colleges since Playfair wrote that eloquent passage, there should still be so great a discordance between the opinions of scientific men and the great mass of the community. Had there been annual gatherings such as this, where they who are entitl d to speak with authority address themselves to a numerous assembly drawn from the higher classes of society, who, by their cultivation and influence, must direct the education and form the opinions of the many of humbler station, it is impossible that so undesirable and unsound a state of things should have now prevailed, as that there should be one creed for the philosopher, and another for the multitude. Had there been meetings like this even for a quarter of a century, we should have already gained for geology the same victory that has been so triumphantly won by the astronomer. The earth's antiquity, together with the history of successive races of organic beings, would have been ere this as cheerfully and universally acknowledged as the earth's motion, or the number, magnitude, and relative distances of the heavenly bodies. I am sure it would be superfluous if I were to declare, in an assembly like this, my deep conviction which you—all of you—share, that the farther we extend our researches into the wonders of creation in time and space, the more do we exalt, refine, and elevate our conceptions of the Divine Artificer of the universe.

Mr. Lyell concluded this discourse by announcing his corroboration of the discovery recently made by Dr. King at Greensburg, thirty miles from Pittsburg in Pennsylvania, of the occurrence of fossil footprints of a large reptilion in the middle of the ancient coal measures. They project in relief from the lower surface of slabs of sandstone, and are also found impressed on the subjacent layers of fine unctuous clay. This is the first well-established example of a vertebrated animal more highly organised than fishes being met with in a stratum of such high antiquity.

COMPARISON OF SCREW PROPELLERS AND PADDLE WHEELS.

(With Engravings, see Plate XVI.)

The Board of Engineers of the United States Navy having been officially directed to inquire respecting the merits of different methods of propelling steam-vessels, presented, at the commencement of the present year two reports (dated in January and May respectively), detailing the result of their enquiries. We are enabled to give the following analysis of these documents.

The first report contains a comparison of the relative effects and values of "Hunter's" and "Loper's" propellers, deduced from the performances of a revenue steamer fitted in the first experiment with the former of these propellers, and subsequently with the latter of them.

The second report compares the effect of Loper's propeller with that of the ordinary paddle-wheel fitted into two vessels of exactly the same size and dimensions. The section fig. 1, plate XVI. will show the plan of gearing on board the *Spencer* (the screw vessel). The steam cylinder is horizontal, and the connecting rod drives a horizontal bevil wheel, which takes into a vertical bevil wheel on the same with the screw-propeller. The propellers are therefore two in number; they project from either quarter of the vessel. The mode of gearing here adopted seems to possess peculiar advantages. It is well known to engineers that bevil wheels *run lighter* than the ordinary spur-wheels, and indeed it may be shown theoretically that they have, *cæteris paribus*, less friction; moreover the teeth of the former will generally, come in contact more gradually and consequently with less concussion and noise. This mode of gearing has also the advantage of compactness and affords peculiar facilities of construction where the cylinders are horizontal.

The vertical wheel contained 75 wooden cogs and the horizontal wheel 60 iron cogs. There seems a slight error of detail in making the numbers of cogs in each wheel bear the relation here stated. In general the respective number should be *prime* to each other, that is, should not contain a common measure. The greatest common measure of 75 and 60 is 15, and consequently instead of each tooth in the one wheel coming into contact with each tooth in the other during successive revolutions, it happens that by the time one wheel has revolved 4, and the other 5 times, the contact of the same teeth commences again. By the contrivance of a "hunting-cog," that is, an additional tooth, in the smaller wheel the numbers (75 and 61) become prime to each other, and this disadvantage is avoided. Cog-wheels driving screw propellers are subject to so much wear and tear that no expedient for diminishing the evil ought to be neglected.

The plan of gearing on board the *McLane*, fitted with paddle-wheels, is exhibited in fig. 2, plate XVI. The cylinder is horizontal as before. On the engine shaft is a pinion of 47 teeth taking into a wheel on the upper shaft of 72 wooden teeth; the wheel and pinion are in diameter 7 feet and 4½ feet respectively, and concussion or jar is diminished by forming each of two similar wheels 8 inches wide with the teeth off-set. The pinion and the wheel driven by it have therefore each a face 16 inches wide. The following extract from the reports will give the remaining particulars.

Dimensions of Vessels, Engines, Propellers, &c.—*Vessels* (iron).

Length between perpendiculars	143	feet.
Beam at knuckle	18½	"
Beam at water line	22	"
Depth of hold	11	" 10 inches.
Displacement at load line	460	tons.
Area of *immersed section*	166	feet.

Engines—Two, non-condensing; *cylinders*, 24 inches diameter, by 3 ft. stroke of piston; steam, *cut* off at half stroke; one *boiler* containing 1,450 square feet of heating surface *combustion*, anthracite coal aided with a blast.

Power.—The horses power of the engines is estimated by the formula—$\frac{S\times(P-f+14\cdot7)}{33,000}$, where S represents velocity of piston in feet per minute. P, means effective pressure upon cylinder piston in pounds, per square inch; and f, the friction of the engines, equal ⅛ of pressure upon steam gauge.

"*Spencer.*"—Two *screw propellers*, 8 feet in diameter, having four blades each, with an area of 11½ square feet on each side. Angle of blades at hub, from plane of axis, 30°; at edge of blade, 54°. Revolutions of propellers, 1¼ for each revolution of engines. Draft of water, 9 feet 8 inches.

"*McLane.*"—Two *side wheels*, 16 feet 5 inches in diameter, in trials 1, 2, 3, and 4, and 15 feet 1 inch in trials 5 and 6; 14 buckets in each wheel, 10 inches by 5 feet 11 inches each. Immersed area of buckets, in each wheel, 24 square feet. *Revolutions* of wheels, 65 for each 100 of engines. Draft of water, 9 feet 8½ inches.

The two vessels being almost identical in form, allowed a comparison by means of simultaneous experiments which were accordingly commenced in April by Capt. Fraser, under the supervision of Mr. Haswell, engineer-in-chief of the navy, and Commodore Perry. From Capt. Fraser's report we make the following extract:—

Great care was taken to trim both vessels as much alike as possible. The coal to be used was the best quality, anthracite, from the same mines, (Beaver Meadow).

Taking into consideration the very defective model of these vessels, and that the engines were constructed for, and particularly adapted to Hunter's submerged wheel, rendering it necessary to use cog wheel geering, no proper estimate of the speed attainable by the side wheel or propeller can be arrived at. Still, their relative value in speed and consumption of fuel may be very satisfactorily determined. It must be borne in mind that the diameter of the propeller, and consequently its effective power, is limited by the draft of water, in order to keep it entirely submerged, and at the same time above the line of the keel, while the diameter of the side wheel may be increased by raising the shaft, thereby increasing the speed.

In the McLane, however, the diameter of the wheels is as great as desirable for sea service.

Both vessels, as exhibited in the annexed drawings, are precisely similar in model and dimensions, and each is furnished with two high-pressure horizontal engines: diameter of cylinder 24, and length of stroke 36 inches.

A sketch of the half cross section of the vessels is hereunto appended, which will clearly exhibit to practical men, that speed under steam, or stability under canvas, are unattainable objects. Plans of the propellers and mode of gearing, are likewise given.

Each vessel is furnished with a single boiler, having 1,450 feet fire surface. The Spencer is furnished with two of Loper's propellers, one projecting from each quarter, and the McLane with side wheels, having 14 buckets each. All the dimensions of the propellers and wheels are hereafter given, and the draft of water, dip of buckets, &c., are exhibited in tabular form, with each day's trial. The buckets of the side wheel were, at the suggestion of Messrs. Haswell and Coney, moved eight inches towards the centre, before making the trial on the last day.

It will be perceived by reference to the drawings, that the relative revolutions of the engines and wheels of the McLane, are as 1 of the former to ·6528, while the relative revolutions of the engines and propellers of the Spencer are as 1 to 1·25. The greatest care was exercised in weighing the coal, and the pressure of steam, revolutions, times, &c., were carefully noted every fifteen minutes. The distances, set, and velocity of the tides, are given upon the authority of the superintendent of the coast survey, and the time of slack water, noted in each day's work.

The trial on the first day, from New London to Falkner's Island, and returning, was under, as nearly as possible, an uniform pressure of steam, and the safety valve was loaded with 45 pounds to the square inch. On the second day, the trial was made by confining the number of revolutions of the engines as nearly as possible to 35, and returning under 22½ pounds pressure of steam.

On the third day, as before mentioned, the buckets of the side wheels were moved eight inches towards the centre, increasing the revolutions under the same pressure, in order to ascertain whether the increased speed attained was commensurate with the increased consumption of fuel, and at the same time to ascertain what distance each vessel could be propelled with 2,000 pounds of coal. This portion of the trial was quite interesting. The second propeller of the Spencer did not stop until the steam gauge exhibited a pressure of but two pounds.

On the first day a strong gale prevailed from the westward, with a turbulent head sea, reducing all the sailing vessels in sight, which were working to windward, to double reefs, and the great differences exhibited in consumption of fuel and speed, between the passage from and returning to the light boat, was doubtless produced by the resistance offered by the wheel-houses of the McLane, when steaming head to the wind, and the assistance afforded when before it, as well as the inefficient operation of wheels of so small diameter in a sea way, while the propeller being submerged was exercising the same effort at all times, and under all circumstances.

A trial of the sailing qualities was not deemed important, for experience has hitherto shown, that by the wind, this model has neither speed or stability.

A full and detailed journal of the trials is next given, but it is not necessary to make an abstract of it, as the general results are included in the official reports of the Engineer-in-chief and Commodore Perry. The joint report of those gentlemen is as follows:—

Washington, D. C., May 18th, 1846.

Sir,—In the execution of instructions contained in your letters of the 8th ultimo, the undersigned proceeded to New London, Conn., for the purpose of witnessing some experiments that were to be made by order of the Treasury Department, with the Revenue Steamers "Spencer" and "Mc Lane," the former fitted with two of Loper's propellers (screw), the latter with the ordinary side wheels.

Upon our arrival at that place, we were met by Capt. A. V. Fraser, temporarily in command of the "Spencer," under whose directions the experiments were to be made—and also by Capt. W. A. Howard, in command of the "McLane," who, in conjunction with the former, afforded us every practicable facility in the prosecution of the object of our attendance.

The necessary preliminary arrangements being made, and the two vessels having been brought to a similar draft of water, and provided with similar fuel (anthracite), it was decided that the trials made, should be to determine the following points:

2. The relative speed of the vessels, and consumption of fuel, with equal pressures of steam, when running under various circumstances of wind and weather.

2. The same points as above, the engines of the "Spencer" being reduced in speed to assimilate, as far as practicable in power, to those of the "McLane."

3. The same points, with the pressures of steam reduced one-half.

4. The effect of the consumption of an equal quantity of fuel (2,000 lb.) with similar initial pressures.

The elements for a comparison of the two vessels, regarding their form, &c., are as follows:—

The hulls, engines, and boilers were constructed from duplicate drawings. One vessel had three and the other two masts, adapted for equal surfaces of canvas. This difference of rig. however, could not in the least have influenced the results of the trials; and especially so, as the vessels were not tried under canvass. The instruments of cutting off the steam differed in some degree,—that of the "Spencer" being a slide valve, and that of the "McLane" a puppet. In the spaces between the grate-bars, there was also a variance, those of the "Spencer" being the greatest, and consequently effecting a greater waste of fuel. The geering of the engines, propellers, and wheels, was similar in its character (cogged wheels), the only mechanical difference being that necessarily due to the peculiar means of propulsion.

The bottoms of the vessels, and the engines and boilers, were, as far as our observation extended, aided with the information received respecting them, in equally good order.

Respecting the proportions of the different propellers, it was clearly shown that they were of sufficient diameter and surface for the purpose intended. There was a point, however, connected with their application which in our opinion materially interfered with the speeds of the vessels, arising from the relative speeds of the engines, and each of their attached propellers. Had the engines been geered so as to have worked faster with equal pressures, there would have been a material increase of power (as the boilers of the vessels were capable of supplying a greater quantity of steam than that they were restricted to in these trials). Had this disadvantage been similar, it would alone have effected the rate of speed; but as it occurred, the engines of the "McLane" were geered so as to preclude the attainment of a power with similar pressure equal to that of the "Spencer." The effect of this, however, is duly considered in determining the results given in statement C, which was prepared by C. H. Haswell; as a substitute for which, M. C. Perry submits statement D; while to those marked A and B, we refer you for details of the information on various points indicated in your letters.

M. C. Perry, *Engineer-in-chief U. S. Navy.*
C. H. Haswell,

Commodore Charles Morris,

Chief of Bureau of Construction, &c., Washington, D. C.

From the concluding sentence it appears that a difference of opinion existed as to the *conclusiveness* of the experiments: the separate statements [C] and [D] refer to those points on which a difference of opinion existed, and are submitted, the former by the Engineer-in-Chief, the latter by Commodore Perry.

[C.]

Results of the Comparisons deduced from the Preceding Elements.

In these the consumption of fuel is not considered, for reasons which will appear obvious when presented.

1. The boilers and engines being identical in capacities, the amount of steam used in the engines is an exact measure of the expenditure of each means of propulsion, which amount is estimated in the calculations of power here given.

2. The steam required was so much below the actual capacities of the boilers to furnish it, and so nearly alike in its quantities, that a hurried combustion of the fuel was unnecessary. Hence the waste consequent upon rapid combustion was not only not incurred in either vessel, but was not incurred by either means of propulsion at the risk of its economy compared with the other.

3. The omission of this element sets aside the effects of the difference in the grate-bars, and of any difference in firing by different individuals.

The computation then, of the powers of the engines is considered a fair and proper exponent of the cost of propulsion; while the cubes of the speeds are taken as the measures of the effects produced, which elements, (those of power and effect) being reduced for each trial, the following deductions are furnished:—

First.—In this trial, the application in the "Spencer" was 1·52 to 1 more efficient than that in the "McLane."

Second.—In this trial, the application in the "Spencer" was 1·14 to 1 more efficient than that in the "McLane."

Third.—In this trial, the application in the "McLane" was 1·16 to 1 more efficient than that in the "Spencer."

Fourth.—In this trial, the application in the "McLane" was 1 to ·82 more efficient than that in the "Spencer"

Fifth.—In this trial the application in the "Spencer" was 1·04 to 1 more efficient than that in the "McLane."

Sixth.—In this trial, the application in the "Spencer" was 1·03 to 1 more efficient than that in the "McLane."

[D.]

"Having stated in the foregoing papers all the particulars connected with the experimental trials of the steamers "McLane" and "Spencer," I find in passing them in review a difficulty in forming any definite conclusions upon the subjects under inquiry.

Notwithstanding the care with which the trials were made under the skilful management of Captains Fraser and Howard, very little of a satisfactory character was elicited. On the contrary, the results tended rather to confuse than to elucidate: certainly they furnished no criterion by which to determine the relative properties of the propeller and the side wheels, and the causes may, in my judgment, be justly ascribed to the defective form of the bottoms of the vessels.

It may be assumed by some, that as the models and dimensions of the two vessels were precisely alike, and the steam force exerted upon their respective propelling power was the same, the results *ought* to be conclusive of the superiority of the propeller—but such is not my opinion.

Captains Fraser and Howard both affirmed, and I give much weight to their professional opinions, that neither vessel would stand up under canvas, that they would not stay under ordinary circumstances, and it was difficult to wear them within any reasonable space, or to keep them to the wind in heavy weather—that in fresh breezes, on the wind, the lee wheel of the "McLane" would be immersed almost to its axis: in a word, that they were unmanageable at sea, and in their belief would be unsafe if thrown upon a lee shore in a heavy gale, even if assisted by steam power.

It is plain, therefore, that no application, whether of steam power or sails, or both combined, to vessels of such unusual model, could by possibility produce any satisfactory results, illustrative of the question of relative merits of the two modes of propulsion: and this opinion is strengthened by the fact, that on the occasion of their first day of trial in the Sound, when there was a strong double-reef topsail breeze from the northward and westward, they were so slow in their movements, that all agreed that any fair *sailing* vessel would have worked from New York to Falkner's Island, and made the run back, in a less space of time than was occupied by the fastest of the two steamers in accomplishing it."

The general result of the experiments is given in the following table of the *Elements of Comparison of the various Trials*:—

The distances given are in nautical miles.

Trials 1 and 2.—Speed and consumption of fuel with equal pressures, and under various circumstances of wind and weather.

	OUT.		IN.	
	Spencer.	McLane.	Spencer.	McLane.
Average* pressure of steam in pounds, per square inch	42·3	47·	42·	46·
Average revolutions of engines per minute	41·5	24·5	42·	28·
Time of running, in hours and minutes ..	4 31	6 42	3 32	3 57
Distance run through the water in miles, the effect of the tide (2 knots) being estimated	24·25	27·75	22·85	22·4
Speed in miles per hour	5·4	4·14	6·48	5·67
Consumption of fuel in pounds per hour ..	1224	928	880	1176
Power of engines in horses	186	129	192	147

Trials 3 and 4.†—*Out.*—Speed and consumption of fuel, the pressure of steam in the "Spencer," being reduced in order to assimilate the power of the engines to those of the "McLane."

In.—Speed and consumption of fuel, the pressure of steam in both vessels, being equally reduced to 22·5 lb. per square inch.

	OUT.		IN.	
	Spencer.	McLane.	Spencer.	McLane.
Average pressure of steam per square inch, in pounds	39·	47·	23·	22·5
Average revolutions of engines per minute	35·	29·6	32·5	22·
Time of running, in hours and minutes ..	1 46	1 31	2 7	2 10

Consumption of fuel in pounds per hour ..	‡	§	925	1260
Power of engines in horses	——	——	220	216

It will be observed that these "elements" do not include the amount of steam evaporated during the experiments. The formula given above for

* In these trials, the cut-off of the starboard engine of the "Spencer" was not used, the effect of which, however, is estimated, and the consumption of fuel given is in accordance with it.

† The throttles of the "Spencer's" engines were constantly closed, to reduce the revolutions in the run out. The effect of this is fully estimated, as the revolutions of the engines of this vessel were ascertained at such pressures as were necessary to determine it.

** In these trials the wheels of the "McLane" were reduced in diameter 16 inches.

‖ In this trial the distances run, and the times of running (equal distances), were very nearly alike, the difference being inappreciable. One of the engines of the "Spencer" continued working for several minutes after all the others had stopped, which increased the time of running of that vessel beyond the other.

‡ While coal lasted 950 lb.

§ While coal lasted 850 lb.

estimating the power of the engines is similar in form to that of Tredgold, and the cylinder pressure is deduced from the boiler pressure by a method independent of the omitted element: that is, the calculation proceeds on the assumption that the boiler pressure and cylinder pressure will bear a constant relation to each other, whatever may be the rate of evaporation. This assumption, De Pambour, in his Treatise on the Steam Engine, has shown to be erroneous, and he contends therefore that the whole of Tredgold's Theory of the Steam Engine is incorrect, and that his formulæ for computing the power of engines can never be correct, except by an accidental compensation of errors.—The views of De Pambour are now generally adopted by scientific men. We will venture at the risk of appearing to differ in some measure from the very high authorities by whom the reports before us are sanctioned, to apply De Pambour's method of calculation to one or two of the results of the experiments just described.

In the report dated January 31 (p. 3), we find the following comparison of two experiments :—

	Expt. (1).	Expt. (2).
Total boiler pressure per square inch	92·2 lb.	63·70 lb.
Revolutions of engine per minute ..	53·5	44·45
Fuel consumed per minute	36 lb.	21·66 lb.

It is assumed in the report that until the steam was cut off the cylinder-pressure was the same as that of the boiler. On De Pambour's principle, however, the conclusion would be very different. In absence of more accurate data we may suppose that since the form and dimensions of the boiler, &c., were identical in the two experiments each pound of coals evaporated effectively the same volume of water (M). Then

	Expt. (1).	Expt (2).
Cubic feet of water evaporated per minute ..	46 M	20·16 M

Now it appears from the table in De Pambour's Treatise on Locomotive Engines (p. 60), that steam at 92·2 lb. pressure occupies 316 times the volume of the water from which it is produced, and steam at 63·79 lb. pressure occupies about 444 times the space of the water from which it is produced. Therefore in the present case

	Expt. (1).	Expt. (2).
Cubic feet of steam evaporated per minute	46 M × 316 = 14536 M	20·16 M × 444 = 8951 M

The capacity of the cylinders was the same in both cases (= N), but in the first experiment the steam was cut off at one-third of the stroke, in the second at one-half of the stroke, consequently taking the number of revolutions of the engine per minute in each case, we have

	Expt. (1).	Expt. (2).
Cubic feet of steam admitted to cylinders per minute	33·5 × ⅓N = 17·83 N	44·45 × ½ N = 22·225 N

Comparing these quantities with the volumes of steam generated in the boiler, we see that in experiment (1) 14536 M cubic feet of steam at a pressure 92·2 lb. were dilated to occupy 17·83 N cubic feet: and in experiment (2) 8951 M cubic feet of steam at pressure of 63·79 lb. were dilated to occupy 22·225 N cubic feet. But by Mariotte's law the pressure of steam is inversely as the space occupied. Hence

$$\text{Expt. (1).} \qquad \frac{\text{Boiler pressure}}{\text{Cylinder pressure}} = \frac{17{\cdot}83\,N}{14536\,M} \qquad \text{Expt. (2).} \qquad = \frac{22{\cdot}225\,N}{8251\,M}$$

Hence we get finally the following relation:

$$\frac{\text{Cylinder pressure (1).}}{\text{Cylinder pressure (2).}} = \frac{\text{Boiler pressure (1).}}{\text{Boiler pressure (2).}} \times \frac{22{\cdot}225 \times 14536}{17{\cdot}83 \times 8951}$$

$$= \frac{\text{Boiler pressure (1).}}{\text{Boiler pressure (2).}} \times 2{\cdot}0208.$$

Showing that the proportion between the cylinder pressures before the steam is cut off, instead of being equal to the proportion between the boiler pressures will be *more than double that proportion*. This certainly seems to show the importance of taking into consideration the relative generation of steam in the boiler and consumption of it in the cylinder.

Let us take another case—the trials 5 and 6 in the second report of which the experimental results are given above. Adopting a method of calculation exactly the same as the foregoing, and considering that in the *Spencer* and *McLane* the cylinders were of the same size, that the steam in both was cut off at half-stroke, and that by De Pambour's table steam at 58·7 lb. occupies 480 times, and steam at 62·7 lb. occupies 450 times the volume of the water producing it—we have

	Expt.	Expt.
Total pressure in boiler	58·7 lb.	62 7
Revolutions per minute	45	40
Fuel consumed per minute	15·4 lb.	20·8
Cubic feet of water evaporated per minute ..	15·4 M	20·8 M
Cubic feet of steam evaporated per minute ..	15·4 M × 480 = 7392 M	20·8 M × 450 = 8360 M
Cubic feet admitted to cylinder per minute ..	½ N × 45	½N × 40
Cylinder pressure / Boiler pressure	7392 M / 22·5 N	8360 M / 20 N

Hence we get the relation

$$\frac{\text{Cylinder pressure (McLane)}}{\text{Cylinder pressure (Spenser)}} = \frac{\text{Boiler pressure (McLane)}}{\text{Boiler pressure (Spencer)}} \times \frac{8360 \times 22{\cdot}5}{7392 \times 20}$$

$$= \frac{\text{Boiler pressure (McLane)}}{\text{Boiler pressure (Spencer)}} \times 1{\cdot}27$$

That is the proportion of the cylinder pressures before the steam is cut off is not that of the boiler pressures, but upwards, of one-fourth more.

The actual relatioo of the boiler pressure to the cylinder pressure in *each* engine is immediately ascertained by giving M and N their proper values —that is, by substituting the size of the cylinder, and the evaporative effect of each pound of coke. It would however generally be more accurate to ascertain the total quantity of water evaporated during the trial, and make a correction for priming according to the method detailed by De Pambour.

We are indebted to the courtesy of an American correspondent for copies of the reports alluded to. The source from which this favour comes, and the very flattering manner in which it is conferred, greatly enhance its value, and induce us to hope that notwithstanding differences of opinion between American and English engineers, we shall have hereafter further opportunities of recording the investigations of our transatlantic fellow labourers in the advancement of practical science.

METROPOLITAN SEWAGE MANURE.

The select committee, which was appointed last session to consider sundry plans for the application of the sewage of the metropolis to agricultural purposes, reported in favour of the Metropolitan Sewage Manure Company Bill, which has since passed into a law, with certain modifications. They declined to recommend its postponement or rejection for the sake of Mr. Wicksted's plan, for carrying off the entire sewage of London, in a tunnel of from eight to twelve feet in diameter, and at a depth of from 40 to 80 feet under the level of the streets, being of opinion that the first experiment of dealing with sewage water had better be tried upon a smaller scale and at a less formidable expense; and, as regarded Mr. Higgs' plan, they conceived that the public mind was not at present prepared to risk the establishment of any such reservoirs as he proposed to construct, although, by the precautions he contemplated, he would probably preclude the possibility of any deleterious or offensive consequences. It appeared, indeed, that the main ground of complaint against the bill by the owners or occupiers of land was, that power had been taken in it to construct reservoirs or tanks for the reception of stagnant and offensive sewage water. That power was, in consequence, relinquished by the promoters. The committee, however, seemed to concur in the propriety of such a step out of deference to public feeling only, being of opinion that the loss of such a provision would, in some degree, impair the efficiency of a measure which proposed at all times to remove from the Thames the daily-increasing refuse of London. As explained by Mr. Smith, of Deanston, the operations of the company are to be limited to the King's Scholars' pond sewer—the contents of that sewer to be received in a well constructed for the purpose, thence to be raised by steam-engine pumps, and carried by a main pipe about eleven miles in the direction of Egham, with branch pipes to the surrounding farms; the distribution of which, however, will depend much upon private arrangement. When used for irrigation, the liquid is to be discharged from one of these service pipes into the channels usually employed for that purpose; when applied to tillage land the service pipe is to be brought to some convenient distance in the field, there to communicate with a hose made of canvas, and capable of being elongated and conveyed to particular spots, from whence the water may be thrown by a jet over as extensive a surface as the pressure upon the pipes will admit—that pressure being derived from a stand-pipe about two feet in diameter, and 150 in height, the entire distribution to be conducted by the servants of the company, with a view to its proper control, aided by an adjustment at the steam-engine, to indicate the quantity of water taken at the extremities, so that the speed of the pumps may be diminished or increased accordingly.

The company expect that the farmers will find it their interest to allow it to be used exclusively for irrigation during the night and during the day by jet and otherwise, so as to equalize the supply in the 24 hours, and prevent the waste which would otherwise occur in the absence of reservoirs. Looking, however, to the difficulties that usually attend a first experiment, and to provide for extraordinary floods, means are to be adopted

for allowing any surplus to flow into the Thames without going back into the sewer; at the same time that the company confidently anticipate, after the farmers shall have had experience of the value of the manure, that the demand will be greater than the supply. The supply is calculated at 60,000,000 tons annually, producing, at 2*d.* per ton, an income of 50,000*l.*, which would leave above the outlay a net profit of 13,000*l.* on an estimated expenditure of 120,000*l.* It will require 28,000 acres to consume the 60,000,000 tons, of which it is expected that two-thirds will be taken for the irrigation of meadow, and one-third for the enrichment of tillage land. As the process of pumping will be conducted in a closed building, so constructed as to carry any fœtid exhalations that may arise from the water during the short period it is exposed to the atmosphere, into the furnace of the steam engine, there to be destroyed, the committee arrived at the conclusion, not only that this station-house will be unobjectionable, but that by the proposed means the liquid will be removed in a far less offensive state than that in which it is now found, when backed in the open sewer by the high tide, and stagnating for hours together in the immediate vicinity of a thickly inhabited district, to be subsequently poured forth at low tide into the open bed of the river. The only remaining danger or inconvenience to be apprehended was from the breakage of the pipes or the ultimate distribution of the water upon the land; but as it had been clearly established in evidence, first, that sewage water is not corrosive in its nature or liable to generate explosive gases, and next that its distribution is not attended with an offensive effluvium unless in hot weather, when, owing to its rapid absorption into earth, the unpleasantness is of very short duration, the committee had no hesitation in believing that it may be as safely conveyed in iron pipes as the water of the Thames is at present by the several companies who supply the metropolis; and that in its application to the land it will be less offensive than manure in its solid state. The report contains some very interesting evidence from scientific men, supported by that of skilful farmers, and showing, that under an improved system of husbandry, by the application of the science of chemistry to that of agriculture, the soil, no matter what its nature or locality, may be rendered by many degrees more productive and more profitable. A minute chemical analysis of the sewer water of London, besides being unintelligible to the general reader, would be out of place in a mere abstract. All capacities, however, can understand the result, as given in the evidence of Mr. Miller, Professor of Chemistry in King's College. He found in it considerable portions of ammoniacal salts, alkaline salts, and earthy phosphates, substances which are found in the soil in only small quantities, but which are nevertheless absolutely essential to the maintenance of vegetable life. These ingredients are principally derived from the ashes of our bodies, resulting from the food we have digested; and as we have received them either directly from plants, or indirectly through animals from plants, it is evident they must be the food of plants, and that plants receive them from the soil, which they gradually exhaust. Mr. Miller stated also this curious fact—that the money value of those ingredients as poured into the Thames from the King's Scholar's Pond Sewer alone, assuming that the quantity falling from that sewer is 12,000 tons a day, amounts to no less than 62*l.* every twenty-four hours, or 22,630*l.* a year. The report likewise contains much useful information derived from the experiments of practical men in the application of sewage water to land, showing in all instances that it possesses a much greater fertilising power than either guano or the ordinary farm-yard manure. A Mr. Thompson, of Clitheroe, in Lancashire, on applying eight tons of it to one acre, fifteen tons of common manure to another, and three cwt. of guano to a third, found that the grass raised by the sewage water, compared with the quantity produced in the other two cases, was as fifteen tons against eight. The Duke of Portland is stated by means of the sewage water of Mansfield, and a cost of 30*l.* an acre for bringing the land into a proper form for irrigation, to have raised its value from 4*s.* 6*d.* to 14*l.* an acre. Mr. Dickinson, an extensive keeper of horses, by the use of liquid manure derived therefrom, got ten crops of Italian rye grass in twelve months, some of them more than three feet high, out of land (on his farm at Willesden, near London), which a Lincolnshire man had previously said he would not give 12*s.* an acre for, if at his own door; and which a Norfolk man declared he would not farm as a freehold. Speaking of the present year, Mr. Dickinson stated, that the first crop was cut in January, yielding more than four tons an acre, that the second gave about double that, and that the fourth, which had been cut in the month of June, had produced at least twelve tons an acre. From his calculations it appeared that one horse supplied sufficient manure for one acre; and when pressed for a direct opinion upon the subject, he replied, that he had no doubt whatever that every animal that lived, by his refuse being economised, would produce more than he could consume. This is an important fact for the agriculturists, especially at the present moment, and it is to be hoped they will not lose sight of it, but endeavour, like Mr. Dickinson, to make their land more productive, and thereby not only benefit themselves and the country, but materially serve the cause of science

---

Fall of Railway Bridges, Embankments, &c. have occurred at numerous places. At Aberdeen, several arches of the inclined plane; between Linton and Dunbar, three bridges; on the Tynemouth Extension line, three yards of tunnel; on the Newbury line, several bridges; fifty yards of cutting on the Brighton and Hastings line.

PORT OF DUBLIN.

Improvements of the Grand Canal Docks at Ringsend.

(With an Engraving, Plate XVII.)

Among the chief commercial interests of the city of Dublin is the extensive trade of the Shannon and the Grand Canal. The enlargement of the canal docks has therefore been long considered a subject of great mercantile importance, and from a Report of Sir John Macneill, now before us, there appears every probability of this great improvement being speedily effected.

The principal features of the undertaking are the formation of a new Tida basin, the diversion of the river Dodder and the construction of a new entrance to the Floating and Graving Docks. The task of preparing a design for effecting these objects has been confided to Mr. McMullen, and has been performed in the most simple and satisfactory manner. The plan proposed by Mr. McMullen is made the subject of a warm eulogium in Sir J. Macneill's report, which speaks of its extreme "simplicity," and the "extraordinary facilities which every where exist for carrying it into execution." The following extracts from the Report, and a reference to the Plate XVII. will sufficiently explain the nature of the proposed improvement.

It is impossible to cast the eye over your Company's splendid Floating Basin, covering, as I understand, twenty-five statute acres, with a depth of water which I find is now steadily maintained at 18 feet or thereabouts, without a feeling of great regret, that facilities, such as are thus afforded, both for the foreign and coasting trade of the port of Dublin, and the important adjacent districts, should not be as available for the advantage of that trade as they unquestionably can be rendered; and for the accomplishment of this most desirable object, I freely admit that I have seen no project or plan at all comparable to that now before me, either as to the extent of the advantages which it is calculated to secure, or the comparatively small cost at which it is capable of being executed.

Of the several operations which the carrying out of the project involves, there is none the necessity for which is so manifest, or the cost of which would be so trifling, compared with its importance, as the turning out of the Dodder upon the South Bull. An enormous deposit is carried down and lodged in the channel opposite the entrance to the docks. The dredging out of the narrow, and as yet quite inadequate channel, forming the approach to Camden and Buckingham Locks, and of that portion of the river immediately opposite, has, this year, as I am informed, occupied the two powerful steam dredgers of the Ballast Corporation, for a period of about two months, at an expense which cannot but be very heavy, and which must recur annually, and inevitably after the winter floods, as long as the river is allowed to remain in its present course. The necessity for an improvement so obvious has been long felt. I find that it was recommended by the Irish House of Commons on various occasions, and attached to their proceedings of the date of 26th February, 1785, there is a ground plan of the new course into which it was proposed the river should then be turned, which scarcely at all differs from that laid down in the present plan. And this was further followed up by the enactment contained in the act, creating the present Ballast Corporation, by which the directors of that corporation are authorized to carry out and complete the measure. In accomplishing it, there is no actual necessity for the removal of the present weir, although this would render the results more useful to the adjacent grounds, and in this case a supply of water to the neighbourhood could be readily obtained from the river above Ball's bridge, and a reservoir formed on the site of the mill-pond of the old distillery, as sketched on the plan. I have examined the ground which it is proposed the new course should occupy. In length it is about 600 yards.

An apprehension has, as I am informed, been expressed in some quarter, assumed to be entitled to attention, and in this way brought under your notice, to the effect that the sand, carried down by the river, and which, in the event of the proposed change of its course, would be deposited on the south strand, might possibly be drifted across the Bay towards the entrance of Kingstown harbour, and produce inconvenience or obstruction there. Such a result I consider to be altogether out of the question, and the anticipated suggestion of it, destitute of the slightest rational foundation.

In turning to the plan for the formation of the Tidal Basin, it is impossible not to be struck with the fact, and it is one of manifest importance, namely, how much of the work has been already done, and how little, for the realization of the whole project, remains to be accomplished? while of this latter, the entire is of the plainest, every-day character, and quite free from any thing which could be regarded as an engineering difficulty. The whole is in fact comprised in the excavation of the ground, the extension of the present south quay wall, the lining of the interior with cut-stone facing, well puddled, and the construction of the entrance gates. The proposed Lock for the admission of steamers of the largest class to the upper basin does not appear so indispensable to the successful working of the plan, as to call for its being immediately undertaken. It may be prudent to wait the result of the trials of the screw propeller now in progress, and in the meanwhile the outer basin will afford a very large amount of accommodation to the ordinary class of paddle steamers. In reference to the excavation of the basin, it is well deserving of notice, that the ground inside of the Queen's and the other adjacent timber yards, is greatly below the level of the quays, and of high water, and that the material excavated may be not only very beneficially and usefully deposited in these yards, but that the close proximity of such a place of deposit will be a source of considerable economy in carrying out this part of the work.

As regards the convenience of the shipping of the port, the portion of the project which, beyond every other, would seem to recommend it to public favour and approval, is the position of the entrance to the Tidal Basin, in a right line with the direction of the River; a fact so manifestly important, and calculated to afford facilities both for ingress and egress, so obvious, that it is quite unnecessary to enlarge upon it.

It will be necessary to continue the main sewer, by which the water is at present discharged from the Gravin Docks, at a sufficient depth under the bed of the Dodder, to the opposite or Ringsend side of it to be carried in a direction parallel with the bank of the river down to the Liffey, east of the Dock entrance, there to discharge at the level of low water spring-tides, and which sewer can also be made use of for unwatering the low ground, south of the docks.

The last in order of the various points to which, in considering the whole of this question, my attention has been drawn, is one which, especially in an engineering point of view, I regard as not only most important, but highly interesting. It is indicated on Mr. M'Mullen's plan, but not on a scale, in my mind, sufficiently extensive to accomplish the object which I should contemplate. I allude to the Break-water which he proposes should be formed from the point at which, by the new course, the Dodder would be discharged upon the South Bull, across to the great South Wall, with an opening in the latter for the out-flow of the water retained within this barrier at each ebb of the tide, and through which opening it would consequently be discharged into the channel of the river, which forms the sailing course, and where it would necessarily act as a scour, in regard to that important portion of the entrance to the harbour. Of the soundness of the principle, and the beneficial effect which would in this way be produced, there can be no doubt; but to render it as effective as the general condition of this portion of the sailing course would appear to require, it must, in my opinion, be carried out on a considerably more extensive scale: the mound to be raised commencing, in any case, as far eastward as the Pigeon House, and terminating at or near to the Martello Tower, on the Sandymount strand. It does not seem necessary that the proposed barrier or mound should be raised to any considerable height, as the effective action of the Scour would occur as the ebb tide approaches to low water. I think that a sufficient mound or barrier could be formed, of such a height as I contemplate, from the heavy clay and gravel, of which the strand in this part of the bay consists, at a very moderate expense. The bridge to form the opening in the wall for the efflux of the water, of whatever number of arches it may consist, should be at the least, from 200 to 300 feet wide. Of the cost of this part of the work I have not framed nor submitted any estimate. It is plain, however, that, with reference to the importance of carrying out such a project, it would be comparatively speaking but inconsiderable.

A glance at the present state of the Bay shows that, as far eastward as the Poolbeg Light, it is divided by the great south wall into two nearly equal portions. The effect of the great north wall, has been to cause the ebb water of the northern division to act upon the bar, and in this respect it abundantly answered the expectations entertained by its projectors. If, in addition to the important and valuable action so obtained from the northern section of the Bay upon the Bar, it shall be practicable, in a similar way, to empound the Tidal Waters of the southern division of it, and, as I confidently contemplate, to produce from their efflux a corresponding beneficial deepening action upon the continuation of the bed of the river, forming the entrance channel to the inner harbour, a result will have been obtained of the most decisive character, not alone as regards facilities of access, and the safety of the shipping frequenting the port, but calculated also to diminish, to a very large extent, the cost annually incurred in dredging out of this channel the vast quantity of silt and mud, which under present circumstances is, and must continue to be deposited in it.

Estimate of the proposed Course of the River Dodder through Irishtown.

THE WYATT WELLINGTON.

Sir—On the appearance of Professor Cockerell's Letter in the "Times," I addressed one to that paper to say that the objections urged by him against the equestrian statue of the Duke being placed transversely across the arch, instead of in the axis of the archway itself, were brought forward nearly eight years ago in a work where it might be supposed they could hardly have escaped the notice of architects, at least not of the architect of the structure, since they were made in the letter-press account given of it in the second edition of the "Public Buildings of London," where that arch forms one of the new subjects added to the original work, and is illustrated by a ground-plan and elevation. Yet, although the "Times" appeared to take very great interest in the affair of the statue, having brought it forward more than once in its leader, the Editor did not think proper either to insert or to offer any reason for rejecting my letter; and as it had then become too late in the month to send to your Journal, my comments on the matter could not possibly appear earlier in it than they do.

The whole affair is a curious one from first to last, and exemplifies more forcibly than favourably the manner in which matters of the kind are managed in this country—the crooked policy, and that species of astuteness which is called cunning, that are brought to bear upon them. No deference has been paid to public opinion, for concealment has, as far as practicable, been studiously kept up, as if the public possessed no right of opinion, and therefore the expression of it in any shape, was no better than unwarrantable interference. Would it then be more becoming in the public to observe the neutrality of silence upon such occasions—to manifest an indifference that would be praiseworthy because not at all troublesome? If so, those are taking a very wrong course indeed who are advocating and seeking to diffuse among the whole community a more familiar acquaintance with art generally, and a more enlightened appreciation of it. On one side, the public are told that they ought to acquire a taste for Art, to take a lively interest in it, and also to watch over its interests; on the other they are told—at least given very significantly to understand, that they have properly no voice in such matters, or their voice no authority, and it may therefore be disregarded as idle clamour.

Those concerned in the management of public works—some people call them *jobs*—will perhaps say that they do not dispute our right of judgment and of freely expressing it; all that they request is that we should not express it prematurely, but wait until the work be completed, when it can be judged of fairly. This is very plausible; it seems at first sight, perfectly reasonable, but only at first sight, for when looked at more closely, it will be found to mean that the public ought to be kept as long as possible in the dark as to what is going on, and be hindered from judging rashly and prematurely by being debarred from forming more than random conjectures and vague surmises, until not only the work, but the mischief that might have been guarded against by a little *premature* criticism, is completed. The most *ill-timed* criticism of all is surely that which comes too late to be of service, because unless it be the bearer of commendation, it brings only reproach and regret,—warning, indeed, for the future, but warning just as useless it seems as mere regret itself. We have had our warnings—our dearly-bought experiences, and much we profit by them. There is Buckingham Palace, which after costing about a million in the first instance—how much more has been expended upon it since it was occupied is not so well-known—is spoken of only for universal scorn and derision as a positive "disgrace to the nation,"—which as far as the nation is concerned is flagrantly unjust, because the nation had no other hand in the matter than paying for that costly piece of architectural brummagem. It was not the nation that forced that precious bargain upon George IV., but just the reverse: so let the "disgrace" fall where it ought. Not but that the nation was to blame too, for its negligence and supineness in not inquiring *prematurely* what was the quality of the commodity—or the *incommodiousness* as it now turns out to be—which it would have to pay for. Nor is that unhappy edifice the only one, by very many, that has been pronounced a failure: the National Gallery is another signal instance of mismanagement; and the hackneyed idea of a mere column was adopted for the Nelson Monument, in defiance of the strong wish expressed for something less common-place. When the façade for the British Museum was begun about two years ago, no regard was paid to the demand then made, that the model should be produced for public inspection;—on the contrary, such a dogged silence preserved that a formal refusal would have been almost courtesy in comparison with it.

To what purpose then, it will perhaps be asked, is it to raise clamours of the kind when we find that they are altogether unheeded? It certainly is to very little purpose merely to raise them, if they are dropped again almost immediately, as is generally the case, wherefore no notice is taken of them; those who might else be forced to do so, feeling pretty confident, that after the first firing the press will have exhausted its ammunition or give up the attack in despair. It is not by a furious momentary discharge, but by a constant and well-directed one kept up determinedly that we can reasonably expect to carry the point on such occasion. Would it not be equal folly and presumption on the part of any individual writer—of myself, for instance,—to imagine he can effect any thing, unless he be publicly seconded by others? But people seem to think that if remonstrances are found to produce no immediate effect, it can be of no use to continue, or to bring fresh detachments of them into the field. On the contrary, when a harder blow than usual has been given,—one that *ought* to stagger and confound, instead of following it up by another still harder, they draw back as if in alarm for the consequences of their own might and valour.

Professor Cockerell appears to be one of the considerate, for he not only considered a very long while before he could prevail upon himself to step forward and protest against the Wellington statue being placed on the Arch, but, lest his interference should derange matters and upset the scheme was so considerate as to keep silence till almost the very last moment, when it was hardly possible that his advice should be followed without great inconvenience; whereby he himself furnished the committee with a good excuse for not adopting it, conveniently reserving to himself the power of saying or fancying that it would have been adopted, had it not unluckily come just too late; still, even the convenience has its awkwardness, for some people are so inconsiderate that they will be apt to ask why he held back till the very last moment. They may also feel a little astonishment at the complete silence observed by the other architectural Professors. Are we to understand it to be equivalent to consent—acquiescence in and approval of what has been so virulently condemned? If so they have been wanting in generosity towards the authors and perpetrators of the scheme. On the other hand, if they agree with Professor Cockerell, they might, without impropriety, have openly sided with him. Or shall we attribute their silence to indifference?—or if not exactly to indifference to that discretion which prompts steady people to cross over the way, or turn into another street where they see a fray going forward? Even if it was no affair of theirs, and they were fearful that the offering any opinion might be considered busy-body officiousness, it did concern Mr. D. Burton, and as he did not choose to appeal to the public when he was sure that the general opinion would have strongly supported him, it may very fairly be questioned whether he cares at all about what has been done to his building. The inference may not be very charitable, nor particularly flattering to him, but it is certainly a very natural one.

After all, however, his Arch does not suffer more than another building does, viz, the house over the way, which now looks more insignificant and undignified than ever. Strange! that of two Wyatts, one thought he could not make the Duke look too big, the other, his house look too little—and too *petite* in style.

L.

REGISTER OF NEW PATENTS.

If additional information be required respecting any patent, it may be obtained at the office of this Journal.

BRICK AND TILE MACHINE.

Alfred Hall, of Coxsackie, in the United States of America, brickmaker, for "*certain improvements in machinery or apparatus for making, moulding, or manufacturing bricks, tiles, and other articles, from earthy or plastic materials.*"—Granted October 2, 1845; Enrolled April 2, 1846.—Reported in *Newton's London Journal.*

This invention relates to the construction of a machine as shown in the engravings, Plate XVI., for making bricks, tiles, and other articles from clay. Fig. 1 is a side view of part of a pug-mill, and the moulding apparatus. Fig. 2 is a plan, and fig. 3 a vertical section through the centre of the moulding apparatus and pug-mill, and fig 4 a front view of the moulding apparatus. A is a pug-mill, set on a brick foundation B and pillar C; in the centre of the mill is a vertical shaft *b*, supported upon a step at the lower part, and at the upper part by a framing, to which is attached a beam for the application of horse-power. On the shafts are fixed a number of horizontal cutters, *c*, set radially, and at the lower end are 4 plates, *d*, set horizontally in two lines at right angles to each other, and slightly inclined from the perpendicular, they extend nearly to the sides of the mill, and are for the purpose of sweeping the clay, as the shaft rotates, into the chamber of the moulding apparatus.

The moulding apparatus consists of a chamber, D, with iron plate sides, *f*, and a cast-iron grating, *g*, for the bottom (shown separately in fig. 5), consisting of a square frame with cross bars forming as many compartments as there are bricks or tiles to be produced at one working in the mould or box, *z*, under the grating. Above the chamber is a shaft, *h*, with bearings at each end in the side plates, *f*, which carries quadrants provided with segmental racks, *i*, and the cover or pressing plate, *k*, extending the whole width of the chamber D, for the purpose of forcing the clay into the chamber through the grating *g* into the mould *z* below. *l* is another shaft with bearings in the side plates *f*, carrying 2 pinions, *m*, that take into the segmental racks *i*, and having a hand-wheel, *n*, keyed on to the end of the shaft, for giving motion to the quadrant racks. *p* is a scraper, the whole width of the chamber, fixed on a shaft with bearings at each end in the side plates *f*; this scraper is for cleaning off the clay from the segmental portion of the pressing plate *i*.

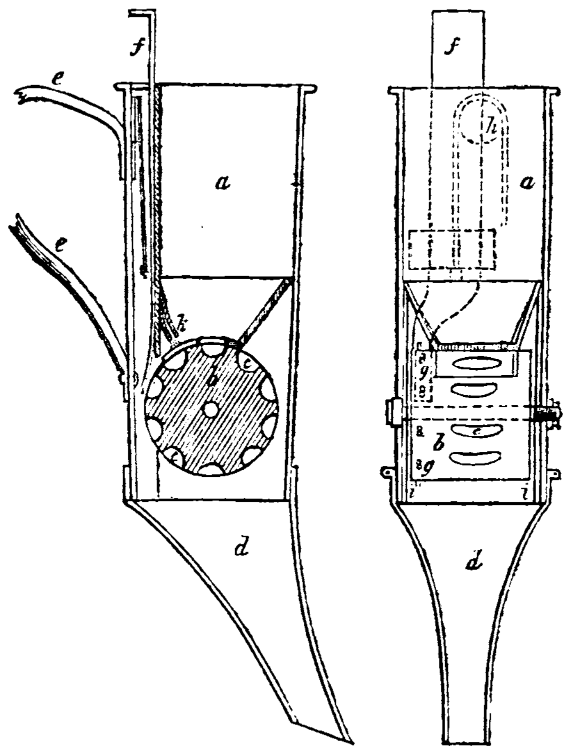
Below the chamber is the frame work, E, with an adjustable framing, F, suspended thereto by 4 pins, which carry the bearing of a horizontal shaft, q^1; shaft supports arms at each end, attached to the framing F, and also at each end a lever, q'; there is also a cross-bar, *r*, to carry the inner end of the framing, F, which is attached to and forms the cast iron tables or grating, *s*, which support the moulds, *z*. s' are rollers for carrying the mould immediately beneath the grating of the chamber. The lower parts of the framing, F, are bearings for a horizontal shaft, which carries a vibrating lever, *t*, with another lever, *u*, jointed thereto, having forked branches on the end in the form of a V, which carry a pair of guide-wheels with flanges, *w*, running in a slot made in the upper face of the framing F, and to the ends of the V lever, a cross-bar, *x*, is bolted, *y* is a lever fixed on the end of the cross-shaft for actuating the lever *t* and the parts connected therewith. and *z* are moulds which are supplied to the machine by hand as they are required.

The action of the improved machine is produced as follows:—Rotary motion being given to the vertical shaft *b*, of the pug-mill, the plates *d* will force the clay through the opening *e*, into the chamber D; and, supposing a mould to be placed upon the rollers 9, in the position shewn at fig. 3, the hand-wheel *n* is turned, which giving rotary motion to the pinions *m*, in gear with the segment-racks, will bring down the pressing plate *k*, and force the clay into the compartments of the mould. The workman then pulls down the lever *y* (at the same time letting go the hand-wheel), which action will cause the lever *t* to vibrate and draw forward the lever *u*, and with it the cross-bar *x*. This bar, guided in its course by the wheels *w*, will push forward a mould previously placed in front of it, as z^1, fig. 3, and drive that mould to the position of mould *z*, now full of clay, from under the grating *g*, in escaping from which the superfluous clay will be removed by the inner edge of the inclined side of the grating. The full mould will then arrive at the position, on the framing, of the mould z^2, from whence it is ready to be carried to the drying ground. By throwing upward the lever *y*, the bar *x* will retire to its former station, and another empty mould being placed before it, the same movement will be repeated after the mould last pushed under the grating *g* is filled with clay, as before described. If, by accident, any stone or other hard substance should get into the clay and stop the proper action of the moulding-machine, it is only necessary to depress the lever 7, on the shaft 4, which will bring down the framing a sufficient distance for the mould to be released.

The claim is, firstly, for the general arrangement of the apparatus, as described; secondly, the peculiar arrangement and construction of the knives and plates for tempering the plastic composition, and forcing it out from the pug-mill; thirdly, the construction and application of an adjustable framing for holding the moulds to receive the plastic composition, such framing being capable of instant depression, as above explained; fourthly, the arrangement of apparatus for placing the moulds successively under the grating *g*, as above described and shewn in the drawings; and lastly, the peculiar arrangement of the grating *g*, with respect to the compartments of the moulds, whereby perfect bricks, tiles, and other similar articles are produced, as above explained.

DIBBLING APPARATUS.

John Fuller, of Beacham Well, Norfolk, Farmer, for "*improvements in apparatus for sowing corn and other seeds.*"—Granted March 5, 1846; Enrolled September 5, 1846.

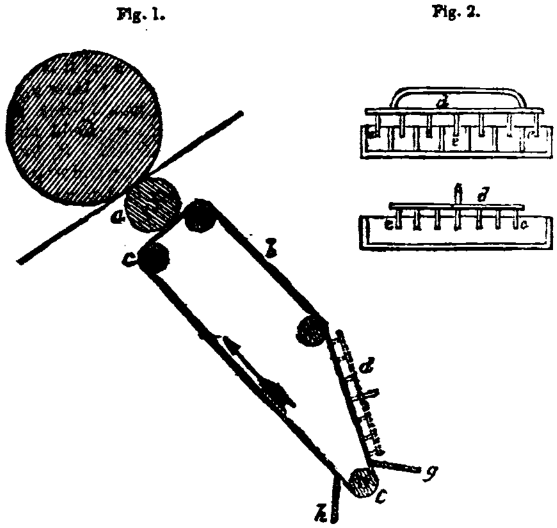


This apparatus, formed of sheet tin, is held in the hand, and used for dropping corn or other seed when dibbling, in place of the fingers. There are three different apparatus described in the specification; the annexed figures shew the application of one of them. Figs. 1 and 2 are sections of the apparatus taken transversely to each other; *a* is a chamber in which the seed is placed, *b* a roller with small recesses *c* in the circumference, of sufficient capacity to deliver the proper quantity of seed through the hopper or spout *d*; *e* is the handle, *f* a slide to be pressed down by the thumb on the top, the lower end acts upon pins *g* on the margin of the roller *b* and forces it round one division; after each pressure the slide is drawn upwards by a self acting spring *h*. *i*, *i*, are friction plates, acting against the ends of the cylinder to prevent it turning unless it be forced forward by the slide *f*, and *k* is a small brush.

PAPER STAINING.

HARROLD POTTER, of Darwen, Lancashire. Paper Manufacturer, for "*improvements in printing or staining paper.*"—Granted April 1, 1846; Enrolled September, 1846.

Fig. 1. Fig. 2.



The improvement relates to the supplying of colour to the surface roller *a*, for printing or staining paper, as shewn in the annexed engraving, fig. 1, by an endless blanket or sieve cloth *b*, stretched over 4 rollers *c*, and to move at the same surface speed as the roller *a*, in the direction shewn by the arrow. The various colours are put on the endles cloth *b*, by a hand-block *d*, fig. 2, having several rows of studs *e*, which dip into a colour-tray, containing as many compartments as there are to be different colours. For staining the paper the studs are dipped into the colours, and then placed on to the endless cloth as shewn at *d*, and the colour so placed will be spread by the cross-bar *g*, covered with woollen cloth, and pressed slightly against the endless sieve; any excess of colour will be scraped off by the bar *h*.

MANUFACTURE OF TILES.

WILLIAM BENSON, of Allerwash House, Haydon Bridge, Northumberland, Gent., for "*certain improvements in machines for the manufacture of tiles and other plastic substances.*" Granted January 15, 1846; Enrolled July 15, 1846.—Reported in *Newton's London Journal.*

The object of this invention is to manufacture tiles, pipes, and other articles, by forcing the clay or other suitable material through dies, secured to the side of a mill, similar to an ordinary pug-mill. In Plate XVI., fig. 1, is an elevation of the machine, furnished with dies for making both drain and ridge-tiles at the same operation, fig. 2 a horizontal section, and fig. 3 a vertical section. *a* is the cylinder of the mill, made of cast or wrought iron, and fastened to a cast-iron bed-plate *b*, by eight screw-bolts *c*; this bed-plate rests upon two pieces of timber *d*, *d*, about six inches square, and secured to the foundation stones by four iron screw-bolts *f*; *g* is the vertical shaft of the mill, with a bevil-wheel *h*, keyed on its upper end, and taking into the teeth of the bevil-pinion *i*, on the shaft *j*, which is driven by steam, horse, or other power. The lower end of the shaft *g* works in a brass step *k*, placed in a square box, and capable of adjustment by means of screws. The upper end of the shaft *g* works in brass bushes, fitted in the iron carriage *n*. Near the lower end of the shaft *g* there is a flange, to which is bolted a cone, *o*, formed of wood or iron. *p*, *q*, are 23 arms or knives, fixed round the shaft *g*, arranged in six planes, but there may be a greater or less number of knives and planes; for instance, a machine which is to be worked by one horse should be of smaller dimensions, and would require a less number of knives and planes, but in no case ought there to be less than three or four knives on the two lower planes, and two on each of the upper planes, and there should not be less than three or four planes of knives. In the lower plane 6 curved knives *q*, are inserted in the shaft *g*, in the second plane 6 straight knives *p*, fixed immediately above the curved ones, the third, fourth, and fifth planes 3 blades, and in the sixth plane 2 blades, all set at an angle of 45°. It is necessary that the bottom of the spindle should be conical, to facilitate the passing of the clay to the bottom of the mill, and as much as possible to the outside of the lower set of knives *q*, which, from their peculiar shape and position, press it through the dies *r*, *r'*. The dotted circles, outside the curved knives, shew the position occupied by the clay when the spindle is in motion, and as the clay descends in the mill, it is pushed towards the dies by these arms, with the assistance of the cone.

The dies *r*, *r'*, are slipped into dovetail grooves *s*, formed on the outside of the cylinder *a*, and in the bed-plate *b* (see fig. 4); the shape of the openings will necessarily vary with the form of the tiles or pipes required to be made; the dies represented in section at *r'*, are for making drain-tiles; and the die at *r* for ridge-tiles. *t*, *t*, are the tables for receiving the tiles or pipes as they come out of the dies, and are furnished with rollers *u*, *u*, which carry endless bands or webs of flannel or other suitable flexible material. In fig. 2 the tables *t*, *t*, are shewn in plan view; Nos. 1 and 3 are covered with the flexible webs, No. 2 is uncovered but with the rollers inserted, and No. 4 shews the top of the frame, without the rollers or web. *w*, *w*, are the tiles, which traverse the endless webs by the motion they receive in coming out from the cylinder *a*; and as soon as a sufficient length of tile has passed on to the endless web, it is cut off by the instrument *x*, commonly called the "horse."

In working this machine, tiles or pipes can be made on the four sides of it at the same time, or at one, two, or three sides therof, or more, if required; and different sorts of tiles or pipes can be made at the same time.

IRON MANUFACTURE.

JAMES PALMER BUDD, of Ystalyfera Iron Works, Swansea, Merchant, for "*improvements in the manufacture of iron.*"—Granted February 11, 1846; Enrolled August 11, 1846.

In burning coal, clinkers are produced and considered as refuse; these clinkers, it is proposed to apply in the manufacture of iron; they may be obtanied where large quantities of coal are burned in furnaces, or from smith's fires and waste heaps of small coal, and also from refuse ash heaps of many works which have fired and burned down, leaving a substration of clinkers near the bottoms of the heaps.

As clinkers are of a light porous nature, of small specific gravity, and contain a large proportion of earthy matter, they will be found peculiarly suitable for use in blast furnaces, with rich oxides of iron, cinders obtained in the manufacture of malleable iron, hemæteter iron ores. The clinkers when mixed with the rich oxides of iron in the blast furnace will lessen the density of the mass and allow a freer passage for the blast, and supply the proportion of earthy matters required for the perfect separation of the iron.

In charging the blast furnace the clinkers are generally to be combined with rich iron stone, iron cinder, or ore in proportion to the quality of the clinkers; if rich in iron ore a smaller quantity is required than when they are comparatively poor; the proportion of iron in the blast must be below 50 per cent—from 40 to 45 per cent is the usual proportion. If the clinkers contain less than 45 per cent. of iron, then a richer material, such as cinders of malleable iron or rich iron ore is to be used therewith. When the furnace is charged the usual fuel and fluxes are to be used with the ore and clinkers.

REVIEWS.

Elementary Text Book for Young Surveyors and Levellers. By HENRY JAMES CASTLE. Simpkin and Co. 1846.

This little work is an abridgement of a larger volume published by the same anthor, and intended principaly for the use of Students at King's College, for which Mr. Castle is the Surveying Professor. The book commences in the usual way with a few useful geometrical problems and theorems, some examples of mensuration, the description and use of various surveying instruments, specimens of field book and general instructions for land surveying and levelling.

The description of drawing instruments partakes too much of the old school; no surveyor now would ever dream of using the parallel protractor or scales engraved thereon, on the plea of the circular one being "too expensive." Those who desire to learn the practice of surveying, must not begrudge good instruments, for upon them of course greatly depend the accuracy of the work. The card-board protractor of Troughton and Sims, used by the Ordnance surveyors, is an excellent one for theodolite service; the centre being cut out, all the meridians or bearings are laid down with the parallel rules, without moving the protractor. This for traversing is invaluable, and particularly if all the work be contained within the circle cut out, which being 12° diameter admits of a tolerably sized plan.

The cross-staff is also described, but this, as well as the parallel protractor, is now entirely eschewed by practical surveyors, the "optical square" being an excellent substitute; it is made upon the reflective principle of the pocket sextant, but being required merely for right angles is much smaller and less expensive.

The off-set staff the author says is a "narrow slip of deal about $1\frac{1}{2} \times 1$, and generally 10 links long, divided into links; and should be furnished at one end with a small notch or hook to put the chain through hedges and be *numbered on both sides from different ends.*" This numbering on both sides is unnecessary, if the staff be divided into 10 parts, the centre having a double line: a little practice will make it perfectly familiar without the figures. The link-staff is best made of round ash, divided as above with a red hot wire, instead of painting or cutting; it should be shod with iron, and have a small hook and spike attached to the top; the diameter at bottom should be about one inch and taper to ¾ at the top, and the hook and shoe should be included in the measurement, namely, within a fraction of 6 feet 8 inches for the whole length.

The field book is likewise described in the old fashioned manner, having figures merely to the off-sets, *without* sketches. It is invariably the best way to sketch in the work on each side of the line as nearly as possible to resemble the objects to be delineated, and although it may take a little more time in the field, the labour is well spent by its assisting the memory in plotting. His system of "naming" the lines by their length, viz., "685 on 731" is confusing; it should be according to the page upon which the number is found, viz., "685, folio 47," and a circle should be made round the figures which are intended for stations. It is likewise very serviceable to the memory to surround those stations that run from, or across, the base line with a triangle, instead of a circle, which will be found to act as a useful index.

A chapter upon the reduction of customary to statute measure, and *vice versâ*, will be found useful,—

"*Reduction of Customary to Statute Measure*, and *vice versâ*.—The statute length of the perch is 16 and a half feet, but it is different in various countries of England.

In Devonshire and Somersetshire, the customary perch, that is, the local measure of the perch, is less, being but 15 feet.

In Cornwall, it is more, 18 feet; while in Lancashire, it increases to 21; and in Staffordshire and Cheshire it is as much as 24 feet.

This is a *lineal* difference. There is, also, in some counties of England, a *superficial* difference in the measure of an acre; an acre, in Wiltshire, containing only 120 square statute perches, instead of 160.

The Wiltshire customary acre is, therefore, one quarter less than the statute acre, and the rood one quarter less than the statute rood.

As property is frequently bought and sold by the customary measure of the county wherein it lies, the surveyor is often called upon to reduce it from one to the other.

Different Values of the Acre.—The number of (statute) square yards in an acre, will, of course, vary with the length of the customary perch of the county.—(An acre consisting of ten square chains or of 160 square perches.)

In the statute acre, a square perch is 272·25 square feet, and the acre, therefore, is equal to

$$272{\cdot}25 \times 160 = 43560 \text{ square feet,}$$
$$= 4880 \text{ square yards.}$$

In the acre of Devonshire or Somersetshire, as the square perch contains 15 × 15 square feet, or 225 square feet.

$$\text{the number of square feet} = 225 \times 160 = 36000$$
$$\text{and of yards} = 4000$$

In Cornwall, where the perch is 18 feet,

$$18 \times 18 = 324 \times 160 \text{ feet} = 51840 \text{ square feet.}$$
$$\text{or } 5760 \text{ square yards.}$$

The Lancashire perch is 21 feet long; the square perch, therefore, must contain 21 × 21 = 441 square feet, which will make the acre to contain 70,560 square feet, or 7840 square yards.

The customary acre in Cheshire and Staffordshire is the largest of the whole, each perch being 24 feet; the acre will consist of 24 × 24 × 160 square feet, which is equal to 92160 square feet, or 10240 square yards; while the Wiltshire acre consists only of ¾ the statute acre, or 3630 square yards.

To reduce Statute Measure to Customary, or one Customary to another.

Rule 1.—Bring the acres, roods, &c., in every case, to square perches; multiply these by the number of square feet in the given perch to bring them into square feet (a foot being the common unit of measurement of both statute and customary measure), and divide by the number of square feet in the required perch; this will bring it into perches; raise these perches to roods and acres and the result is the area in acres, roods, and perches of the customary measure required.

EXAMPLE 1.—Reduce 25 acres, 2 roods, 16 perches, statute measure, to the customary measure (Derbyshire) of 15 feet to a perch.

25A. 2R. 16P. = 4096 statute perches,

but the square feet in a statute perch = 272·25;

∴ 4096 × 272·25 = 1115136 square feet.

$$\text{Whence } \frac{1115136}{15 \times 15} = \frac{1115136 \text{ cust. perches.}}{225} = 4956 = 30\text{A. } 3\text{R. } 36\text{P.}$$

Ans. 30A. 3R. 36P. Derbyshire measure.

To bring customary into statute measure, reverse the preceding rule.

EXAMPLE 1.—How many statute acres are there in 28 acres, 3 roods, and 15 perches, of Devonshire measure?

28A. 3R. 15P. = 28·84375 Devonshire acres

if the Devonshire acre = 1; the statute acre = ·826447 statute acres,

whence 28·84375 × ·826447 = 23·8378 = 23A. 3R. 14P.

Ans. 23A. 3R. 14P.

Scotch Measure.—The acre in Scotland consists as in England of 10 square chains, (each chain divided into 100 links,) and is reckoned in acres, roods, and *falls*, which are equivalent to the English perches; 40 falls making one rood, and 4 roods one acre. The Scotch chain, however, is 8 feet longer than the English, being 74 feet instead of 66.

The acre being 10 square chains = 10 × 74² = 54760 square feet.

And as 10 square chains = 160 square perches,

$$\frac{54760 \text{ feet}}{160} = \text{one square perch;}$$

Therefore one square perch or = 342·25 square feet.

To bring English Statute Measure into Scotch.

Rule 1.—Reduce the given area into English perches, and then into square feet by multiplying by 272·25, the number of square feet in an English statute perch; divide this product by the number of square feet (342·25) there are in a Scotch fall, and you obtain the area in terms of Scotch falls, which bring back to their proper quantities in roods and acres.*

* To bring Scotch measure into English, reverse the preceding rule.

EXAMPLE 1.—Reduce 32A. 3R. 25P. English statute measure, into Scotch measure.

32A. 3R. 25P. = 5265 square perches.

272·25 × 5265 = 1433396 square feet in the given area,

And dividing by 342·25 = 4188 square falls = 26A. 0R. 28P.

Ans. 26A. 0R. 28P."

The THEODOLITE is next described with some examples of its use; then follows the CIRCUMFERENTOR, another old fashioned instrument, which, by most London surveyors, is superseded by the theodollite.

Examples are shown for laying down "the variation of the needle," but unless it can be *precisely* ascertained at the date of the survey, it is much better to omit it and show the magnetic bearing only—for inasmuch as the variation of the needle is different in different countries, it is safer to put the needle-bearing only, which answers all practical purposes. Many other hints and examples follow which may be more or less useful to the beginner.

The treatise on levelling is of the usual description, but does not give sufficient examples, omitting for instance, all mention of cross sections, that mostly puzzle the beginner. The author describes the staff-holder as "having considerable responsibility reposed in him." We advise therefore that this duty be simplified as much as possible, and in order to facilitate the most important part of it, that of keeping the staff upright, there should be attached two small spirit levels placed at right angles on the staff, one being at the back and the other on one side, about four feet high from the ground. Some levellers attach a circular bubble at the back, which answers the same purpose, also a handle for holding the staff without concealing the figures. The staff-holder should also carry a small iron tripod to place under the staff whenever used—this should not be attached to the staff, for it is requisite sometimes to leave it, whilst observations are being made with the same staff, at other plac s. It is always adviseable to level with two staves; when one only is used there is much liability to error, for should the instrument be out of adjustment or be turned it round, there is no means of again taking the back set. The bubble must always stand in the middle whenever the level is turned round or the work will not be correct. We mention this on the knowledge that many levellers neglect it, considering it of no importance so that the bubble is in the centre *when* the observation is made.

Origin and Reclamation of Peat Bog, with observations on the Construction of Roads, Railways, and Canals in Bog. By BERNARD MULLINS, C.E., *Vice-President of the Institute of Civil Engineers of Ireland, and* M. B. MULLINS, A.M., C.E. Dublin: Oldham, 1846; 8vo., pp. 48; five lithographic plates.

This treatise contains the subject of a paper read before the Institute of Civil Engineers of Ireland, and the result of long professional experience, makes its appearance opportunely at the present time, when the execution of public works in Ireland attract peculiar interest.

Many fallacies are exposed in the present work. It seems to be shown pretty clearly that bogs are the cause, not the effect, of the destruction of ancient forests; that, in fact, the accumulated vegetable matter which covers one-seventh of the area of Ireland (nearly three millions of acres) does not arise from the decay of trees, but from the bog moss, which only flourishes in comparatively cold climates, and entirely different from the vegetation of the morasses of warmer countries.

The absurdity of the recommendation in various Parliamentary Reports *not to drain too deep* is successfully shown, and the value of draining by deep drains for purposes of agriculture and also for the construction of solid foundations of roads and railways is considered at length. Messrs.

Mullins show that Smeaton and his successors have entertained erroneous views respecting works constructed in bog lands, and suggests methods which are recommended by experience and common sense. In addition to the valuable information which it contains, the work has the advantage of being written in a concise and perspicuous style.

Elements of Physics. By C. F. PESCHEL; translated from the German by E. WEST. Part II. *Imponderable Bodies.* London: Longman, 1846. 12mo. Vols. 2 and 3. Woodcuts.

The publication of the second part of this work has been hastened by the rapid sale of the first. This circumstance is a gratifying indication that the public taste for sound knowledge of physical science is on the increase. The volumes before us are similar in plan to that already reviewed (*ante* Nov. 1845), and treat of light, heat, magnetism, electricity, electro-magnetism, and magneto-electricity. Of all elementary treatises on the philosophy of what are termed "imponderable bodies" which we have examined, the present gives by far the clearest and most accurate account of the state of scientific knowledge up to the present time. The author, from national prejudices, occasionally assigns too large a share of the merit of important discoveries to the experimentalists of Germany; but even this defect has its compensating advantage, for it enables the English reader to regard science from a new point of view, and familiarises him with worthy names with which he has hitherto been little acquainted.

The tables of the tension of steam do not seem happily chosen. Southern's formula is accurate for a low pressure only, and Tredgold's is not trustworthy, except for pressures ranging between 1 and 4 atmospheres. The experiments of the French Academy apply only to very high pressures. The translator would, we think, have been justified in giving the far more complete tables in De Pambour's treatise on locomotive engines. The theory of the power of steam engines, developed in the same treatise, might have been substituted for the totally erroneous theory given in § 421 of the work before us, in which the evaporative power of the boiler is not taken as a numerical ingredient of calculation.

The number of errors is, however, exceedingly small in reference to the extent and variety of the subjects embraced. The author has, in many cases, given practical hints for the construction of apparatus and performance of experiments, deduced from his own experience: the collection of the matter contained in this treatise must have cost him much labour and research, and his efforts have been well seconded by the translator, who has produced a very perspicuous version of the original texts.

A Reply to some Observations in a Review of the Pamphlet entitled Metropolitan Bridges and Westminster Improvements, in the Civil Engineer and Architect's Journal, September, 1846. Addressed to the Editor of that Journal.

Sir Howard Douglas has written a reply to that part of our review of his pamphlet entitled "Metropolitan Bridges, &c.," in which the accuracy of some of his views respecting the stability of Hungerford Bridge is questioned. The following extracts from the "Reply" will, we trust, fairly represent the arguments brought against us: we had prepared some remarks in answer to these arguments, but are compelled to defer them till next month. The reasons for differing from Sir Howard Douglas were expressed with caution, and remain unchanged; but we have to express our acknowledgments of the very corteous spirit in which he has addressed to us the present vindications of his opinions:—

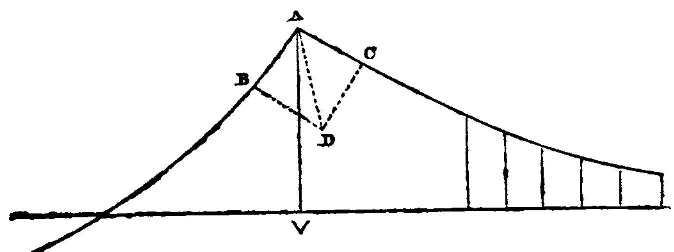
The reviewer's first objection is, that it is not confirmed by very conclusive reasoning, that the strength of the suspension chains ought to be greater than three times the strain to which they may be exposed. This can only be derived from experience. In rigid or inflexible works, this strength may be sufficient; but in suspension bridges, subject to considerable motion, and an increased strain, arising from vibration, undulation, and momentum, it is quite clear that additional strength ought to be given to those parts which support the strains; and Mr. Davies Gilbert's rule, that the strain ought not to be greater than one-sixth of the weight which the chains are capable of sustaining, appears to be well founded.........

The reviewer's next objection is, that the curve is not, as assumed, a common (simple) catenary. This observation is correct, but no error arises from considering the curve as such. In fact, it has been demonstrated by mathematicians that, when the abscissa or height of the curve bears no greater proportion to its length than that which exists in any suspension bridge which has yet been constructed, the horizontal tensions, or strains, whether the curve be a simple or a loaded catenary (a slender chain, or one from which, for example, a heavy bridge is suspended) will vary directly as the ordinate or span, and the length of the curve, and inversely as the abscissa or height: it may here be added that, when the height is small, compared with the span, the curve coincides very nearly with the common parabola (and such curve Galileo supposed it to be). In the pamphlet reviewed, the curve was assumed to be the simple catenary, merely because precise values could on that supposition be given to the tensions. But whether a catenary be simple, or whether it be considered as such a curve, modified by the weight of a road-way and suspension rods, the values of the horizontal tensions (corresponding to a or a') vary directly with the length of the chain above a given point, and with the span, or ordinate; therefore the heights, or abscissæ, being equal, the term corresponding to a' is less than that which corresponds to a, in a higher ratio than y' is less than y, which was all that it was intended to express.

The reviewer's third observation is, that, in finding the strains on the curves at the two extremities, "a formula has been applied to a case with which it has no connection:" it is added that "the value of a' is taken from the tension in a chain at its lowest point, when the lowest point is horizontal;" and it is observed that "the shorter chain, where it is attached to the abutment, is inclined to the horizon at a considerable angle," implying that there is a difference between the horizontal strains in different parts of the length of a chain suspended between two points. In this the reviewer has, however, overlooked the first principles of mechanics, respecting the properties of the catenarian curve; and it may be added, the equilibrium of an ordinary arch, since it is demonstrated by mathematicians that, both in the catenary and the equilibrated arch, the tension, estimated horizontally, at every point in the curve is the same. Hence, if a chain suspended from two fixed points in a horizontal line be in equilibrio, and if, while the chain remains fixed at one of the points, any portion be removed, the lower extremity of the portion which remains being attached to a fixed point, that portion will still be in equilibrio. The abutment chains of a suspension bridge, instead of descending at a considerable angle with the horizon to a point of the abutment much below the platform, as in Hungerford Bridge, should be fixed at points so situated that each of those chains may assume a figure precisely equal and similar to half the chain between the piers. In Hungerford Bridge, "*the chain attached to each of the abutments being shorter than half the chain between the piers,*" and "*descending to the ground at a considerable angle,*" is precisely the cause that the horizontal tensions of these chains are less than those of the chains between the piers, and that a power (represented by $(a-a')$ is constantly acting at the head of each, to draw it towards the middle of the river.

The Reviewer appears to doubt this, observing that "if the saddle were acted upon by an accelerating (qy. *moving*) force as $a-a'$, it would be set in motion;" and he probably intends to imply that the motion of the saddle would prevent the pier from being disturbed. He asserts, moreover, that "the pressure of the rollers upon the top of the pier is normal to the surfaces in contact, and is *therefore wholly vertical.*" Now, with respect to this assertion, the use of the rollers is to permit the saddles, to which the chains are attached, to shift their places, or slide, on the piers with the vibrations of the bridge; and in so far, certainly, they diminish the shaking of the piers; but, though the shaking is *diminished*, it is not removed; it exists to a great degree on account of the enormous friction, arising from the weight of the bridge, which takes place both on the saddles and piers, and when, in consequence of great strains arising from sudden accessions of weight on the bridge, the saddles are drawn to the limits of their motion on the tops of the piers, they cease to relieve the latter from the effects of such strains. This is a defect which exists in all suspension bridges; and even the ingenious expedient of the shifting saddles is incapable of removing it. The evil is, moreover, rather augmented in Hungerford Bridge, in consequence of the strains introduced by the convex figure which has been given to the platform, the height of the convexity being about four feet in the middle of the bridge.

With the suspension bridge, if A B and A C,—or to speak more mathematically, if the tangents to the curves, formed by the chains at the heads of the piers, do not make equal angles with the vertical line A V, even if the tensions of A B, A C, were equal (which is not the case in Hungerford



Bridge), the resultant of the strains at A would be in the direction of a line A D, drawn from the point at which the tangents meet, to bisect the angle B A C, and would therefore not be vertical; thus there is an excess of force acting horizontally towards the middle of the bridge, at the end of a lever whose length is equal to the height of the pier, by which the pier is continually strained, and the uniformity of pressure, on the foundations of the piers, destroyed. A very considerable error of this description exists in the Hungerford Bridge, "by the shorter chains descending at considerable angles to abutments greatly beneath the level of the floor of the bridge;" moreover, the defect, not having, so far as the author is aware, been previously noticed, he deemed it right to call the attention of practical engineers to this important circumstance, in the note, page 7, &c., of the pamphlet; and now finding that a writer in so respectable and influential a periodical as the *Civil Engineer and Architect's Journal*, asserts "that the conclusions at which the author has arrived upon this subject, are merely imaginary," assuming that notwithstanding the inequality of the angles formed by the chains with the piers, "*the pressure on the piers is wholly vertical, because it is normal to the surfaces in contact*," the author addresses to the editor a proof of the fallacy of the assumption, and trusts that, in justice to the author, as well as in consideration of the practical importance of the subject, he will not permit his Journal to sanction the repetition of so serious an error.

NOTES ON FOREIGN WORKS.

Triumphal Arch at Munich.—Besides the new portal which is to be erected at the end of the Brienner Strasse, Ludwig-street also will be adorned by a new entrance hall, which is already up to the architrave. It is to be called the *Sieges Pforte* (Arch of Victory), and has been planned after the triumphal arch of Constantine, at Rome. Its details are worked out to an astonishing nicety and beauty by the architect de Gärtner. The material used is a marble of a greenish grey colour, and its fine grain admits of a very careful elaboration. On the attic of this splendid monument there will be placed a statue of "Bavaria," mounted on a pedestal, with victories at the four corners. The models for this statuary have been made by the sculptor de Wagner, at Rome, well known by his large frieze in the Walhalla, and are to be cast in the Government brass foundry of Munich.

Latest Architectural Publications of Munich.—One of the most active and deserving authors in the Bavarian capital is G. G. Kallenbach. His work, entitled "Chronology of German Mediæval Architecture," in 48 oblong folio plates, comprises specimens from the beginning of the Romanic style, about the year 1000, to the last fading of the Germanic. It is accompanied by a short text, which, to the great advantage of the student, is placed beneath the engravings. This work is only the nearer explanation of an architectural collection of M. Kallenbach, unique in its kind, brought together by the dint of most zealous exertions, during a number of years, comprising about seventy models of mediæval buildings, ecclesiastic and private, made on the spot, after an accurate survey of the originals, and finished in their most minute details. They are made to one scale, which much enhances their value. Another publication by the same artist, entitled "Album of Mediæval Art," contains copies of the remains of mediæval sculpture in its relation to architecture and all its subordinate branches; most faithfully copied after the originals—and which is intended to dissuade the artisan from a mere repetition of machine-made models, and induce him to the study of real art originals.—Professor E. Metzger is the author of a work of great importance for the technical parts of buildings, entitled "Doctrine of Architectural Construction." It will contain 200 plates of geometrical plans, with a concise, yet comprehensive text, printed beneath the plates (a plan worthy of general imitation). The first part will treat of the different methods of construction in stone, iron, and wood; the second, of their practical adaptation to the different styles and forms of buildings, as derived from the study of architectural structures.—The Government architects of Munich continue to publish the works, with the execution of which they are intrusted. Amongst them is M. de Gärtner's work on the Royal Library and Record Office in Ludwig Street, containing, on the 20 plates hitherto published (some splendidly coloured), the different elevations, ground plans, and longitudinal and transverse sections of this splendid and extensive structure; and also the detail of the ornaments, and a view of the fine staircase supported by columns, which unites the fronts of the two buildings.—The first part of M. Lange's (the royal building counsellor of Greece) "Works of high Architecture" (*höherer Baukunst*), contains the plans for a royal residence, which was exhibited at the last Munich Art Exhibition. The same work will contain M. Lange's plans for the completion of the Munich *Frauenkirche*, which has to lose its characteristic, though unhandsome, octagonal cupola, instead of which a Gothic spire is to be raised.—Building-inspector Anger has published a work on the remarkable private buildings of the Bavarian capital, and such as serve for public and benevolent purposes.—To crown this, even the pupils of the architectural section of the Munich Academy of Fine Arts, publish the plans, made by them according to the programme of the Academy.

Academy of Sciences, Paris.—M. Person made some experiments for determining the necessary heat for fusing alloys of metals, and thinks that it is possible to determine that point, from the knowledge of the temperature which each of the component metals requires for the same process. The solution of this problem confirms perfectly the results which M. Person had drawn from his experiments on fusion—viz., the law that the latent heat of the fusion is given by the formula $(160 + f)\ d = l$.—M. Walchner announced to the Academy a most curious fact, that copper and arsenic were to be met with in *all substances and bodies*—in every sort of iron, in mineral waters, and even in meteoric stones. M. Flandin said he had analyzed the mineral waters of Passy, but had not found even a trace of copper or arsenic, either in following the procedure of M. Walchner or that of Marsh. More important is what M. Walchner says on the copper and arsenic contents of the soil of burial grounds. It has been a hitherto unresolved question whether the contents of these substances in the bodies of poisoned persons were entirely ascribable to that cause, or to the *natural* contents of the soil surrounding them. He had found both substances in the soil of cemeteries, but in very minute proportions, and he has collected a number of specimens of these soils.—M. Pierre submitted to the Society his experiments on the dilitation of fluids. The author divides liquids into two categories, and these again into nine groups. The first division comprises the bodies composed of chloride of bromine and one simple element—phosphorus, arsenic, tin, titanium, and silicium. The second category comprises the compositions of chlorine, iodine, or bromine, with any compound element, ethyle or methyle. The law which results from these experiments is this—two fluids formed by the combination of any common with any isometric element, follow (from the point of their respective temperatures of ebullition) very different degrees of contraction; or, in other terms, equal volumes of liquids thus constituted, considered at their respective temperatures of ebullition, will not preserve that equality at degrees equidistant from their temperature of ebullition. The difference, in most cases, is considerable.—M. Blanquard Evrard has forwarded to the Society two samples of photography on paper, obtained by an especial process. The samples surpass everything hitherto seen, even those of M. Bayard.

Prague and Dresden Railway.—This huge undertaking occupies alone, in the neighbourhood of the former city, 3,000 workmen, and the greatest difficulties to be overcome are from the Prague terminus to Kralup, a distance of about 16 miles. The viaduct from the terminus north to Karolinenthal and Bubna will be 580 cubits long, with 85 arches,—certainly one of the largest works hitherto accomplished in Austria. There are three minor water-courses of the Moldau river, a branch between two islands, and the main branch, which must be bridged over. A number of bridges are required to pass the numerous water-courses and islands. The bridge over the main arm will be 535 feet long, and consist of 5 arches. The arches of the main bridges will have a span of 78 feet in the clear, and form a segment, the height equal to one-sixth of the span, and are to be built of granite. The quantity of granite and sandstone to be conveyed by land and water is astonishing, some of the blocks weighing between six and seven tons. The expenses of this part of the line alone are calculated at $1\frac{1}{2}$ million of florins. There will be a small terminus in the Baumgarten (a place of public resort two miles from Prague), which will afford the humbler classes the advantages of country air at a merely nominal price.

Berlin Bresslau Railway.—This most important undertaking has lately been completed, and is open for traffic. The distance of $47\frac{7}{10}$ German miles (nearly 200 English) is performed in 18 hours, including stoppage for dinner, and thus a journey, which even Frederick the Great could never perform in less than 36 hours, is made in a few hours at a trifling expense. The chief works of the line are some very long and costly embankments—for instance, that at Frankfort-on-the-Oder, 100 feet high. The great viaduct of Gorlitz, over the Neisse, does not lay on the main, but a branch, line, connecting the lower Silesian and the Saxon-Silesian. Its length is 1500′, the height of the arches 122′ above the level of the river, and the foundations of the arches are 40′ lower, making a total of 162′. It has cost between 600,000 and 700,000 dollars, and Europe does not yet possess a work of equal magnitude. The viaduct over the Bober at Bresslau is an equally imposing structure. It is 1550′ long, and has 35 arches of a height of 76′ built of blocks of white grit. This is the longest line in the North of Germany, under the same administration. It is the more important, as being laid out afar from the hitherto commercial road, or the valley of the Oder; it passes a tract of land hitherto little connected with industry and commerce. The renting of this huge line is a matter hitherto unascertainable, which costs 18,000,000 dollars—400,000 dollars per German mile. A great drawback is that this line has only one line of rails, by which much delay and trouble are occasioned.

Prague, Austria. Sculptures.—Excavations of the Archeological Committee of the Bohemian Museum.—M. Veith, a large proprietor in Bohemia, has resolved on the curious, though praiseworthy, plan, of erecting a national Walhalla at his own expense. Professor Schwanthaler is the artist entrusted with the execution of the statues, of which twelve are ready in small models, and six in a size above life. Ready for casting are the statues of Kings Ottakar II. and George of Padiebra (the latter a sort of Bohemian Cromwell), and of Elizabeth, wife of King John of Luxembourg.—M. Max, the sculptor, is also executing some large marble statues for public establishments.—M. Raphael has made the bust of Mozart for the public library, and of Dr. Krombholz, the great physician, for the University.—Parson M. Krolmus has been successful in his excavations of heathen tumuli, hitherto very scarce in that country. He has found in the Scharka, near Prague, two stone sacrificial tables, several well preserved cinereal vases, bronzes, &c. Another heathen sepulchral ground has also been found on excavating for the Dresden railway, near Prague.

Australian Mines.—The wages of a good miner in the Borraborra lead-works, in South Australia, are £170, per annum. Even those of other artizans, masons, carpenters, wheelwrights, &c., are in proportion.

Winter Garden at Berlin.—The King of Prussia has subscribed £120,000 for the erection of a covered garden in the centre of the city.

New Pinacotheca.—The King of Bavaria has just laid the first stone of the new Picture Gallery, which will contain paintings of the present century only.

NOTES OF THE MONTH.

The Royal Institute of British Architects will commence their meetings on Monday evening, November 2, at eight o'clock, at their Rooms, No. 16, Grosvenor-street, Grosvenor-square.

Menai Tubular Bridge.—The experiments have been renewed at Millwall.

Nelson Monument, Trafalgar Square.—The proverb "a joke is a joke" has its exceptions, and the Nelson monument is one of them. The man and the boy renewed their operations upon this elegant structure a few weeks ago, but now seem to have again given them up in despair.

Coast Defences.—The Martello tower, between Hastings and Seaford, are being covered in with stone.

Chinese method of Boring.—The Southampton Water Committee have voted £150 for trying this method at their Artesian well.

Salford, Manchester.—A new church has been erected in the Early English style. Mr. Lane is the architect.

A New Institution of Mechanical Engineers has been formed at Birmingham for the advancement of various branches of mechanical knowledge, which do not fall within the province of the present Institution of Civil Engineers.

Cemetery at Cambridge.—Nine acres of land have been selected, and will probably be allotted in separate portions to each of the 13 parishes.

The South Devon Railway.—The sea wall has again been greatly injured by the wind and waves.

Public Message Delivery Company.—Of the schemes of the day, one of the most curious is a proposition to establish electro-telegraphic communication between numerous stations in every part of London, for the conveyance of messages at a low charge.

The Baths and Wash-houses in Manchester since they were opened in September have been attended by 3,000 persons.

New Dock at Honfleur.—The greater part of the wall has been destroyed by the water getting between it and the earth.

Lord Rosse's Telescope.—The report that an attempt had been made to injure this instrument has been formally contradicted.

Gold in Australia.—A valuable auriferous vein has been discovered in one of the copper mines, and the shares have risen 900 per cent.

The Wellington Statue.—Lord Morpeth has addressed a circular to all the Royal Academicians, requesting their opinion respecting the present position of the statue on the arch.

St. Michael's Ottery has been consecrated. The style is Early English; the architect Mr. Wollaston.

St. Alkmund, Derby.—This new parish church is built entirely of stone, in the late decorated style. The spire rises 112 feet above the tower, which is 92 feet high. Mr. Stevens, of Derby, is the architect.

City Improvements.—The Court of Common Council have agreed to a report, presented by Mr. R. L. Jones, recommending the formation of a new street from King William-street to the south side of St. Paul's Churchyard.

Collision of the Prometheus at London Bridge.—Propeller vessels have been very unfortunate of late. The Irish steamer Prometheus, during the month, has suffered severely, by being carried against an abutment of London Bridge. The screw propeller was unable to resist the force of the tide, which was running very strong; the stern bulwarks were crushed in, and the masts and funnel swept away.

Gun Cotton.—There are numerous claimants of this invention. Dr. Otto, Professor of chemistry in Brunswick, states, in the *Hanoverian Gazette*, that he has invented an exploding cotton, independently of Schonbein and Bœttger. His preparation, which was suggested by an observation of Pelouze, in his Journal of Chemistry (Vol. I., page 126), consists in immersing well-cleaned cotton in highly-concentrated nitric acid for half a minute, and instantly afterwards soaking it in water, which must be constantly renewed, in order to effectually free the cotton from the acid. The preparation, when dried, is ready for use. It may be exploded with a hammer on an anvil, but is capable of being rammed in a gun, in the ordinary way, without danger. M. Morel, an engineer at Paris, has recently exhibited before General Gourgaud, President of the Committee of Artillery, a fulminating cotton, which may be burnt on the hand without causing pain. It leaves little residue in a fowling-piece, and is nearly noiseless. M. Chodsko, a Polish refugee, has exhibited another fulminating cotton, which resembles the last, except in that it leaves a residue in the fowling-piece. The materials prepared by M. Morel and M. Chodsko both ignite by a blow of iron upon iron, but not of iron upon wood. The English Government have instituted experiments with Schonbein's gun cotton, which have been attended with success.

The Drainage of Haarlem Lake is to be continued by three enormous steam engines, which are to complete the work in 13 months. The Cornish engine already at work discharges a million tons of water daily.

The Great Britain.—This luckless vessel still remains a-ground on the Irish coast. She is to be protected by a floating breakwater; and the last accounts state, that an attempt will be made to rescue her by the method of flotation. Why was not this plan adopted in the first instance, instead of the violent experiment of dragging her off by main force? Had the steam tugs sent to the aid of this vessel reached her, and succeeded in drawing her into deep water, she would have been in danger of foundering. Mr. Marris Dinsdale has proposed a method of buoying her up by rafts, with Greenland oil casks on either side of the vessel, and connected by chains underneath it. This method was first proposed by him for the Prince Frederick, on Corton Sand.

LIST OF NEW PATENTS.

GRANTED IN ENGLAND FROM SEPTEMBER 24, 1846, TO OCTOBER 17, 1846.

Six Months allowed for Enrolment, unless otherwise expressed.

Thomas Bartlett Simpson, of Islington, Middlesex, gentleman, for "certain Improvements in propelling, and in machinery connected therewith."—Sealed September 24.

Albert Robert Cunningham, of Sydenham, Kent, gentleman, and Joseph Threlfall, Carter, of the same place, engineer, for "certain Improvements in the propelling carriages on railways."—October 1.

William Wild, of Salford, Lancashire, moulder, for "certain Improvements in machinery or apparatus for manufacturing barrels and other vessels of capacity."—October 2.

Peter Fairbairn, of Leeds, machine-maker, and Peter Carmichael, manager for Messrs. Baxter, Brothers, and Co., flax spinners, Dundee, for "Improvements in machinery for drawing, roving, and spinning flax, hemp, silk, and other fibrous substances."—Oct. 2.

Pierre Bryere, of Rue Boileau, Nantes, France, for "Improvements in the manufacture of boots, shoes, and clogs."—Oct. 2.

Edm. Morewood, of Steel-yard, Upper Thames-street, merchant, for "certain Improvements in machinery for separating certain fibrous substances; from seed and other extraneous masses."—Oct. 2.

William Wield, of Manchester, mechanical draughtsman, for "Improvements in certain mills for grinding, and in the manufacture of certain parts of mills."—Oct. 2.

Charles Marie Fouillet, engineer, of Paris, for "Improvements in railways."—Oct. 2.

Samuel Holdsworth, of Norwood, Surrey, gentleman, for "certain Improvements in apparatus to be applied to railway carriages, to prevent accidents thereon."—Oct. 2.

William Farthing, of the town and borough of Kingston-upon-Hull, for "certain Improvements in the manufacture of glass."—Oct. 8.

Robert Wilson, of Woodhouses, Lancaster, weaver, for "certain Improvements in looms for weaving velvets and other piled goods; and in the machinery or apparatus for cutting the pile or nap of the same."—Oct. 8.

Samuel Heseltine, jun., of Bromley, in the county of Middlesex, engineer, for "certain Improvements in the construction of lamps to burn oil."—Oct. 8.

John Warburton, of Kearsley, Lancaster, tin-smith, for "certain Improvements in machinery or apparatus, for preparing, slubbing, and roving cotton wool, and other fibrous materials."—Oct. 8.

William Fairbairn, of Manchester, in the county Palatine of Lancaster, civil engineer, for "Improvements in the construction of iron beams for the erection of bridges and other structures."—Oct. 8.

Francis Naider, of Cheapside, warehouseman, for "Improvements in the manufacture of gloves."—Oct. 8.

Marcel Tean Milon, of 27, Rue Fronches, Paris, gentleman, for "Improvements in making roads and ways."—Oct. 8.

John Bombley, of Sunderland, engineer, for "Improvements in capstans and windlasses."—Oct. 8.

George Lowe, of Finsbury Circus, civil engineer, for "Improvements in the manufacture of and in burning gas, and in the manufacture of fuel."—Oct. 8.

Price Struve, of Swansea, engineer, for "Improvements in railway transit, and in moving or raising weights."—Oct. 8.

John Taylor, of the Adelphi, gentleman, for "Improvements in the manufacture of explosive compounds." (A communication.)—Oct. 8.

James Farnsworth, of Sheffield, in the county of York, engineer, for "certain Improved machinery or apparatus, for "the manufacture of bricks and tiles." (A communication.)—Oct. 8.

Michel Louis Ferant, of 361, Oxford-street, gentleman, for "Improvements in treating oils." (A communication.)—Oct. 8.

George Frederick Muntz, Esq., M. P., of Ley Hall, Birmingham, for "an Improved manufacture of metal plates for sheating the bottom of ships or other vessels."—Oct. 15.

John Condie, of Glasgow, engineer, for "Improvements in machinery used in manufacturing malleable iron."—Oct. 15.

Francois Durand, engineer, and Onesiphore Pecqueur, engineer, of Paris, for "Improvements in forming leather into tubes, cylinders, switches, cases, sheaths, hats, and other articles."—Oct. 15.

James Kite, of New North Road Bridge, Hoxton, in the county of Middlesex, gentleman, for "certain Improvements in steam engine-chimneys, in furnaces and flues, in vent and exhaust pipes, and in other like smoke and air conductors, and in the machinery or apparatus connected therewith."—Oct. 15.

Arthur Millward, of Birmingham, gentleman, for "certain Improvements in producing figured surfaces, sunken and in relief."—Oct. 15.

William Palmer, of Sutton-street, Clerkenwell, manufacturer, for "Improvements in the packing of, and in the gaining, and the manufacture of products from fat, or fatty matters."—Oct. 15.

John Hornby Maw, Esq., of Hastings, Sussex, for "Improvements in the manufacture of pens."—Oct. 15.

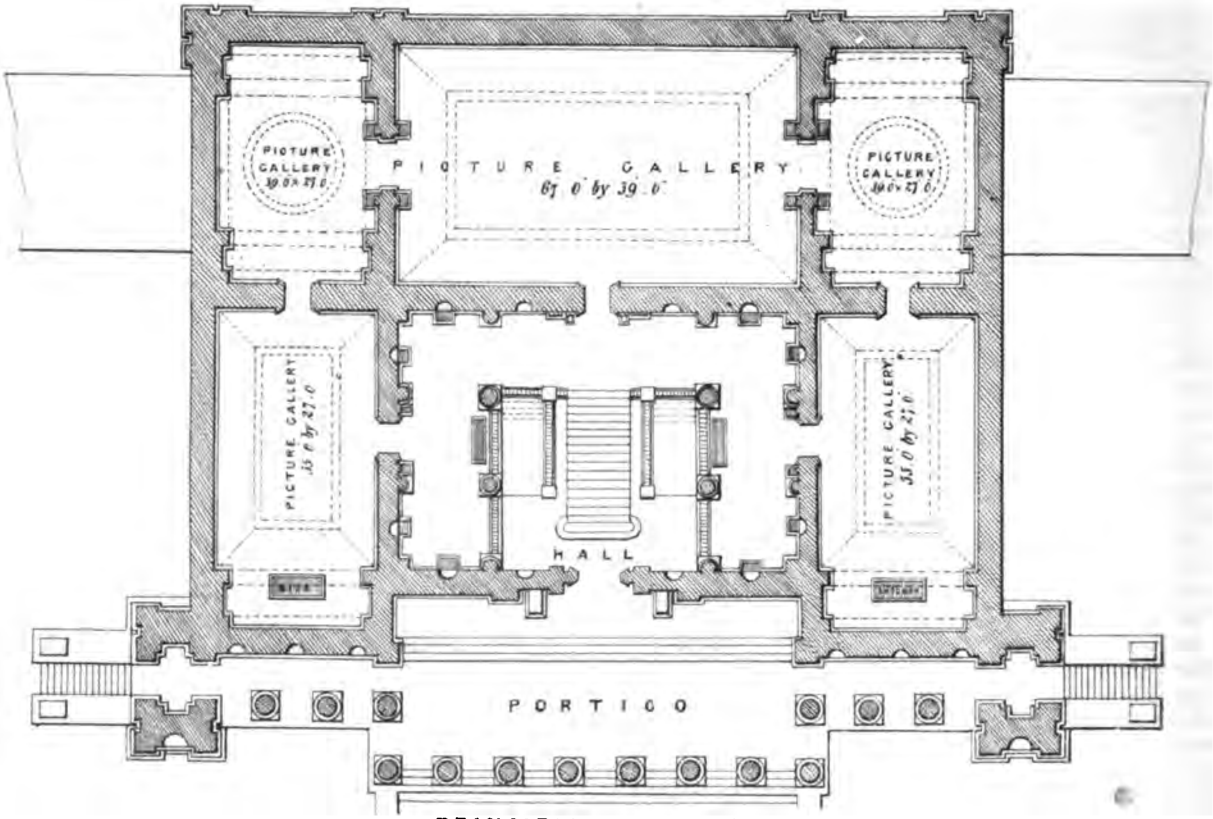
John Donkin, of Grange Road, Bermondsey, civil engineer, for "Improvements in the manufacture of paper, or in the machinery employed therewith, and in the process of bleaching paper, linen, and other manufactures in which chloride of lime is employed." (A communication.)—Oct. 15.

Ebenezer Southworth, of Chorlton-upon-Medlock, near Manchester, draper, for "certain Improvements in engines, to be worked by steam or other power, and applicable to raising and forcing water, to the propulsion of vessels, and other similar purposes."—Oct. 15.

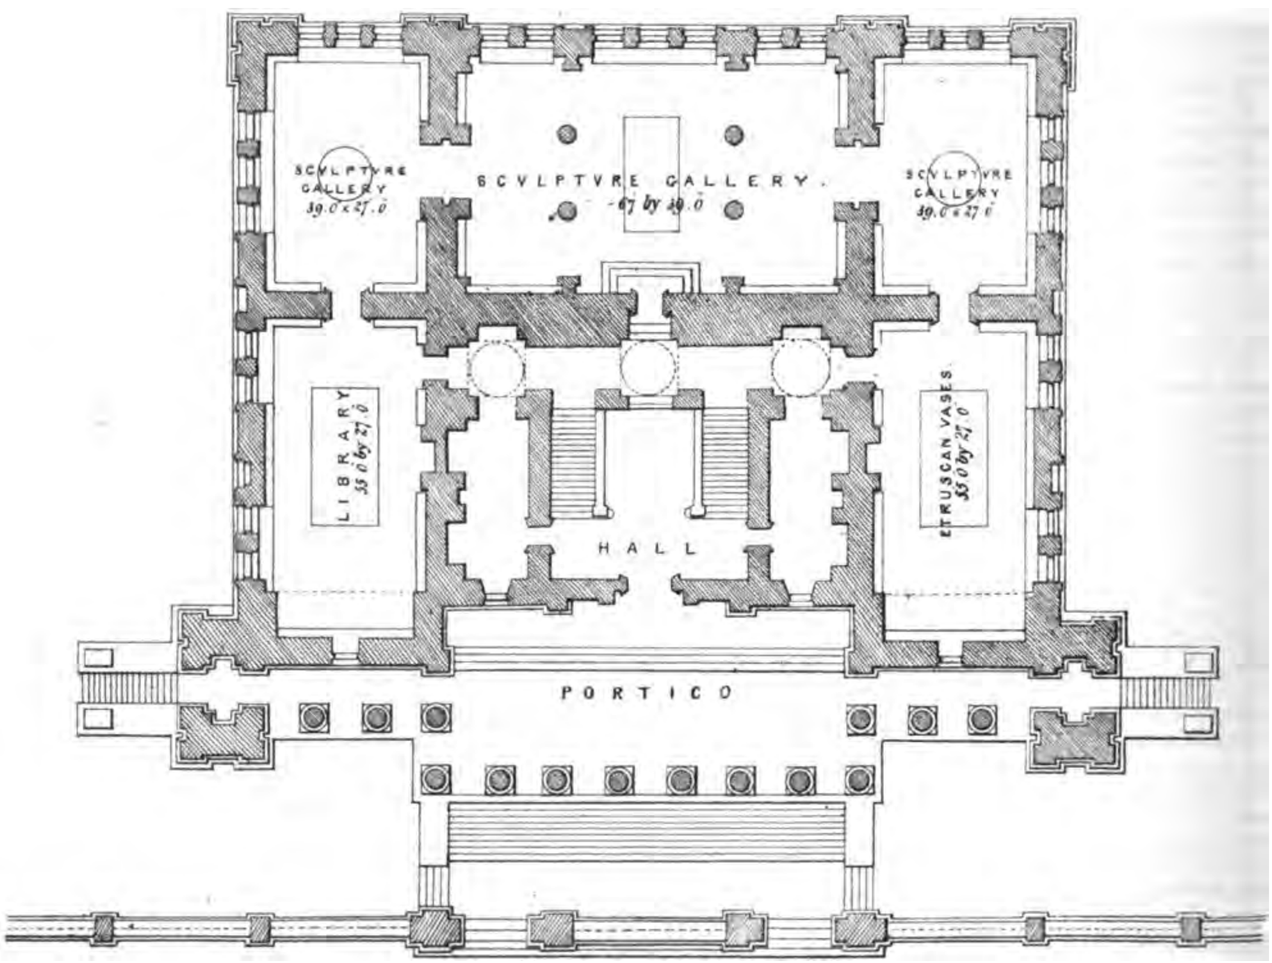
George Winslow, of Binton Crescent, merchant, for "Improvements in machinery for manufacturing files and rasps."—Oct. 15.

John Ryan, of the Royal Polytechnic Institution, doctor of medicine and professor of chemistry, for "certain Improvements in the preservation of organic and other substances."—Oct. 17.

FITZWILLIAM MVSEVM + CAMBRIDGE.



PRINCIPAL - FLOOR



GROVND - FLOOR.

SCALE FEET.

C B.

THE INTERIOR OF THE FITZWILLIAM MUSEUM.

(With an Engraving, Plate XVIII.)

The accompanying engravings exhibit the internal arrangement of the Museum at Cambridge, of which the façade is represented in the Journal for May last, page 129. The building is occupied internally by a ground floor, and an upper or principal floor. The latter is approached by a staircase of most magnificent dimensions, leading from the hall to the sculpture gallery which extends round three sides of the hall and staircase. The architectural and sculptural ornaments of this gallery are to be of the richest and most elaborate description, and this part of the building alone will, it is estimated cost when completed £10,000. Here will be deposited the valuable collection of statues bequeathed by Earl Fitzwilliam and others. Several of these works are master-pieces of the highest class.

The principal floor contains a picture gallery 67 feet long by 39 feet broad; the height of the frieze being 27 ft., and the height of the frieze is 3 ft. 6 in., which is a correct copy of the Elgin Marbles at the British Museum, and from it springs a richly ornamented coved ceiling, which curves inwards from the sides to the centre of the apartment; above the four upper boundaries of this cove rise a vertical lanthern light, between each light are beautifully draped and winged figures, and above is a horizontal ceiling divided into compartments and most elaborately enriched with open panels, and above which are conical sky-lights; the whole height of the room from the floor to the conical sky-light is 53 feet. The floor will be of wainscot, with an inlaid border, and all round the apartment there is a scagliola dado of *Rossi broccata*, with a plinth of black and gold marble. The side picture galleries communicate with that which we have been describing, by arched openings, of which the archivolts and pilasters are decorated with various kinds of scagliola.

The ground floor of the building will be occupied by another sculpture gallery under the long and two end galleries, a library beneath one of the side galleries, and a museum of terra cottas and vases beneath the other side gallery. There is a large space under the hall and the portico, occupied by vaults, which we think might be usefully occupied as a sepulchral museum.

There appears to be some intention to remove the frieze containing a copy of the Elgin Marbles,—we most sincerely trust that this wasteful alteration will be resisted by the Senate. The frieze is thought to detract from the height of the room; we think however that when the walls are filled with paintings, the appearance in the height will be increased, and besides, it is perfectly useless to have paintings where the frieze now is, which is 27 feet from the floor—for who will be able to see them to appreciate their merit at so great a distance from the eye?

Mr. Cockerell has obtained permission to substitute real for imitative marbles in the work yet to be undertaken, and he deserves great praise for having effected this alteration. The enrichments and carving are admirably executed, from the designs of the late Mr. Basevi, by Mr. Nichols, of Grafton-street, London, whose name deserves to be recorded with great commendation; and we understand that it was Mr. Basevi's intention that all the enrichments should be picked out in gold and polychrome.

We are very desirous of seeing the brick fence wall now enclosing the ground at the back of the Museum removed, and replaced by a ballustrade similar to that at the front. This would open the back view to Peterhouse ground, and form a great improvement to the Sculpture gallery, as well as to the College grounds.

When the Museum is finished, we hope there will be a greater liberality shown to the public in allowing them to view the magnificent works of art that will adorn it, than at Oxford, where the Taylor Institute has all the gates and doors closed, and admittance is only obtained either by an introduction by a member of the University, or by *permission* of the porter. Of course, as at many other public establishments, a fee is expected.

As we were lately strolling through the College grounds of Oxford, we asked a member of the University if permission could be obtained for viewing the interior of Christchurch Cathedral, the Taylor Institute, Radcliffe Library, &c. He said he had no doubt it might by speaking to the attendants; of course they would look for a fee to be paid them for their trouble. The jealousy with which Academical and Ecclesiastical corporations guard the edifices committed to their trust is on every account to be regretted.

TRABEATE AND ARCUATE ARCHITECTURE.

SECOND ARTICLE.

In order that any branch of human knowledge may become a science, it must be founded on exact principles which distinguish it from every other science. The mere compilation of facts and opinions, however valuable and accurate in themselves, will not lead to systematic and definite results unless the facts be referred to, and the principles deduced from fundamental axioms.

The application of these considerations to architecture is very simple. Facts and dogmas innumerable relating to architecture have been recorded, but we have been too apt to estimate them according to their intrinsic, not their relative, value. Now the most valuable aid to the advancement of architecture will be the systemizing our present knowledge of it: it has hitherto been seldom regarded as a system. If every critic is to pronounce on the merits of each new edifice as it looks to *his* eye, it is obvious that his criticism will have no higher than an individual authority, that it may be disregarded by contemporaries and reversed by posterity. But if some great architectural principle be universally received by both critics and the criticized as the basis of all criticism, and if this principle be so comprehensive as to include every style of architecture, it is clear that much less will be left, than before, to the fallibility of individual judgment, and that the conclusions obtained will possess the value of being systematic.

We search in vain for any other principle than that of constructive faithfulness, which receives universal consent. There are, it is true, many architects and architectural writers, who find it their interest to resist the *application* of this principle, but none are now bold enough to deny its abstract truth. It is curious to observe how completely the general opinion has changed on this point. Now it is conceded on all hands that (theoretically at least) the decoration of an edifice ought to be the exponent of its construction—yet it is not a very long period since a doctrine the direct reverse of this was maintained. The Abbè Laugier in his *Observations sur l'architecture* (Haye 1765) condemns Pointed architecture, because edifices built in that style exhibit too evidently their mechanical structure. Some of his remarks are so directly opposed to the doctrines of the best writers of the present day, that the following version of a few sentences may be interesting, if not valuable. All the requirements of solidity (says he) consist in establishing a proper equilibrium between the arch which thrusts and the abutment which receives the thrust. Buildings, however, ought to be so constructed that no part of them may appear to exert or resist pressure.... Up to the present time we have been too much subject to this grand defect of Gothic churches; not until it was high time, did a man of genius teach us to do better. The arches of the new church of St. Genevieve are sufficiently supported, but no one can see how they are so. Nothing external announces resistance and effort. The spectator has no observations to make on the strength or weakness of the buttresses. Delivered from all anxiety on this point, he gives himself up to undisturbed contemplation of the beauty of the edifice.

Since the Abbè Laugier wrote this curious passage, architectural knowledge has so greatly increased, that it would be superfluous to show here the fallacy of his opinions. They are quoted to prove how ingeniously an error may be disguised, and to show that, in his time at least, it was admitted that the architecture subsequent to the Pointed was inconstructive. This is a most important admission, and one which many a modern practitioner would like to retract.

The importance of distinguishing between entablature and arch architecture was, we think, first insisted upon by Hope, in the invaluable Architectural Essay, which it may be presumed has by this time been carefully read by every one who professes a knowledge of architectural principles. The unsparing denunciations which Hope commenced against the showy unreal decoration employed during the last three centuries, in consequence of a confusion of the principles of trabeation and arcuation, have been admirably followed up by Professors Willis and Whewell, in the works from which we quoted in the preceding article on the present subject. Until, however, the laws which Hope suggested, and which Whewell and Willis developed, be practically applied, they remain almost barren speculations. The object set before us is not so much to elucidate existing architecture as to promote its future advancement. To this end it is requisite to see how far the laws in question tend to facilitate or impede the improvement of modern decorative construction.

It may be objected that in making architectural decoration immediately dependent on mechanical structure, we restrict the art to purely utilitarian rules. To this objection two satisfactory replies may be given. In the first place, architecture differs from other fine arts, such as painting or sculpture, in that it is not an imitative or representative art. The ends of painting and sculpture are the gratification of the taste by the representation of beautiful natural forms. But architecture is restricted by the economic purposes of the materials upon which it works. In one sense it stands alone among the fine arts, and is the noblest of them; for while the results of other arts have no value except their beauty, the results of architecture have a two-fold value—beauty and practical utility. The direct and accurate imitation of nature, which in painting or sculpture is the perfection of excellence, in architecture is simply impracticable. And therefore we come to this conclusion, that while other works of art are judged by their beauty alone, the works of architecture are to be judged not merely by their beauty, but by their FITNESS also. This consideration has been much lost sight of by those who attempt to draw analogies between the laws of architecture and those of painting: the neglect of it led, for instance, to Sir Joshua Reynolds's eulogium of the works of Vanbrugh.

But there is another strong defence against the charge of utilitarianism; which is, that the restrictions which we would lay upon architecture have been proved experimentally to be neither oppressive nor unnecessary. If it were found practically impossible to comply with this restriction without making the architecture formal and unvarying, a ground of complaint against the strictness of the rule might exist; but, in point of fact, the buildings which have displayed the greatest freedom and variety of form have been those in which the canon of constructive faithfulness has been most scrupulously obeyed. We observe, moreover, in the works of nature, from which all the principles of beauty must ultimately be derived, that the most graceful forms exhibit a wonderful fitness for the useful purposes to which they are applied. The petals of a flower are not merely beautiful ornaments; they serve effectually for the protection of the reproductive organs of the plant. The slight swelling or entasis of the stalk of corn not only renders its form graceful, but adds also to the strength necessary for its preservation. Smeaton, in constructing the Eddystone lighthouse, took for his model the trunk of the oak, which increases in breadth towards its base, meeting the ground in curved lines which experience has proved to be the most effectual for resisting the violence of storms. Lastly, anatomy teaches us that those forms and proportions of the human frame which the sculptor considers most beautiful, are the very same which best enable the several members to perform their respective functions.

Throughout the whole economy of nature this rule is maintained, of making beauty dependent upon utility. The love of the grotesque, or *bizarre* —that is, of forms without purpose—is seldom exhibited except in art. It must, therefore, be regarded as a thoroughly artificial taste—a taste, moreover, unknown in the best periods of art. To revert, therefore, to the rules of criticism, it is clear that there are two distinct ways of estimating the merits of a building,—one by the eye alone, the other by the eye and judgment. We will not be so intolerant as to assert that all architecture which satisfies the eye alone, and not the judgment also, is to be rejected; but this may be safely set down, that the beauty of such buildings is of a superficial and inferior character, and therefore undeserving of modern imitations. There are, in fact, many buildings, which, from their magnificent size and gorgeous ornament, produce a dazzling effect which gradually diminishes as the eye becomes familiarized with it. But those glorious piles, which exhibit in every part a logical fitness, derive an inner beauty, a tenfold deeper and purer eloquence, from the gratification of the judgment. They do not appeal grossly to the senses, the eye does not weary of them after the first impressions are faded; for every renewed view serves to discover new meaning, and, therefore, new delight. They satisfy the highest test of works of art—they bear studying.

Applying these considerations to what is usually considered the most magnificent edifice in London, St. Paul's Cathedral. Can the eye fail to be impressed with the depth of shadow, the proportion and variety of the lines, the graceful contour of the dome, and the apparent boldness and skill by which it has been raised at a vast height above the rest of the structure? But how does the admiration lessen when the judgment comes into exercise; when we find that this boldness in the construction of the dome exists in appearance only? This dome is not the thing it looks to be,—it is a mere juggle, an ingenious delusion of the sight. It *looks* a massive, ponderous structure, and an integral portion of the building; it *is*, in fact, a mere frame-work of wood, stuck upon the building, and not belonging to it. It appears to rest firmly upon its base; but, in reality, derives its support from hidden props and chains, and other delusive contrivances. The architect has shown vast ingenuity; but he has, in this instance, mistaken his vocation, and invaded the province of the theatrical machinist. A dome should be vaulted, resting nowhere but upon its abutments; but this sham dome is not vaulted; it is supported at every part of its concave surface. Had it been made of pasteboard, or canvas stretched on a frame, and painted, it would have looked just as well.

And the upper half of the side walls of the Cathedral are delusions also. They serve only to conceal the flying buttresses behind them. They do not add to the internal capacity of the building; and if they were removed altogether, the alteration would not be visible from the interior. On the outer or conspicuous side, little columns are affixed midway in the air—for show. Had these columns, and the walls to which they are attached, been also of painted pasteboard, their present purpose would have been answered fully as well as by more solid materials.

NOTES ON THE HYDRAULIC RAM.

The invention of this singular engine is due entirely to the genius of the celebrated Montgolfier, who made it known in 1797; the peculiar simplicity of its construction, as well of its mode of action, attracted the attention of hydraulic engineers, and of mathematicians, and in 1804, Eytelwein conducted a series of experiments upon a well digested plan, to develop the power, the proportions, and other relations requisite to its greatest efficiency. The oscillatory motion of the water in the ram, and the alternate action of the valves, indicate the physical causes which produce the effect of this machine; they are nevertheless still very far from being sufficiently understood to furnish the basis of a mathematical theory. The passive resistances, and especially those arising from the shock or blow given by the valves, interpose difficulties in affixing their value, which render any estimate of the *whole dynamic effect* almost impossible. Experiment alone can instruct us as to the *useful* effect it is capable of affording.

D'Aubuisson de Voisins has given a succinct account of the researches of Montgolfier and of Eytelwein, and these notes are chiefly derived from it.

The parts of a ram are, a pipe connecting a reservoir of water with a case or chest containing two valves—an air chamber, and a rising or supply pipe. The pipe attached to the reservoir was by Montgolfier termed the body of the ram, and the valve chest its head. Further description of the construction of the machine and of its mode of action is unnecessary here, as it may be readily found in every modern work on hydraulics.

The largest ram ever erected was put up at Mello, near Clermont sur Oise, by the inventor's son. Its principal dimensions were,

Length of body pipe . . .	108 feet.
Diameter of ditto . . .	4·3 inches.
Weight of ditto . . .	3190 lb.
Weight of head . . .	440 lb.
Contents of air chamber . . .	1½ gallons.

The tail or stop valve consisted of a horizontal metal plate pierced with seven holes, each covered by a hollow ball 1¼ inch diameter; it beats 60 strokes per minute. This ram worked under a head of water of 37 feet, discharging 31½ gallons per minute, and raising 3·85 gallons to a height of 195 feet. The ratio of the useful effect to the labouring force expended was ·653. The comparison of effect is made without taking into account the *velocity* of the motion; it is the weight of water raised to a certain height in a determinate time. Calling p'' this weight, and H'' this height, the effect is $p''\,H''$.

The corresponding force (P being the weight of fluid furnished by the stream in the same time, and H the height of the fall or head of water), is expressed by P H.—The ratio of these is consequently $\frac{p''\,H''}{P\,H}$, or since $p'' : P :: q : Q$, the ratio is $\frac{q\,H''}{Q\,H}$.

The following table shows the ratio and the effect of ordinary rams. The first experiment was made upon the ram constructed by Montgolfier himself, at his house at Paris; the second upon that erected by his son, above cited; and the others upon rams in the neighbourhood of Paris, mentioned in the Traité des Machines, p. 101.

	Height.		Water per minute.		$\frac{qH''}{QH}$	
	Fall. H.	Elevation. H''.	Expence. Q.	Delivered. q.		
1	8' 6"	52' 8	15	1·37	·57	
2	37 ·2	195 ·0	31	3·85	653	Mean ratio $qH'' : QH = ·65$.
3	34 ·9	111 ·11	18½	3·74	651	
4	3 ·3	14 11	437	59·18	·629	
5	22 ·10	190 ·10	2·86	0·22	·671	
	Ft. In.	Ft. In.	Gallons.	Gallons.		

Eytelwein made, at Berlin, 1123 experiments, gradually and successively varying the dimensions of the several parts of the hydraulic ram. He confirmed the effect produced in each case, and deduced rules for the dimensions and arrangement of the parts, suitable to the greatest effect.

The following table contains some of the experiments upon the largest of the rams he employed, in its most advantageous arrangement, viz.:—

Length of body pipe . . .	43 feet 9 inches.
Diameter of ditto . . .	0 2¼
Capacity of air chamber . .	1·94 gallons.
Area of opening of tail or escape valve .	3·74 square inches.
This area in the first experiment was raised to	6·2 square inches.

The valves were clack valves and the escape valve was placed between the air chamber and the reservoir. These experiments may have their result expressed by the following formula,

$$\frac{q\,H''}{Q\,H} = 1{\cdot}42 - {\cdot}28\sqrt{\frac{H''}{H}}$$

But as this has been deduced from experiments which in some measure refer to the maximum effect of which the water ram is capable, we may obtain the ordinary results exact enough by reducing the numerical coefficient about $\frac{1}{4}$, and we get

$$p\,H'' = 1{\cdot}2\,P\,(H - {\cdot}2\sqrt{H\,H''})$$

See D'Aubuisson, p. 503,—also Taffe, Application de la Mechanique, p. 278.

No. of Strokes per Minute.	Height in feet of				Ratio.	Gallons of water per minute.		Ratio $\frac{q\,H''}{Q\,H}$.		Ratio $\frac{Q}{q}$

26	4	6½	32	4	7·2	5·23	0·495	0·672	0·67	10·7
31	5	0	38	7	7·7	8·05	0 704	0 667	0·65	11·54
23	4	1	38	8	9·47	11·11	0 649	0·548	0·56	17·2
17	3	0	32	2	10·7	10·8	0·479	0·473	0·51	22·6
15	3	8	38	8	11 9	12·34	0 363	0 352	0·45	33·8
14	2	6	38	8	15·5	11·95	0 22	0·284	0·32	54·6
10	1	11½	38	8	19·3	9·81	0·088	0·181	0·18	106·6

According to Eytelwein, the length of the body pipe ought *not* to be *less* than $\frac{1}{4}$ of the height to which the water is to be raised. Its diameter in inches, (when Q'' is the number of gallons *expended* per *second*) $= 4\frac{1}{2}\sqrt{Q''}$. The diameter of the rising or delivery pipe should be one-half of this. The air chamber should be as large as the cube content of the rising pipe. The two valves should be close to each other, but it is of little moment whether the escape valve is above or below the air chamber, with regard to the stream of water. The opening of the escape or tail valve should not be less than the section of the body of the ram.

Example.

Let it be required to raise 220 gallons of water per hour to a height of 46 feet; the disposable head of water being 4 feet;—to determine the expenditure of water per second, and the principal dimensions of the ram—

220 gallons per hour = 2200 lb. = 36·6 lb. per minute;

$$36{\cdot}6 \times 46 = 1{\cdot}2\,P\,(4 - {\cdot}2\sqrt{46 \times 4}).$$

$$\text{or, } P = \frac{36{\cdot}6 \times 46}{1{\cdot}2\,(4 - {\cdot}2\sqrt{184})} = \frac{1403}{1{\cdot}29} = 1087{\cdot}6 \text{ lb. per minute;}$$

and 108·76 gallons per minute = 1·81 gallons per second.

Diameter of body pipe $= 4\frac{1}{2}\sqrt{1{\cdot}81} = 4\frac{1}{2} \times 1{\cdot}346 = 6$ inches, nearly.

Length of ditto should not be less than 44 feet,—say 50 feet.

Diameter of rising pipe $= \frac{6}{2} = 3$ inches.

Content of ditto $= \frac{3^2 \times {\cdot}7854 \times 46}{144} = 2\frac{1}{4}$ cube feet = capacity of air chamber.

Diameter of opening for escape valve = 6 inches.

If ball valves are used, their weight should be twice that of the corresponding bulk of water.

D'Aubuisson, p. 504, makes the following important remarks:—"The hydraulic ram has only been employed, hitherto, in raising small quantities of water, and, therefore, in producing small effects. The greatest effect obtained by Eytelwein from 1123 experiments was only 1476 lb., raised one foot in a minute; and the greatest from the rams used in France is but 7500 to 8500 lb., raised one foot in a minute, or about one half the work done by a horse, harnessed in a gin."

It is very doubtful whether the ram can be used for raising large volumes of water. The violent shock of the valves, and the heavy pulsations of the machine, derange the frame and the foundations made to support it. This it has been attempted to obviate by materially increasing the weight of the ram, and in this way the loss of effect arising from the movement of the machine may be diminished, and the evil remedied up to a certain point.

The strong frame-work and heavy masonry, constructed to support large rams, have been entirely destroyed after a certain length of time; and it is much to be feared, that the employment of this engine, in other respects so remarkable, will continue to be restricted, and that its sphere of usefulness will not extend beyond the supply of water to an isolated house or manufactory.

1, Lancaster-place, Nov. 5, 1846. J. H.

STABILITY AND STRENGTH OF HUNGERFORD BRIDGE.

In our last number (p. 358) we published extracts* from some remarks addressed by Sir Howard Douglas to the editor of this Journal, respecting the stability and strength of Hungerford Bridge, and promised to reply to the objections raised respecting the sufficiency of that structure. The objections are chiefly these—that the main chains are not strong enough—that the piers are not sufficiently stable, being liable to horizontal strains at their summits, which the shifting saddles do not entirely remove. The first point which we will consider is

The Instability of the Piers.

It is asserted that, owing to the difference of the form, &c. of the catenaries on either side of each pier, its head is subject to a force, tending to overturn it, which is represented by $a - a'$, where a and a' are the horizontal tensions of each catenary respectively.

Now this horizontal force $a - a'$ acts upon the shifting saddle. Let us consider the object of this contrivance. If it recede (that is, move towards the bank of the river), it increases the span of the centre chain and dimi-

* In order to make the extracts more complete, the following words ought to have been inserted, after the word "destroyed," which concludes the sentence referring to the diagram, "And these unequal strains which exist even when the bridge is at rest, are greatly increased by the vibrations to which it is subject, and particularly by the action of storms of wind. Unless the error be extreme, these unequal strains may not be productive of immediate disaster, but they are constantly acting, and by so much they aggravate the defects which have been pointed out as attaching more or less to all suspension bridges. Applying the above diagram to an accurate elevation of the bridge, and producing A D till it meet the horizontal line at the base of the pier, we may see to what extent the stability is endangered, and it is evident that beyond a certain point, the strain at the head of the pier would cease to be supported in the direction of the resultant A D. Seeing that this error has in point of fact been committed on several occasions, in constructing suspension bridges—that insecurity and failure have ensued—that in one instance which proved fatal, the error was of such magnitude as to make the angle on one side of a pier 71° 28', and on the other 56° 50', and that a very considerable error of this description exists in Hungerford Bridge," &c.

nishes its deflection:—*both* these alterations tend to increase the horizontal tension of the middle chain. At the same time it tends to diminish the span of the side chain and increase its deflection:—*both* these alterations tend to diminish the horizontal tension of the side chain. So that on the whole, if the horizontal tension of the side chain exceed that of the middle chain and the shifting saddle recede, there are *four* causes in operation to establish equality of tension. Conversely, if the horizontal tension of the middle chain exceed that of the side chain, and the saddle *advance*, there are four causes in operation to establish equality of tension.

But there are two ways by which the establishment of this equality may be prevented. Either the friction of the saddles on the piers may restrain them from moving, or a sufficiently large range of motion may not have been provided for in the construction of the bridge.

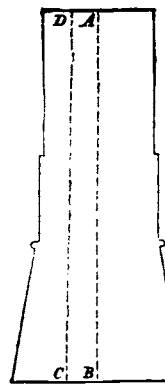
Let us consider first the effect of friction. By reference to the last volume of this Journal, p. 165, it will be seen that between the saddle and the top of the pier a number of rollers are interposed in such a manner that the friction is wholly of the nature of *rolling* friction: there is no *rubbing* friction, such as that at the axle of a wheel, or the pin of a pulley. It is known by experiment that rolling friction is exceedingly small, almost inconsiderable, compared with rubbing friction.

From experiments by Babbage, it would appear that weights placed on wooden rollers, 3 inches in diameter, can be moved with $\frac{1}{10}$th of the force required to move them when placed on wooden sledges. The friction of metallic rollers is a subject which, notwithstanding its importance, seems to have been greatly neglected. Of all the laborious and careful experiments upon friction which have been instituted by numerous investigators, comparatively few relate to rolling friction.

The rolling friction of any material depends not so much on its smoothness as upon its hardness: for it principally arises from the slight flattening of the roller where it is in contact with the plane, and the slight depression of the plane itself. Now in the shifting saddles of Hungerford Bridge these causes must operate very slightly, for each saddle rests upon 60 rollers placed almost close together and arranged in an ingenious manner so as to work with the utmost regularity. As we said, however, little more than a rough estimate of the friction can be arrived at; but we think that an inspection of the saddle itself will instantly satisfy any one that the coefficient of friction cannot be nearly so great as in a railway carriage. Now the friction of a railway carriage is about $\frac{1}{400}$th of its weight. This friction consists of two parts: the rolling friction at the circumferences of the wheels, and the friction of the axles. These axles are about half the diameter of the rollers at Hungerford, and the rubbing friction of the former must greatly exceed the rolling friction of the latter. Moreover, in the railway carriages the axle friction is only a part of the resistance, and therefore would be represented by a smaller coefficient than $\frac{1}{400}$; the roller friction of Hungerford Bridge would be represented by a still smaller coefficient. If then we make the friction on each saddle half the friction of railway wheels, or $\frac{1}{800}$ of the weight, we probably shall have considerably over-estimated it. Now the total weight on each pier will be scarcely 800* tons, supposing the passengers packed together as closely as they can stand, (a most improbable supposition.) In this case the utmost resistance to the motion of the saddle will be less than a ton. Consequently, if the "power represented by $a - a'$" exceed 1 ton, the saddle will begin to adjust itself.

It is impossible to suppose that masses of brickwork such as those which form the piers of Hungerford Bridge can be overthrown by a force of one ton. We believe, however, that we have greatly over-estimated the amount of this force. In addition we must remember that the vertical pressure on the pier has an effect as well as the horizontal, and that the former tends to the stability of the pier. In the extracts given, ante p. 358, there is a diagram in which the line A D represents the magnitude and direction of the resultant of the forces acting on the head of the pier. Let us suppose the diagram slightly altered, by constructing a parallelogram in which the *vertical* and *horizontal* pressures, instead of the tensions of the chains, are represented. Then A D represents the resultant of those pressures, and it is the diagonal of a parallelogram, of which the sides are in the proportion 1 (ton) : 800 (tons). We see then how extremely oblique is the direction of A D. If when produced it fell with the base of the pier, the pier would be stable, even if it had no weight, and the mortar no cohesion.

To illustrate this important point a little more fully, let us actually construct the diagram. Let A B C D be the parallelogram of the forces



applied by the saddle to the top of the pier, and let A B be the resultant of the *vertical* pressures exerted by the rollers: this resultant will always be somewhere near the centre of the tower. Let A D represent the horizontal friction of the rollers: then the diagonal joining A and C will represent the direction and magnitude of the resultant. Now, B C is only $\frac{1}{800}$th part of A B, and therefore, since the pier is 80 feet in height, the diagonal A C will, at the base of the pier, be only the $\frac{1}{10}$th of a foot out of the vertical. The base of the pier is 40 feet wide. If, therefore, the position of A B be supposed to be exactly central, the friction or horizontal force must be *two hundred times* what we have supposed it to be, before the resultant can fall beyond the base. If we take into account the effect of the weight and cohesion of masonry itself, the horizontal force must be still further multiplied, before the stability of the pier can be endangered.

Limits of the Motion of the Shifting Saddle.

The next point to be considered is, whether the motion of the shifting saddle has a sufficient range. We think that it may be satisfactorily shown that the saddle has ample room to adjust itself to any variation of the horizontal tensions of the chains which is likely to occur. It is difficult, in a subject so complicated as the theory of catenaries, to work out general solution of the problem; a little attention, however, to the case before us, and an allowable simplification of it, will furnish all the information required.

Let us first see the effect of a slight diminution of the span of the central chain, everything else remaining unaltered. In the tract on "Metropolitan Bridges," p. 10, the following useful approximate relations are given:—

$$2x^2 = 3y(s - y) \ldots\ldots (1) \qquad a = \frac{3y^2 + x^2}{6x} \ldots\ldots (2)$$

where s is half the length of the chain, y the half-span, x the deflection, and a the length which measures the horizontal tension. In the case of the Hungerford Bridge (supposing the curve to be a common catenary), the values of these quantities are—

Half the central span, y	338·25 feet.
Deflection, x	50·
Half length of the chain, s . . .	343·
Length measuring horizontal tension, a .	1152·5

where the first two quantities are found by actual measurement, and the two latter are those calculated by Sir Howard Douglas from his formulæ.

Now let us suppose the half-span to become 337 feet—that is, to be diminished by 1½ foot; and the length of the chain being unaltered, let us see what will be the new value of a. By equation (1),

$$2x^2 = 3 \times 337 \times 6\text{; or, } x = 3 \times \sqrt{337}.$$

Therefore, by equation (2),

$$a = \frac{3 \times (337)^2 + 9 \times 337}{6 \times 3 \times \sqrt{337}} = \frac{1}{6}\sqrt{337} \times (337 + 3) = 1054 \text{ feet.}$$

It follows, therefore, that by the small diminution of the span here supposed, a very great alteration of the horizontal tension is produced—namely, from 1152 to 1054, or in a ratio of about 11 : 10. The length a indicates not the actual value of the tension, but its proportion to the weight of the chain. Hence, whatever proportion the horizontal tension bore to the weight of the chain in the first case, it would bear $\frac{10}{11}$ths of that proportion in the second case. Now, in the construction of the Bridge, provision has been made for giving the saddles on each pier a play or range of three feet. And we have made the case far too unfavourable for our own view of it; for we have neglected the consideration that, when the saddle moves, the horizontal tension of the side chains is increased at the same time that the horizontal tension of the central chain is diminished. So that the adjustment would take place much sooner than has been here supposed.

The adjustment neglected in the above calculation is by far the most important in point of magnitude. For a variation of span would not nearly so much alter the tension of the main chain as that of the sides chains, of which the curvature is very small. The latter are stretched almost in a straight line between their points of attachment, at the banks of the river and the top of the piers. So that it may be doubted whether an increase

* The total weight of the centre chain when loaded is 1000 tons. One-half of this weight presses each abutment, and 300 tons more may be added for the side chain.

of their span much beyond a foot, would be geometrically possible if the length of these chains be supposed constant. We know that if the chains were absolutely straight, their tension would be infinite, and as an approximation to the straight line must produce an enormous increase of tension, there need be no fear that the range of the saddles of Hungerford Bridge would be insufficient for the requisite adjustment.

Approximations similar to those used above would scarcely be suitable for calculation of the variations of the side chains, of which the tension alters so rapidly for slight alterations of span that the approximate expression must be continued to a much greater number of times to be at all satisfactory. This objection does not however obtain respecting the main chain, in which the variations of tension are not so rapid.

We have also followed Sir Howard Douglas in assuming the chain to be a common catenary, and the load to be distributed uniformly along the curve. These suppositions might be dangerous, if the strength of the chain were being discussed, but for the purpose of estimating roughly the effect of variations of the span, they seem sufficiently accurate. We may as wel remark that the calculation of the strength of the main chain, which is quoted in the last volume of this Journal, Vol. VIII, p.65, is exceedingly incorrect and unscientific.

In the tract on Metropolitan Bridges, and in the Reply to our remarks, several analytical difficulties have been suggested which certainly appear to militate against the conclusions here arrived at. These difficulties are not however insuperable, as the consideration of the following passage, which we quote from the original pamphlet will show.

"In the case of the Hungerford Bridge, however, the catenaries at the two ends when completed, have a considerably less span than the central curve, but they have the same droop or deflection. Hence if $2y$ be the span of the centre arc, $2y'$ the span of the curves at the two extremities when completed; and a, a', the corresponding tensions at the lowest points, we have

$$a = \frac{3y^2 + x^2}{6x} \qquad a' = \frac{3y'^2 + x^2}{6x}.$$

And as y' is considerably less than y, a' will evidently be less than a in a still higher ratio. Hence there will be a constant horizontal strain, equal to $(a - a')$ acting at the top of each pier."

The supposition that the side chains "have the same droop or deflection" as the central chain, is a misapprehension as to a point of fact—they have a considerably greater deflection. Hence in the second of these equations we must put for x, a larger quantity x'. This correction is a satisfactory solution of the difficulty suggested. The extracts quoted last month from the Reply, contain the following clause in the sentence explaining the diagram.

"If the tangents of the curves formed by the heads of the piers do not make equal angles with the vertical line A V, even if the tensions of A B, A C, were equal (which is not the case in Hungerford Bridge), the resultant of the strains at A would be in the direction of a line A D," &c.

It seems to have been overlooked that the fact alluded to in the parenthesis, and the fact suggested just previously, are of a compensating nature If there be an inequality, not only of the amount of the two tensions, but also of their angles of inclination, the resultant *may* be vertical—if only one of these inequalities exist, the resultant cannot be vertical.

To Sir Howard Douglas belongs the merit of having suggested for discussion a subject of great interest to engineers and the public generally; and of having considered the question in that purely argumentative manner which always ensures respect in a scientific controversy. He will, we are sure, give us credit for having the same object in view as himself—that of ascertaining the truth; and if our reasoning should appear erroneous, we shall be quite ready to be set right. Of the strength of the main chains of the bridge we have not as yet said anything, as we are not in possession of all the data. These however are promised to us, and a separate paper on this part of the subject shall, if possible, appear in our next number.

AMATEUR ENGINEERING.

The English Government is distinguished from those of other countries by its reluctance in assisting or rewarding the efforts of mechanical inventors. There is no doubt that from the operation of this rule many valuable discoveries are lost to the country, which has a direct interest in promoting those scientific labours which tend to the benefit of the whole community. At the same time, it is certain that an indiscriminate encouragement of inventors would subject the country to an overwhelming number of claims on the behalf of futile immature and valueless schemes.

The restrictive rule observed by our Government is however occasionally relaxed, and it happens, unfortunately, that the occasions chosen for this relaxation are those where the least benefit results to the country, and the consideration shown to favoured individuals is least deserved. We allude to public encouragement of amateur ship-building and marine engineering. It would be invidious to point out all the instances in which the public money has been recently squandered in constructing war steamers upon plans suggested by persons whose occupations and previous studies by no means qualified them for the task undertaken by them. Of course the inventors themselves stoutly deny the failure of their plans, and can overpower us with proofs of their success; but the professional engineer will immediately recall numerous instances in which persons possessed of Parliamentary influence, or the advantage of titles to the peerage, have been able to waste many thousands of pounds of public money in the manner alluded to. We may, however, take one instance where failure has been so obvious that denial would be impossible. The *Sidon*, the offspring of Sir Charles Napier, was intended to have been a lesson to all future engineers; and such indeed it has proved—in the way of salutary warning.

If it be determined that the rule of discouraging inventors is to have exceptions, they ought not surely to be so selected that the possible failures shall be productive of the *greatest* amount of loss. Judging *à priori*, we might suppose that naval construction on which the strength of Great Britain depends, and of which the operations are necessarily of the most costly kind, would be the very last branch of the industrial arts chosen to be subjected to the experiments of inexperienced amateurs. We might suppose that the building of steam and other vessels of war, involving as it does, in every case, a vast expense to the country, would be conducted with the utmost caution, and would be intrusted solely to careful and experienced hands. It would seem a matter of common prudence that if amateurs must be encouraged in their taste for practical mechanics, they ought to try their 'prentice hands on some work a little less costly than ship building.

But the Government is not alone responsible for the errors in question, which have been largely participated in by companies of private individuals. A clever busy man, with a good deal of intrigue and energy, may often get up a company, which he can coax into an encouragement of his own private schemes, or those of the *clique* to which he belongs. The *Great Northern*, built at Londonderry, by some one who, from modesty (or more probably. from prudence), has not trumpetted forth his name, was to have been a model of Irish steamers for English engineers; but alas, turned out but ill The restorative applications of London engineers—Miller, Ravenhill and Co., were found requisite *intus et in cute* before the unfortunate victim of mechanical dabblings could be brought to a state of vigorous healthy action.

The *Great Britain* again was a woeful example of amateur patchwork. The public were invited to inspect and admire this gigantic specimen of ship-building; and attracted by her magnitude and showy decorations, they inspected and admired accordingly. Could a promiscuous crowd of visitors be supposed likely to scrutinise the proportions of the engines, the size, shape, and arrangement of the small and inconspicuous parts, and all those *minutiæ* which, as the professional engineer knows, constitute the excellence or worthlessness of a marine engine? The history of this vessel has been a series of unfortunate mistakes from beginning to end. First, she was built in docks of which the opening was too narrow to permit her exit. The chrysalis grew and increased in stature, and when the time came for quitting its wingless state, and going forth freely into the world, was found unable to emerge from its integument. However, these difficulties, the result of gross bungling, were at last got over. But the troubles had only just commenced. The engines were found to be—what engines might have been predicted to prove, which were constructed by men who had never undergone the discipline of an engineer's workshop. Professional engineers were again called to the rescue, and this time, Mr. Field, of the firm of Maudslay and Field, was the re-operator.

At present, the Great Britain lies upon the coast of Ireland, beaten and buffetted by the wind and tide. No one knows how she got into her presnet position; this, like all her previous adventures, has the charm of mystery about it—a mystery which baffles human penetration. There is a convenient complexity about the story, which averts condemnation by puzzling the judgment. Bristol charts not drawn as they ought to be, the Isle of Man appearing where it ought not to be, the captain's notions of time and space, the advantages of an untried course to the north of Ireland, the directors complaisance, and barrels of gunpowder placed behind the vessel to blow her—not up—but off:—these are the materials of the story; of which the only certain part is the event—namely, that the Great Britain lies ashore in

Dundrum Bay, beaten and buffetted by wind and tide, as aforesaid, and that she is reserved for further amateur experiments.

As no lives have as yet been lost in these experiments, one would not grumble at their having been carried on with a view to the advancement of practical science, if they had been conducted with some regard to economy. But what is chiefly to be complained of is, that experience has been purchased at so dear a rate. Fifty thousands to a hundred and twenty thousands of pounds are not trifling sums to pay in experimenting. Are we to suppose that engineers like Watt, Maudslay, Miller, Seawards, Penn, or Napier, acquired in a day the experience necessary for the construction of marine engines of from 500 to 1000 horse power? A man must flatter his inventive talents most outrageously if he supposes that they can compete against the *accumulated* knowledge of others, who, even if for argument sake we suppose them greatly inferior in individual capacity, have yet been working together for years in the same pursuits. It is impossible to imagine that the abilities of one man can ever so greatly surpass those of the rest of mankind as to enable him to contend against the long-continued and *co-operating* efforts of his fellow labourers. We do not wish to give to experience more than its due share of merit; but it is obvious to every one who knows any thing of marine engines, that the most profound scientific knowledge, and the most brilliant inventive talents, will not alone constitute a practical engineer. Long, laborious, even painful, experience must be superadded.

That every man is to be trusted in his own art—*cuique in suâ arte credendum est* is a proverbial expression, and like other proverbial expressions involves both truth and falsehood. The man who is constantly in practice of the technical rules of his profession, and who trusts to his experience alone, will frequently become the slave of routine. He has got into fixed habits of thought—like the mill-horse he can only go his round: and a valuable idea which would occur to a mere bystander may be overlooked by him. The extra-professional suggestions of clever amateurs or men of science are not discouraged: and the professional superciliousness with which such suggestions are frequently met is destestable. But there is a great difference between encouraging the suggestions of inexperienced persons, and suffering such persons to carry out their ideas independently of professional control; especially when the works undertaken are of such magnitude as the *Sidon*, the *Great Northern*, or the *Great Britain*.

THE NEW PLANET.

The dispute respecting the discovery of the new planet is likely to be brought to a satisfactory termination. At a meeting of the Astronomical Society, held during the last month, the Astronomer-Royal read a paper, tracing the investigations from the commencement, and distinctly assigning to Mr. Adams his priority of right and title to the discovery. Professor Airy has been in correspondence with both M. Le Verrier and Mr. Adams, and his paper was supported throughout by original letters and other authentic documents, of which the dates are indisputable. He allows fully to M. Le Verrier the merit of having performed his investigations independently, and of having, in the first instance, announced his results in a more public manner than Mr. Adams. The latter contented himself with depositing in the Greenwich and Cambridge observatories the calculations necessary to facilitate the search for the planet with the telescope.

It is very important to remark, that the calculations of Mr. Adams were not only the earliest, but by far the most ample and recondite. M. Le Verrier contented himself with publishing last June the heliocentric longitude of the planet. *In addition to this*, Mr. Adams announced its *mass*, *longitude of perihelion*, *and eccentricity* — infinitely more difficult and complicated investigations than those to which M. Le Verrier restricted himself. No one would wish to detract from the merit of the latter, but to compare his labours with those of his scientific opponent would be ridiculous.

It is very gratifying to learn that the paper read by the Astronomer-Royal, and Mr. Adams's investigations, are about to be published. The world will then have the opportunity of examining the two independent investigations. Men of science will confine themselves to the examination of them on their own merits, irrespectively of all considerations of the time when they were made, and we doubt not that even the French philosophers will allow the superiority, in this respect, of the claims of the Englishman. The publication of the paper read by the Astronomer-Royal will also confirm, on the highest authority, the assertion made in these pages last month, that Mr. Adams's claims were prior in point of time, as well as intrinsic merit.

The opponents of this view of the question are now shifting their mode of attack—a sure sign that they are losing ground. They say that the announcement to the French Academy was *more public* than that to the English astronomers, and that according to a conventional rule in these matters, the discovery belongs to him who makes his announcement in the most public manner. But what more could be required of Mr. Adams than that he should deposit his results in the principal public observatories of Great Britain? He made known his discoveries to the Astronomer-Royal, and through him to the whole body of English astronomers—Sir John Herschell, for instance, was perfectly aware of Mr. Adams's investigation, though the information reached him in no other way than through the Greenwich observatory. Besides, the papers were deposited in the very places where alone the requisite telescopic observations could be undertaken. Had Mr. Adams the least suspicion that any attempt would be made to wrest his rights from him, he might, with the greatest ease, have precluded the attempt effectually. The French Academy may hug their self-conceit, and extol M. Le Verrier for having flattered it by addressing his communication to them; but let them not accuse Mr. Adams because he has not imitated this course, but acted more soberly and quietly. The publication made by him was quite sufficient for all *useful* purposes—not quite sufficient, it seems, for show and ostentation.

Many great mathematical discoveries have heretofore been communicated in a far more private way, and yet the claims of the discoverer remain incontestible. John Bernoulli first announced the general principle of Virtual Velocities in a private letter to Varignon. Is therefore the merit of his discovery the less because he stated it through the medium of ordinary correspondence? The different modes of making a discovery known are comparatively trifling; and certainly if in the case before us a comparison must be made, it results in favour of Mr. Adams, who chose the method most advantageous—not to his own fame—but to the interests of science.

There is one consideration however which may perfectly satisfy us in all these disputes. Whatever discussion may now exist as to the proper *conventional* method of making known a discovery, posterity will concern itself little in a debate so trifling and artifical. Future generations of philosophers will be more anxious to know the author of the discovery, than the *etiquette* which ought to be observed on the occasion. These foolish ephemeral quibbles will be forgotten with the authors of them; and the great sterling fact will alone remain, that our countryman was the first man in the history of the world who looked into the firmament with prophetic sight, and discerned there a new world—weighed it, measured it, and traced the course of it, while as yet unseen by human eye.

One of the magazines speaks of Mr. Adams as an under-graduate! It is provoking that these "scientific journals" do not confine themselves to subjects of which they know a *little*. Mr. Adams took his degree as senior wrangler, is fellow and lecturer of St. John's, and the University moderator for next year.

The following may be relied upon as an accurate sketch of the history of Mr. Adams's labours. We should not perhaps be justified in stating the authority for this statement, but the reader may be assured of the accuracy of the dates. The resolution of endeavouring to account for the perturbations of the motion of Uranus by the action of another planet, was first formed by Mr. Adams in the year 1841; and it appears, from memoranda, that finding, in the summer of that year, the labour of calculation to be so great, that, if undertaken at that time, it would seriously interfere with his academical studies, he resolved to defer, until after taking his degree, the investigation which was to determine approximatively the place of the disturbing planet, and thus assist astronomers in discovering it by actual observation. In the course of 1843 *(three years ago)*, the first approximation to the place of the planet was arrived at by Mr. Adams, and the calculations, though comparatively rough, were sufficiently close to satisfy him that his hypothetical explanation of the anomalies in the motion of Uranus was a correct one. In February, 1844, having obtained from the AstronomerRoyal the observations made at Greenwich since 1781, he renewed the investigation of the problem, and this time rendered it much more complete than before. Several solutions were obtained, differing but very slightly from each other; and by successively taking into account more and more terms of the series expressing the perturbations, first in April, 1845, again in May, and finally in September of that year, the ac curate solution of this wonderful problem was at last obtained, and was immediately communicated to Professor Challis, and in the following month to the Astronomer-Royal. Both Professors were therefore in possession of the perfectly complete solution upwards of a year ago.

MOVEABLE JIB CRANES.

Remarks on the utility and defects of the Moveable Jib Crane, according to the construction now generally used in Glasgow, with proposed Improvements to obviate its defects. By William Gale, Glasgow. ***Read at the Institute of Civil Engineers. (With Engravings, Plate XIX.)***

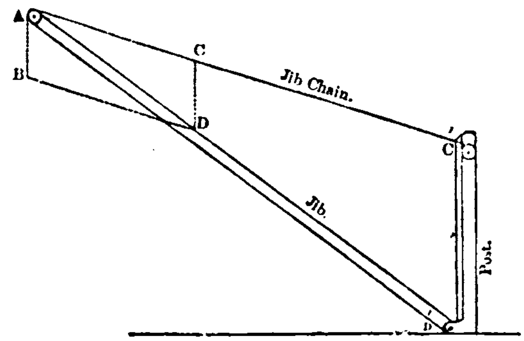
The author's attention having been recently drawn to an examination of the causes of numerous accidents (many of them attended with fatal consequences) during the erection of some of the public buildings in Glasgow and the neighbourhood, he found that one of the most fruitful sources of these accidents was the defective construction and injudicious use of the moveable jib crane. This crane, it may be remarked, has nearly superseded all others used by builders in Glasgow, and is at present employed at most of the public buildings in course of erection. It has, however, undergone material alterations since its introduction by Francis Watt upon Mr. Stevenson's works, during the erection of the Bell Rock Lighthouse; but while undergoing these modifications and changes to suit convenience, the principle of construction has undergone a change, which has increased the strains to a very considerable extent.

As originally constructed, the post or upright *a* was from 20 feet to 30 feet long, the jib *b* being of about the same length; the upright was supported by gye-ropes or chains, similar to the mode usually adopted in quarries; but at present the post is reduced to 15 feet in height, and the jib is extended to 50 feet in length, whilst the inconvenience or rather impracticability of getting the gyes fastened in many cases, such as in erecting street buildings or quay walls, where there is a great traffic, led to the substitution of the two arms *c*, *d*, and the framing (Plate XIX. fig. 1); and, in order to prevent it upsetting, the framing is loaded with stones, or other heavy materials, or when placed on the upper stories or roof of a building, which is frequently done, the framing is lashed down with chains to some fixed points beneath. It will at once appear evident that this alteration in the construction, by shortening the post or upright *a*, and lengthening the jib or derrick *b*, must have increased the strain on the jib chain to an enormous extent, and in many instances the accidents occurred from the snapping of the chain.

No one who has seen this crane in operation can call in question its great utility to the builder, on account of the expedition and ease with which heavy blocks can be bedded over a considerable extent of front, without moving the position of the crane after it has been once fixed down; but the point to be objected to, is the great amount of strain thrown on the jib chain, even with moderate weights attached, when the jib is worked at a great inclination from the perpendicular, and when it is considered that a weight of 4 or 5 tons is frequently suspended from it, it is certain that if builders were only made sensible of the risk, they would be more scrupulous in hazarding the lives of those under their charge, and fewer accidents would be heard of.

From what has been stated it will be obvious, that the total strain thrown on the jib chain depends upon various causes. 1st, The length of the jib. 2nd, The height of the post. 3rd, The inclination of the jib. 4th, The weight attached. 5th, The proportion of weight due for the jib itself, with its mountings and chains; and 6th, The friction. Aware of the danger of trusting to theory alone, in making an accurate investigation into these sources of strain, the author had recourse to a variety of experiments, by model, being at the same time sensible of the fallacious nature of the results deduced therefrom, unless increased size and weight, and consequently increased leverage and friction, were all accurately calculated and allowed for. After numerous experiments, however, it was found, that a near approximate agreement took place betwixt the results brought out by the model and those deduced from theoretical investigation for the full-sized machine.

In the theoretical investigation of the question, the weight to be raised being known (which must include the proportion of weight due for the jib, &c., along with that due for friction), it is only necessary to apply the parallelogram of forces in the usual way, in order to obtain data whereby to ascertain the strains; thus if A B represent the total weight, B D = A C gives the strain on the jib chain, while A D represents the strain on the jib. Or if C′ D′ represent the total weight, A C′ and A D′ respectively represent the strain on the jib chain, and the jib or derrick.



Keeping in view, that the great utility of this crane, for street erections, consists in its having a long jib and short post, it became an object to improve the acknowledged defective part of the machine, the jib chain, not by adding strength to the chain itself, which had already been done by builders, until it was rendered quite inapplicable for winding round a barrel of 8 or 9 inches in diameter, but simply by introducing a pulley between two rods of iron, bolted to the point of the jib *b*, as shown in Plate XIX., figs. 1 and 2, and having the end of the chain attached to the top of the post or upright *a*, instead of attaching it to the point of the jib. A mechanical advantage was thus gained, and a much lighter chain than had hitherto been used, could with safety be adopted. The loss of speed was more than compensated by the increased ease with which the jib could be worked; but speed in this part of the crane was of little importance, as the jib was generally placed at the required angle, or nearly so, before commencing to raise the block. This is the chief improvement, which it is intended to suggest where this description of crane may be found suitable. It is preferable also to increase the diameter of the pulleys from 10 or 11 inches to 18 or 20 inches. The importance of using large pulleys does not, however, seem to be sufficiently appreciated by the builders, otherwise they would not allow their machines to be fitted up with smaller ones. Lastly, the friction caused by the angle of the jib chain, after passing the pulley in the post to either side of the barrel of the wheel and axle, may be obviated to a considerable extent, by confining the chain to a barrel of from 20 to 24 inches in length, (fig. 3.)

The strength of chain necessary for working the jib of this crane will depend on the nature of the work, but for general purposes a chain made of the best iron, $\frac{5}{8}$ths inch or $\frac{11}{16}$ths inch diameter, will be found amply sufficient.

As some builders might prefer using a rope instead of a chain for working the jib, the back view of a crane (fig. 3), and the jib head (fig. 4), are shown. Two pulleys are introduced at the end of the iron rods, the other end being bolted to the end of the jib, as in fig. 1, and a third pulley is fixed to the top of the post. The rope is fastened to the barrel of the wheel and axle, thence it passes over a pulley fixed on one side of the post, and then over one of the pulleys at the end of the iron rods; it then returns to the pulley at the top of the post, and passing over the other pulley at the rods, returns to that fixed on the other side of the post, and is fastened to the barrel of the wheel and axle. Thus there is one continuous rope, equally strained by means of the pulley at the top of the post. By having also the barrel of the wheel and axle divided into two compartments, as shown in fig. 3 (back view), the one compartment being about two inches larger in diameter than the other, the whole of the pulleys will be set in motion when the jib is working. The rope necessary to work this crane may vary from $1\frac{1}{8}$ to $1\frac{3}{4}$ inch in diameter, according to the weight of the materials used, and it would be preferable to a chain, where this construction is adopted. Fig. 5 is another view of a jib head, showing the attachment of the rope and pulley to the jib head. The scale of Fig. 1 is drawn to a scale of 10 ft. to $\frac{3}{8}$ of an inch, and the remainder of the figures double the size.

WARPING HAULAGE ON CANALS.

A new system of haulage has been tried for the first time in this country on the Regent's-canal, through the tunnel under St. John's wood, Paddington. It is the invention of Captain Beadon, and is said to have completely succeeded. We have some impression that a similar system has been adopted in America for passing up the rapids. That does not detract from its merits, but otherwise, proves that the invention is a practicable one. The plan consists of a steam tug-boat and ropes, as shown in the annexed engravings. Fig. 1 is a side view, and fig. 2 a plan view, of a vessel fitted with steam power and the haulage ropes.

A A engine and boiler, B C two reels or cylinders, carrying wire ropes D and E, passing out fore and aft of the said boat. These reels have in front of them guides to regulate the wire ropes in winding up, and passing off such reels, and they are connected with the driving shaft of the engine by endless chains, shewn in fig. 2, and are placed in the boat fore and aft the engine and boiler. Each reel contains six miles of wire rope, which is alternately laid down in the bottom of the canal. The ends of these ropes are attached to the reels, and the two other ends of such ropes are fastened to posts in the canal banks; and when the one, say the rope D, is wound up, the entire working end of the other, E, is down in the canal. The reels are thrown in and out of gear by the reversing motion of the engine.

Fig. 1.

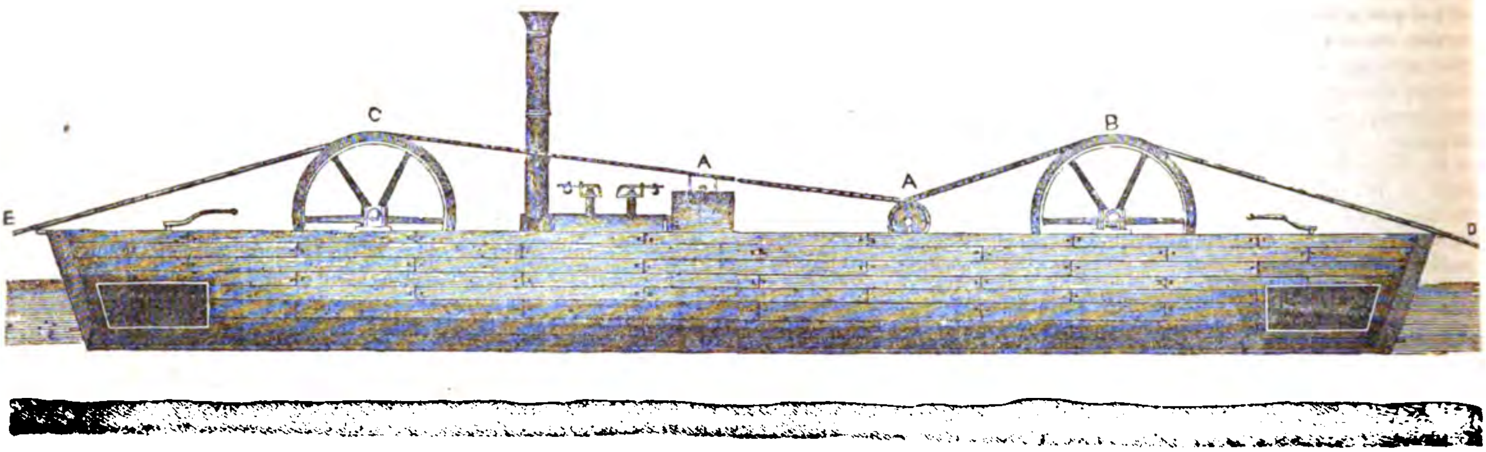


Fig. 2.

The action of the boat is as follows: the reel C is thrown out of gear, and the reel B into gear, the engines are set in motion, and the cylinder or reel B revolves and winds in the rope D, whilst the cylinder or reel C being out of gear with the engine, is free also to revolve, and does so by the traction of the rope E, which is thus gradually delivered down into the canal as the boat proceeds along. As soon as the boat arrives at the end of the rope D, the engine is reversed, the cylinder or reel B is thrown out of gear; this then begins to wind the rope A, and the cylinder B to deliver the rope D; so that, in fact, by simply winding in and out of the two ropes is the boat propelled along backwards or forwards six miles each time.

To tow barges or boats along, they are attached by a tow-rope to this boat, and proceed with it to the end of its rope or station. They are then disconnected from the boat, and attached to another similar one, and taken other six miles, and so on to the end of their journey. The canal is thus divided into a series of stations, having tug-boats to start at appointed times, so that boats, as they arrive, are forwarded with regularity.

RAILWAY CURVES.

Sir,—At the time I handed you the sketch and description of my instrument for simplifying the tracing of railway curves on the ground, and published in your Journal for November, p. 332, you called my attention to a method suggested by your correspondent, "*An Engineer out of Employment*," in the Journal for October, p. 300.

Where the extremities of a chord line have been already ascertained and given, and seen, there can be no doubt of the simplicity and accuracy of your correspondent's method, provided the localities be suitable for its execution. Indeed, I am much inclined to think that, under those circumstances, it is superior, being less complex, to any other method I have met with.

I would suggest that it is better to avoid referring to tabular information; but to be as independent of it as possible. The *versed sine* of any arc may be readily found, where the radius and chord are given, by the 47th problem of the First Book of Euclid:—From the square of the radius deduct the square of half the chord of the arc, and the square root of the difference deducted from the radius, will give the versed sine, or offset, for any segment. After this, the time and trouble of chaining the whole length of the chord of half the arc may be saved, for it will be found to be equal to

$$\sqrt{\tfrac{1}{4}\,(\text{the chord of the arc})^2 + (\text{versed sine})^2},$$

so that only the half of it will be required to be measured; and, at this point, its versed sine may be found as in the whole arc; that is—From the square of the radius of the whole arc, deduct the square of half the chord of half the whole arc; and the square root of the difference, deducted from the radius of the whole arc, will be equal to the versed sine of half the arc; and so on, *ad infinitum*.

The chief object I had in view, in recommending the use of my instrument, was its applicability, almost, I may say, under any circumstances. When obstacles occur, for instance, the tangent may either be made to work past them, or to stop short of them, &c.; a new calculation will of course be requisite to be made at each alteration of the tangent, but that can very soon be done. Another advantage is, that it does not require to see further than the length you choose, or find it convenient to make the tangent.

Wm. Tait.

Military Library, 30, *Charing Cross.*

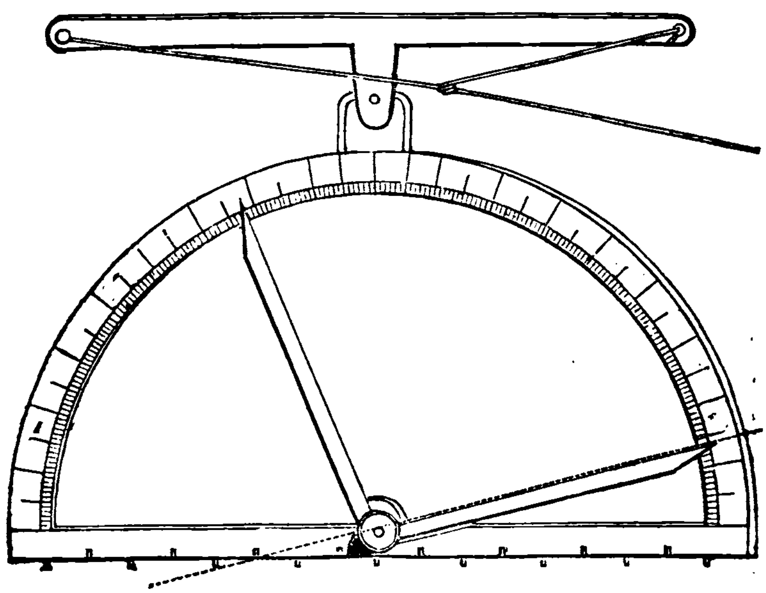
N.B.—In the description of my "Curve Tracing Instrument," "*a b*" is used for *c b*, and "effect" for *offset*.

EARL'S GONIOMETRICON.

(Registered by Mr. George Earl, *School of Design, Peckham.**)

The great recommendation which this instrument has received from the *Pictorial Times* induces us to lay it before our readers. We doubt not it will be found to be a very serviceable appendage to the travelling architect. The following is a description of the instrument as given in the above journal.

Fig. 1.



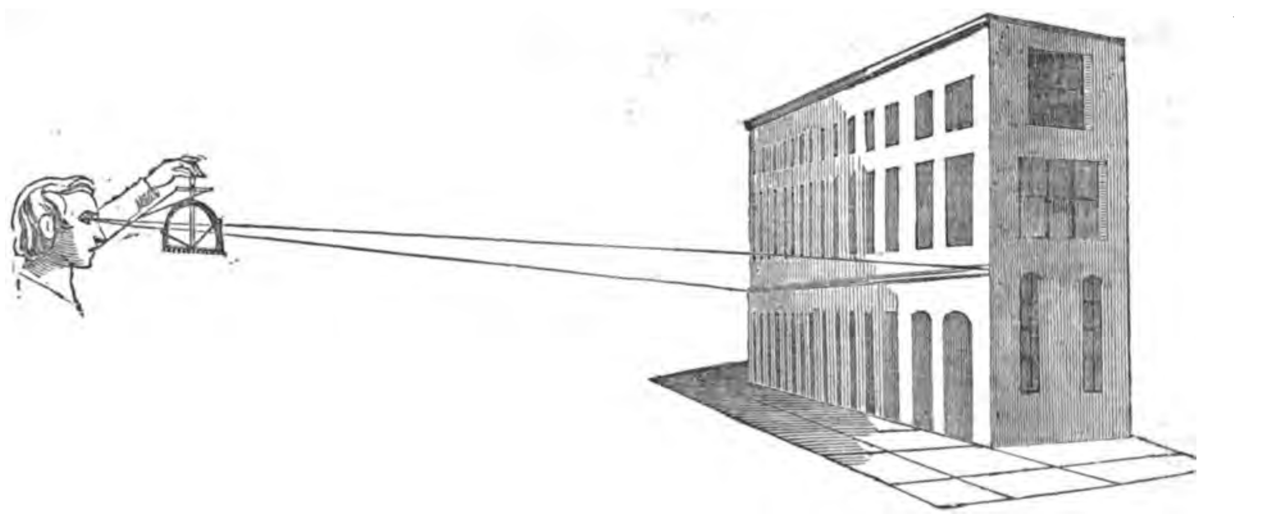
"This neat, elegant, and portable delineator has been contrived to enable persons unskilled in drawing to find the perspective direction of the vanishing or receding lines of objects. This it does with an ease and accuracy which is almost fascinating. All practitioners, and persons in the habit of sketching architectural or other complicated views, know the extreme difficulty of getting the leading lines of the picture projected with accuracy, and how easily the subordinate parts fall into their places when once these are obtained. This difficulty the goniometricon obviates, and with its assistance the most uninitiated may hereafter master the art of drawing in correct proportionate perspective. The mode of using the instrument is thus described by Mr. Earl:—Place the instrument between the eye and the object to be outlined, which is done by holding it with the finger and thumb of the left hand, at a point between the top of the arc and the universal joint. It is then fixed in that position at an angle of 60 degrees with the line of vision, a task accomplished by taking a small ivory acorn attached to the instrument by a string, and placing it firmly between the teeth, when the connecting string is stretched to its fullest tension. This done, the instrument is moved till one of the indicators (which in the cut looks like the hand of a clock,) coincides with the line whose downward or upward direction it is sought to ascertain. That point discovered, the instrument is laid flat on the drawing-paper with the horizontal bar parallel with its lower line, and gently moved to the required position, when the line of direction is ruled off from the edge of the indicator. The bottom of the instrument is set with divisional points, to assist in sketching the proportions of figures, trees, and objects of irregular form or outline.

"We have only to add to our recommendation of the goniometricon, that it is much used by artists and travellers, and recommended to general use by no less a person than the Astronomer Royal."

The Engraving, fig. 1, is a front view of this very ingenious and useful instrument; fig. 2 exemplifies the manner of its application.

Besides the valuable testimonial referred to, from Professor Airey, we observe there is one from Mr. Reynolds, of the Kew Observatory, who says—"Your instrument is precisely what Dr. Priestley, in his valuable work on perspective, hoped some mechanical man would discover, in order to make the science of perspective tangible to the comprehension of all."

Fig. 2.



* We are indebted for the use of the wood engravings to our cotemporary, the "Mechanics' Magazine."

BLASTING UNDER WATER.

Paper on the application of Gunpowder as an instrument of engineering operations, exemplified by its use in blasting marl rocks in the River Severn. By George Edwards. *Read at the Institute of Civil Engineers.*

Many plans have been proposed at different times for the improvement of the Severn. It is sufficient, however, for the present purpose to state, that in 1842 an Act was obtained under the advice of Mr. W. Cubitt, V.P. Inst. C.E., for the improvement of 43 miles of its length, from Stourport to Gloucester; over which distance, in many places there was not 2 feet depth of water during the summer season. The object of the proposed works i to increase this depth to 6 feet of navigable water during all seasons. Above Worcester the additional depth is obtained partly by dredging, but chiefly by a series of four weirs, varying between 300 and 400 feet in length, with side locks for the the traffic. Between Worcester and Gloucester (a distance of 29 miles), it is proposed to obtain the required depth, partly by contracting the channel by embankments of fascines, and partly by dredging. Messrs. Grissell and Peto having undertaken the entire completion of the works, from Stourport to Gloucester, the superintendence of the dredging operations was entrusted to the author. The shoals to be removed by dredging are generally isolated, varying from 100 yards to half a mile in length, and they require excavating to a depth of from 3 to 5 feet. A large proportion of these shoals consist of alluvial gravel, without flints, but principally of quartzose and granitic pebbles, varieties of porphyry and of compact and granular sandstone. This material, although very hard in some places, offered no engineering difficulties. Other shoals consist of denuded beds of hard red marl; this material being found in every instance, when the river impinges upon the eastern or western limits of its valley. In most places it was so hard, as to render its removal by the dredging machine quite impracticable; and it is the object of the present communication to describe the method of blasting, or breaking up this material, with gunpowder, so as to render it capable of being dredged up with facility.

That part of the river Severn, above described, traverses nearly north and south the great plain of red marl of the new red sandstone formation, the bed of the river from Stourport to about a mile below Holt bridge, near Ombersley, being formed through the upper strata of the new red sandstone; upon this lies the great bed of red marl (in places saliferous), dipping at a small angle, but irregularly, to the south east. The river traverses the whole of this strata, which is probably more than 1000 feet in thickness, passing through the upper strata, and entering the lias formation above Gloucester.

The red marl is generally considered by geologists to be formed from the debris of older rocks, and it appears to be totally devoid of organic remains. It lies generally in beds, rarely exceeding 15 inches in depth, and often much less. It is divided occasionally by strata of greenish grey marl, and near the upper part of the formation by thin, but very hard, beds of shaly, or imperfect lias.

It is difficult to describe the comparative hardness of materials, but when it is stated, that in many places it was impossible to cause a steel chisel-pointed boring tool to enter it by any ordinary exertion, by hand, from a boat, it will be conceived that it could not be readily raised by dredging. After exposure to the action of the air it breaks up into small fragments, almost like the slaking of lime, so that solid blocks, which could only be broken by the application of considerable force into sharp-edged fragments, would, in the course of a few days, fall to pieces and afford no criterion of its hardness in an undisturbed state.

When the dredging machine was tried upon one of these marl shoals, it was found impossible to raise above 50 or 60 tons per day, and that with constant risk and repeated accidents to the machine; but such rate of progress was totally incompatible with the required progress of the work. Attempts were first made to break it up by driving iron bars into it, and prizing it up, but this plan did not answer. A second attempt was made to loosen it with a very strong plough, something like a "subsoil" plough, which was proposed to be pulled through the marl by a powerful crab fixed on a barge, the plough being guided by a strong pole; the effect produced was, however, so superficial, and the expense of labour was so great, that this method was also abandoned, and experiments were made to ascertain the effect and probable cost of using gunpowder. These were so satisfactory, that it was determined to blast all the marl shoals, previous to dredging them. In January, 1845, as soon as the requisite materials and establishment could be prepared, this operation was commenced, and has since been carried on with no other interruptions than those occasioned by freshes in the river; the total length of blasting required (about a mile and a half,) being now nearly completed, and a considerable portion of the marl since dredged up, at the rate of 200 or 300 tons per day with perfect facility.

The most economical method of using powder, to break up a depth of rock like that described, would probably be to obtain a face of the required depth at one end of the work, to put in a row of shots at the back of it, and after each discharge to remove the loosened marl; continually repeating the process; but this method would have been open to many serious objections. The dredging machine and the blasting gang would have been constantly waiting for each other, and having but two dredging machines to perform the work, it was of great importance to economise their time in every possible way. By such proceedings also, a constant obstruction to the navigation would have been created, equal to the whole width of the new channel. The number of men that could have been employed in blasting would also have been very limited. These objections, in this particular instance, far outbalanced any little saving of gunpowder. It was therefore determined to put in perpendicular shots, throughout the site of the channel, at such distances as experience might prove to be best, and proceedings were commenced with spaces of 6 feet from centre to centre of the shot holes.

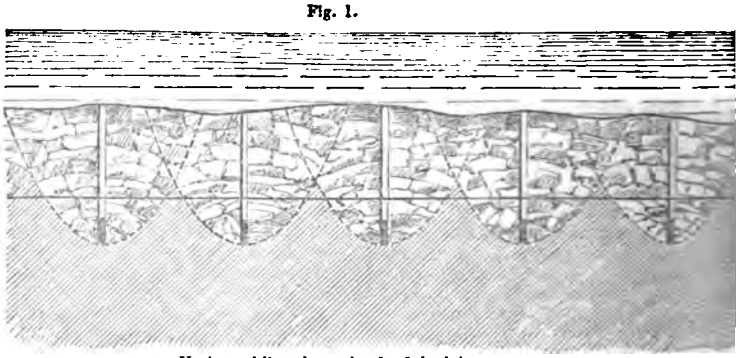
Six rafts were used, as stages to work from: they were each formed of four baulks of timber, about 40 feet long; the baulks, placed in pairs, were secured at a distance of 4 feet apart, by cross pieces, 6 inches square, well spiked to the baulks at intervals of 6 feet; these were covered with deals 3 inches thick, laid lengthways of the raft, a space of 12 inches in width being left open along the centre. The ends of the rafts were provided with strong ring bolts to moor by. These rafts were confined to one bank of the river by ropes, and retained at the required distance from it by a series of "sets," or booms, abutting against the bank. At the up-stream end of the raft was a large barge fitted up as a blacksmith's shop, for the necessary repair of the tools, with dwellings for the watchman, the ganger, &c. The bows of the barge were strongly fortified, and a strong oblique boom of large baulks reached from it to the shore, so as to protect the whole fleet from the craft coming down the river. At the down-stream end was another barge, fitted up as a powder magazine and as a shop, furnished with every necessary for the manufacture of the cartridges and for the storing of their material. The words "powder magazine" in large letters were painted on both sides of this vessel.

The first operation consisted in placing and securing in their proper positions, the pipes through which the holes were to be bored. Small stakes, painted with a series of numbers, were first driven into the bank, parallel to the work, at distances of 6 feet apart; as far behind them as the slope would allow, was another row of stakes parallel with the first, so that a line drawn through two stakes would be at right angles with the river, and a person standing behind the two stakes could readily direct the workmen when to lower the charge-pipe, which was then secured in its place, in the opening of the raft, by a "timber dog," driven into the raft on each side of it. The pipes were of wrought iron, drawn for the purpose by Messrs. James Russell and Sons, of Wednesbury: they were 3½ inches in diameter, $\frac{3}{16}$ths inch thick, and 9 feet long.* Two collars, half inch square, were shrunk on them near the upper end, for the purpose of retaining a rope, by which they were secured when the charge was fired. When the depth of the water increased, these pipes could be lengthened 4 feet by an additional piece, prepared for that purpose; this joint was made by shrinking on a collar, 6 inches long, over the joint. The pipe being in its place, was driven through any gravel that might remain and a few inches into the marl. The gravel was generally so thick upon the marl, that it was requisite first to remove it by means of the dredging machine. To protect the thin edges of the pipes whilst being driven, a cast iron cap, or plug, was used, which received the blows from a heavy wooden beetle; the interior of the pipe was next cleared of any sand, or gravel, that might have entered while putting them down. The principal tool used for this purpose was an iron bucket or cylindrical tube, 2 feet in length, of as large a diameter as would pass down the whole; it was furnished at the bottom with a valve opening inwards, and was jointed to a round rod, of the requisite length, half an inch in diameter, and when used with a pumping motion, quickly brought up whatever could not enter at the valve.

The boring then commenced; a gang of three men being stationed at each pipe. The first operation was that of the jumper, which was made with a single steel edge, a little rounded. The jumpers were of round iron, 1⅛ inch diameter, except 2 feet in length at the lower end, which was 1¼ inch diameter. For general use they were 15 feet long, and weighed about 52 lb. each; after working them till they were nearly set fast, an auger was inserted to raise the plug of loosened marl and to render the hole true. The shell of the auger was 20 inches long and nearly closed up, the better to retain the loosened borings.

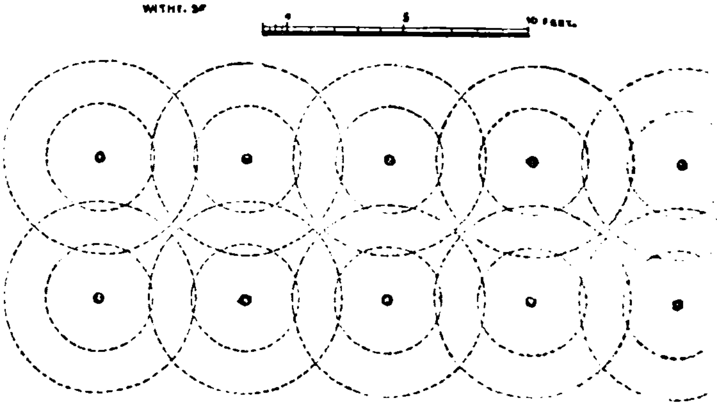
The shot holes were bored two feet below the proposed bottom of the dredging, as it was expected that each shot would dislocate, or break into small pieces, a mass of marl of a conical or parabolic form, of which the

Fig. 1.



Horizontal line shows depth of dredging.

Fig. 2.



* Where the marl was so deep as to require 8 or more pounds of powder, it was found that the cartridges of such diameter as could be used in these small bores were so long as to lose part of the effect of the gunpowder; subsequently, pipes of 4 inches diameter were used with advantage.

bore hole would be the centre, and its bottom the apex, so that four adjoining shots would leave between them a pyramidical piece of marl, where the powder would have produced little or no effect. By carrying the shot holes lower than the bottom of the intended dredging, the apex only of this pyramid was left to be removed, and in practice this was found to form but a small impediment (figs. 1 and 2). A second reason was, that if the removal of the shoals should cause the level of the summer water to fall lower than was expected, the marl might still be found sufficiently broken, to enable a greater depth to be obtained without further blasting.

The cartridges, or charges, were formed of strong duck or canvas bags, somewhat tapered at the bottom; these were filled with the required charge of powder, varying from 2 lb. to 4 lb., according to the depth of the marl;* the end of a coil of Bickford's patent fuse was inserted to the centre of the powder, and the neck of the bag was carefully gathered up round the fuse, and well tied with small twine. If the cartridge was small, it was then dipped into melted pitch, which had about one-fourth of tallow melted with it, or otherwise the melted pitch was ladled over it, till it was uniformly coated; in this state, the cartridges were hung to drain and stiffen. When hard, they were well rubbed over with tallow, and lastly powdered over with dry whiting. The tallow, whilst it insured the stopping of any little cracks in the pitch, facilitated the passage of the cartridge down the hole; the whiting also prevented the pitch from adhering to anything. It has already been stated, that the powder was ignited by means of Bickford's patent fuse; but as this material is never made in lengths exceeding 48 feet, it was found expedient, in order to save waste, to use the whole coil, cutting it off at the requisite length when absolutely in the hole, and using the remainder in the same way till the whole was used up.†

The charge was carefully pushed down into the hole by a wooden ramrod of suitable diameter, with the end rounded; the same instrument was used for ramming down the tamping. The material found to answer best for this purpose was the small fragments of hard marl, separated by the action of the weather from the lofty escarpment at each of these shoals; this was gradually filled into the holes, and rammed solidly, till the bore was full up to the surface; the timber dogs which held the pipes were then removed, the pipes were loosened from the marl, ropes were attached to the pipes and to the raft, or to some loose pieces of timber, and the shots were fired. Generally there was little external effect beyond the pipes being lifted a few inches, though sometimes they would be blown up several feet, and occasionally the water would be forced up through the pipe to a height of 40 or 50 feet. All the gangs commenced their holes in the morning, and they were generally all ready to fire at the same time, which was always done, as it caused least interruption to the work.

It was a rare occurrence for a shot to miss fire—probably not once in a hundred shots; the failure arising generally from a leak at the joint between the fuse and the bag. If the leak was not very serious, the shots were often saved by the following somewhat singular expedient. An iron bar, ⅜ inch in diameter and of sufficient length, pointed at the end, was kept in readiness, and when required the end was heated red hot, put quickly through the water into the tamping, through which it was driven as rapidly as possibly into the powder, which in nine cases out of ten it was still hot enough to ignite.

The result of the whole work being invisible, great care was necessary in order to prevent mistakes and omissions. As each shot was ignited, a red mark was laid against its corresponding stake upon the bank; when it had gone off, each shot was carefully examined with a steel chisel-pointed searcher, to prove that the required effect had been produced to the determined depth; when so found, the red mark was inserted into the top of the stake, as a certificate of that shot having passed examination; the numbers so certified were then transferred to a book kept for that purpose, and if a shot was found ineffective, another was put in the same place.

To afford space for the workmen, every alternate hole was first made, and afterwards those which had been left between them; one line being completed, the whole line of raft was moved 6 feet outwards to the next line, and so on till the required width was obtained. The whole establishment was then dropped down the length of the rafts, and the process was repeated. When the men had become used to the work, each gang would sometimes get down four shots per day, to that with fifteen gangs sixty shots have been fired per day.

It may be objected to the use of the patent fuse, that the ignition of a number of charges simultaneously by the galvanic battery would have produced better effect, at less cost, and in a more scientific manner. The author commenced the work under a different impression, and subsequent experience with the battery has not altered his opinion. When it is required to separate a large stone from its bed in the quarry without breaking it, nothing can be better than the numerous simultaneous discharges, which can only be obtained by the use of the battery, but the object in this work, on the contrary, was to break the mass to pieces as much as possible, which it is conceived would be more likely to be effected by distinct discharges.

Then as regards cost: the patent fuse No. 3, carriage included, cost $\frac{6}{10}$ths of a penny per foot; if the average length is taken at 15 feet, that is just nine-pence per shot, a sum which would barely pay for making the arrangement of wires necessary for the galvanic ignition. It was also found, from the compressible nature of the canvas cartridges, that the arrangement of the wires was very liable to be disturbed, during the insertion of the cartridge into the hole, or by the subsequent ramming of the tamping. After considerable experience, therefore, and the use of nearly 100,000 feet of the patent fuse, the author feels that he is only doing an act of justice to the Messrs. Bickfords, in stating the perfect satisfaction which the use of their ingeniously manufactured material has afforded him, in the prosecution of the work now described.

There now only remains to be given the cost of the operation above described. The first cost of the establishment or plant, sufficient for 6 months' work, was £300. This includes the waste and use of timber, in the raft, stages, booms, &c., hire of barges, and cost of fitting them up for the work, cost of pipes for boring, iron and steel for tools, deducting estimated value when done with, sundry ironmongery, waste and loss of ropes and other small stores.

More than four thousand shots have already been fired, and in the six months, at a low computation, six thousand will have been fired. This number gives just one shilling per shot, as the proportionate share per shot of the cost of the plant; this would of course be much less if the work was to be continued.

The cost of labour per shot varies from 2*s.* 6*d.* to 4*s.*; this sum, however, must be understood to cover the wages of the whole establishment as under: Superintendent of the work.—Foreman and timekeeper.—Examiner of the shots.—Maker of cartridge and two assistants.—Carpenter.—Blacksmith and hammer man.—Labourers, some at 3*s.*; majority at 2*s.* 6*d.* and 2*s.* 9*d.*—Watchman.—Thus the total cost per shot is as under:—

	s.	*d.*
Use of material	1	0
Labour, average	3	3
Pitched bag	0	3
3 lb. of powder, at 5½*d.*	1	4½
15 feet of patent fuse	0	9
Pitch, tallow, twine, coals, &c., say	0	4½
	7	0

If, therefore, the shots are 6 feet apart, and an average depth of 3 feet is broken up, 4 cubic yards are prepared for dredging at the cost of one shot; or the cost of the whole operation is 1*s.* 9*d.* per cubic yard. Distances of 5 feet apart were used in some very hard shoals, and spaces of 7 feet were tried in some that were softer than usual; spaces of 6 feet apart, however, appeared to be generally sufficient.

ON THE CORROSION OF METALS.

Paper by R. Adie, of Liverpool, *read at the Institution of Civil Engineers.*

This communication is intended to give an experimental proof of the fact, that water saturated with common salt, preserves to a great extent, the surface of the oxidizable metals from corrosion by the joint action of air and water. From some trials upon metals placed beside water in closed glass tubes, it was shown that water, or water containing a saline solution, does not act as a corroding agent, without the aid of the oxygen of our atmosphere. The details of some experiments, made to ascertain the quantity of oxygen dissolved by water under different circumstances, showed that brine and some other saline solutions contain much less dissolved oxygen than sea or ordinary water, which was the fact that induced the trial of salt water as a preserver of iron. The object of the last set of experiments was to determine by trial, the rates of corrosion of metals in fresh water, sea water, and brine; the results of these show that sea water corrodes the quickest, fresh water less rapidly, and brine very much slower than either.

On the rate of action of brine, sea and fresh water, in corroding.

These experiments were made with weighed pieces of metal immersed in the three solutions under examination. Those which are compared together, were tried in every respect under similar circumstances, as to weight and surface of metal; size and form of vessel; quantity of water employed; light and temperature.

The experiments on zinc were made with that metal in connexion with a piece of copper, so as to form a galvanic couple; for zinc, when unconnected with a less oxidizable metal, is soon covered with a crust of oxide, so that pieces, after a month's immersion in water, are found to be slightly heavier than at the beginning of the experiment. This is not the case when a piece of silver or copper is in metallic connexion with zinc; for then the white oxide of the metal is gradually precipitated to the bottom of the containing vessel.

A plate of zinc, 1 superficial inch in area, immersed for 60 days in sea water . . .	lost 1·0 grains.
A similar experiment in fresh water . .	„ 1·15
A plate of zinc, 7 superficial inches in area, immersed for 90 days in fresh water . . .	„ 4·9

---

* The weights of powder used for depths of 4 feet, 4 feet 6 inches, and 5 feet, were respectively about 2 lb., 3 lb., and 4 lb.

† The short remaining ends, though useful for less depths, were of little value, from the difficulty of splicing them together. This operation, though troublesome, was resorted to with success on one occasion whilst waiting the arrival of a parcel of fuse. On returning the short ends to Messrs. Bickford they allowed half the length of new fuse in exchange.

A similar experiment in brine, or the saturated solution of common salt tested as above for dissolved air	„ 1·4
Wrought iron wire:—	
Twenty pieces of iron, weighing 374 grains, immersed for 80 days in fresh water . .	lost 1·9 grains.
A similar experiment in sea water . .	„ 2·6
A similar experiment in brine . .	„ 0·1
Cast iron:—	
Three rods of cast iron, weighing 787 grains, immersed for 62 days in fresh water . .	lost 1·6 grains.
A similar experiment in sea water . .	„ 2·0
A similar experiment in brine . .	„ 0·4

On comparing together the loss of weight of metal in the fresh water, sea water, and brine, it will be observed, that in sea water the corrosion is about one third more than in fresh water; while in brine, the loss of weight is about one-fourth part of the loss in fresh water, and one-fifth part of that experienced in sea water; showing that brine possesses considerable power for preserving metals from corrosion. The carbonates of potash and soda are still more effectual in arresting oxidation; for in saturated solutions of these salts, iron wire remained immersed for sixty days without any amount of corrosion being detected. The surface of the plate of zinc, when taken from the brine, was the same as at the commencement of the experiment, excepting in three spots, where there was deep corrosion. The principal of these being around the point, where the copper wire connected the plate with the negative element. The difference shown between fresh water and sea water, in their power of oxidizing metals, is in the reverse order of the quantities of oxygen dissolved by them, as given in the preceding experiments; where the sea water is to the fresh as 78 to 85. The principle on which the preserving power of alcohol is attempted to be explained may, in like manner, be here applied to pure water. Although the experiments on the corrosion of iron were continued for eighty days, the difference between the action of common water and brine may be made apparent in one day. In the fresh water, the hydrated peroxide of iron is seen forming; while in the brine, only a slight tinge of a greenish infusion can be detected, a sure indication of the scarcity of oxygen.

The experiments given to determine the respective rates of corrosion in fresh and sea water, are only correct for pieces of metal wholly immersed in them. Where the surfaces are subject to be wet and dry, the corrosive effect of sea water will greatly increase; on the same principle that iron once coated with rust, decays much faster after the rust has provided a lodgment for moisture. Take for example a bar of iron in a field, and a similar piece on the deck of a ship. On the first, the dew of night deposits water, which corrodes until the return of the sun dries it all off. On the second, on the deck, it deposits spray, which acts like the dew, until the sun dries it off; but when dried, there is left a thin deposit of salt, with a powerful affinity for moisture, which on the return of evening will attract moisture from the atmosphere, long before the dew wets the metal in the field. Thus it is that a coating of salt or rust, keeps metals much longer in a wet state, than if their surfaces were clean.

Remarks.—The experiments which showed that brine (by which term, he supposed, a saturated solution of common salt in water was meant) should be found to be less corrosive of iron than sea water, was consistent with the circumstance, that less air was contained in water which was saturated with any solid substance, than was contained in water only slightly impregnated with such substance, and there was no doubt, but that the atmospheric air performed a principal part in the oxydation of iron, which was exposed to the weather. Air containing water in solution, corroded iron rapidly; and water containing air in solution did the same; and alternate exposure of iron to water and to air, corroded it still more rapidly; particularly when by the warmth of the sun, and the blowing of the wind, the film of water which was left on the surface of the wetted iron was evaporated, or dried away from that surface, before a fresh wetting occurred. Perfectly dry air was very slightly, if at all, corrosive of iron, and water completely freed from air by boiling, was not actively corrosive, in the manner that air and water were. Respecting salt, there was nothing corrosive of iron in its own nature; it contained no oxygen, but although it was a great cause of corrosion of iron, the corroded iron was found to be an oxide, not a muriate of iron. The salt when dissolved in water, greatly increased the corroding effect upon iron which was immersed in the salt water, and still more if the iron was frequently wetted, or washed with salt water and dried by the sun and the wind, in the intervals between successive wettings. The concurrent effect of air, water and salt, was extremely corrosive of iron. It was well known, that dry salt was not at all corrosive of iron, for in stoves for drying salt, the flues were frequently made of iron plates, and the salt in lumps being laid directly upon the iron, did not corrode it at all, the iron being always kept hot and dry; in the same stoves, if they were not used, and allowed to cool, the salt absorbed humidity from the air, and became very corrosive of the iron work. Iron salt-pans, for boiling brine, did not become oxydated as rapidly as might be expected; indeed, they were scarcely affected at the parts of the upright sides of the interior surface of the pans, which were always beneath the surface of the hot brine and were not exposed to the action of fire. The manner in which salt operated, to increase the oxydation of iron, was probably by an electro-chemical action, the chief part of the oxygen which the iron absorbed, being derived from the atmospheric air, the other part from the water, and none from the salt. In heaps of old iron exposed to water, it might be observed to lodge in the hollows, and to occasion rapid rusting of the iron, attended by a smell of hydrogen, and a thin pellicle floating on the surface of the water, showing dingy prismatic colours. The paper which had been read, mentioned absorption of oxygen from the air by water; it was generally understood, that when water absorbed air from the atmosphere, the nitrogen of the air, as well as the oxygen, were both absorbed together by the water, in their accustomed proportions, as they existed in the atmosphere, so as to be an absorption of atmospheric air by the water.

Mr. Lowe said the paper led to the consideration of the change which was induced in cast iron, by continued immersion in various fluids. This had been frequently discussed at the Institution, and it would be desirable if Mr. Adie would continue his experiments, with a view to elucidating that question, as the conversion of cast-iron into carburet of iron, or graphite, appeared, under certain circumstances, to be so rapid, as to have rendered necessary the substitution of other and more expensive metals. In breweries, for instance, the change had been produced so very speedily, wherever the acid wash came into contact with metal, that copper gratings had been of necessity substituted for cast iron.

Sir John Rennie, President, stated, that the earliest example in his recollection of the change produced by sea water in cast iron, was in some iron guns which were fished up in 1822 off Holyhead. They were supposed to have belonged to a pirate vessel which was destroyed there about 100 years previously. When found they were quite soft, but after exposure to the air for a time, they became so hard, that they were used to fire salutes, when George the IVth passed through Holyhead, on his way to Dublin, and it was remarked that the report from them was louder than from any other iron guns of a similar size.

REVIEWS.

Turning and Manipulation. By Charles Holtzapffel, Vol. II. Illustrated by upwards of 700 woodcuts. Holtzapffel. London: 1846. 8vo.

This large octavo volume of upwards of 500 closely printed pages, is only one of a series of six, in which the subject of Mechanical Manipulation is intended to be comprised. The first volume (reviewed, *ante*, vol. VI, p. 1843), treated of the properties of various materials used in the arts, and their preparation, &c. The present volume describes the various kinds of cutting tools used by the hand, such as boring tools, saws, and planes, and their modification when worked by steam-engine power. The third volume will refer to abrasive processes, such as grinding and polishing; the fourth to simple hand turning; the fifth to complex turning; the sixth to amateur mechanical engineering. It is intended that the first three volumes should form a general preliminary work with an index in common.

The volume before us is of so thoroughly technical a nature, and affords the most minute and practical information on the subjects of which it treats; at the same time, it is written and arranged in a very perspicuous manner, and abounds with interesting accounts of successive improvements of different machines, the extraordinary perseverance and skill of the mechanicians to whom these improvements are due, and the beautiful accuracy of their final results. While therefore the chief value of this work will be the practical guidance which it affords respecting peculiar classes of industrial art, it has also an interest for the general reader, and especially to the engineer pursuing some branch of his profession collateral to that here considered, because it exhibits to him the important mutual dependence of the arts to each other. The introductory chapter (the 22nd of the work) gives general remarks on cutting tools, the variations of the cutting angle of the tool, (that is the inclination of the surfaces meeting at its edge) and the variations of the angle of inclination to the material to be cut, which of course depend on the hardness of the material.

In the next chapter the plane and planing machine and their modifications are described, together with a great deal of minute information about joiners' benches, bench stops, adjustment of bench planes, and other mysteries of the workshop. The subsequent chapter treats of turning tools for hard and soft woods, ivory, brass, iron, and steel, and the manipulation of these instruments. Next comes a chapter on drills of all kinds, watch drills, press drills, ratchet and lever drills, corner drills, differential screw drills, &c. The following chapter is a most interesting one upon cutting machines, and traces the construction of the screw from the simple method invented by Pappus to the most refined processes of modern art. The four following chapters are devoted to saws, files, shears, and punches, respectively, and the application of those instruments on a large scale by steam or other engine power.

We offer the following extract from the chapter on screws, of an account, which we have ourselves read with great interest, of the successive improvements in the manufacture of the screws. The great difficulty is to make the inclination of the thread uniformly regular, and the extraordinary and microscopical accuracy which has been attained in this respect may be considered among the most admirable triumphs of practical science. The ingenuity, skill, and perseverance of the mechanicians engaged in this pursuit can be but little known to general readers.

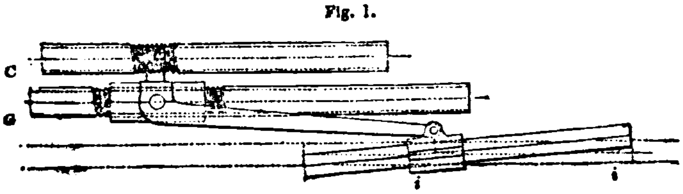
"The late Mr. Henry Maudslay devoted an almost incredible amount of labour and expense, to the amelioration of screws and screwing apparatus; which, as regarded the works of the millwright and engineer, were up to that time in a very imperfect state. With the view of producing screws of exact values, he employed numerous modifications of the chain or band of steel, the inclined knife, the inclined plane, and indeed each of the known methods, which however he remodelled as additions to the ordinary turning-lathe with a triangular bar; a natural result, as he was then in the frequent habit of constructing that machine, and which received great improvement at his hands.

"It was noticed at page 581, that of all the methods he gave the preference to the inclined knife, applied against a cylinder revolving in the lathe, by means of a slide running upon the bar of the lathe; which besides being very rapid, reduced the mechanism to its utmost simplicity. This made the process to depend almost alone on the homogeneity of the materials, and on the relation between the diameter of the cylinder and the inclination of the knife; whereas in a complex machine, every part concerned in the transmission of motion, such as each axis, wheel and slide, entails its risk of individual error, and may depreciate the accuracy of the result; and to these sources of disturbance, must be added those due to change of temperature, whether arising from the atmosphere or from friction, especially when different metals are concerned.......... The relations between the guide-screw and the copy were varied in all possible ways: the guide was changed end for end, or different parts of it were successively used; sometimes also two guide-screws were yoked together with three equal wheels, their nuts being connected by a bar jointed to each, and the center of this link (whose motion thus became the *mean* of that of the guides) was made to traverse the tool. Steel screws were also cut, and converted into original taps, from which dies were made, to be themselves used in correcting the minor errors, and render the screws in all respects as equable as possible. In fact, every scheme that he could devise, which appeared likely to benefit the result, was carefully tried, in order to perfect to the utmost, the helical character and equality of subdivision of the screw.

"Mr. Maudslay succeeded by these means, after great perseverance, in making a very excellent brass screw about seven feet long, and which, compared with standard measure, was less than one-sixteenth of an inch false of its nominal length. Taking the error as the one-thousandth part of the total length of the screw, which was beyond its real quantity, to make from it a corrected screw by the system of change wheels, would have required one wheel of 1000 teeth, and another of one tooth less, or 999; but in reality the error was much less, and perhaps nearer the two-thousandth of an inch; then the wheels of 2000 and 1999 teeth would have been required; consequently the system of change wheels is scarcely applicable to the correction of very minute errors of length.

"The change of the thousandth part of the total length, was therefore given to the tool as a supplementary motion, which might be added to, or subtracted from, the total traverse of the tool, in the mode explained by the diagram, fig. 1, in which all details of construction are purposely omitted. The copy C, and the guide-screw G, are supposed to be connected by equal wheels in the usual manner; the guide-screw carries the axis of the bent lever, whose arms are as 10 to 1, and which moves in a horizontal plane; the short arm carries the tool, the long arm is jointed to a saddle which slides upon a triangular bar *i i*.

Fig. 1.



"In point of fact, the tool was mounted upon the upper of two longitudinal and parallel slides, which were collectively traversed by the guide-screw G. In the lower slide was fixed the axis or fulcrum of the bent lever, the short arm of which was connected by a link with the upper slide, so that the compensating motion was given to the upper slide relatively to the lower.

"The triangular bar *i i*, when placed exactly parallel with the path of the tool, would produce no movement on the same, and C and G would be exactly alike; but if *i i*, were placed out of parallelism one inch in the whole length, the tool, during its traverse to the left by the guide-screw G, would be moved to the right by the shifting of the bent level, one tenth of the displacement of the bar, or one-tenth of an inch.

"Therefore whilst the guide-screw G, from being coarser than required, moved the principal slide the one-thousandth part of the total length in excess; the bent lever and inclined *straight* bar *i i*, pulled back the upper or compensating slide, the one-thousandth part, or the quantity in excess; making the absolute traverse of the tool exactly seven feet, or the length required for the new screw C, instead of seven feet and one-sixteenth of an inch the length of G. To have lengthened the traverse of the tool, the bar *i i* must have been inclined the reverse way; in other words, the path of the tool is in the diagram the *difference* of the two motions; in the reverse inclination, its path would be the *sum* of the two motions, and *i i* being a straight line, the correction would be evenly distributed at every part of the length.*

"Whilst Mr. Maudslay's experiments in perfecting the screw were being carried on, his friend Mr. Barton†, paid frequent visits to his manufactory, and also pursued a similar course. Mr. Barton preferred however, the method of the chain, or flexible band for traversing the tool the exact quantity; because the reduction of the diameter of the pulley or drum afforded a ready means of adjustment for total length; and all the wheels of the mechanism being individually as perfect as they could be made, a near approach to general perfection was naturally anticipated on the first trial. This mode, however, is subject to the error introduced by the elasticity or elongation of the chain or band, and which is at the maximum when the greatest length of chain is uncoiled from the barrel.

"These two individuals having therefore arrived, by different methods, as near to perfection as they were then respectively capable of; each made a screw of the same pitch, and 15 inches long, and the two when placed side by side were found exactly to agree throughout their length, and were considered perfect. The two screws were submitted in 1810 to the scrutiny of that celebrated mathematical instrument maker, the late Mr. Edw. Troughton, F.R.S., &c., who examined them by means of two powerful microscopes with cross wires, such as are used for reading off the graduations of astronomical instruments; applied like a pair of the most refined compasses, to measure the equality of some 20, 50, or 100 threads, taken indiscriminately at different parts of the length of the screws.‡ From this severe trial it resulted, that these screws, which to the unassisted sight, and for almost every purpose of mechanism, were unexceptionable, were found to be full of all kinds of errors, being unequally coarse at different parts, and even irregular in their angles, or "drunk." This rigid scrutiny led both parties to fresh and ultimately successful efforts, but of these our limits will only allow us to notice one, apparently derived from the use of the *two* microscopes.

"Mr. Barton employed *two* pairs of dies upon the one screw; the dies were fixed at various distances asunder upon one frame or bar, and the screw was passed through them. This was found to distribute the minute errors so completely, that little remained to be desired; as it is obvious that at those parts where the screw was too coarse, the outer sides of the threads were cut, and which tended to shorten the screw; and where it was too short, the inner sides were cut, which tended to lengthen the screw; in fact the two parts temporarily situated within the dies, were continually endeavouring to approximate themselves to the fixed unvarying distance, at which the dies were for the time placed.

"Mr. Barton informed the author that he employed the screw corrected in the above manner, in his engraving machine, employed for cutting with the diamond, the lines as fine as 2000 in the inch, on the steel dies referred to in the note on page 42, vol. i.; and he said 'that such was the accuracy of the mechanism, that if a line were missed, the machine could be set back for its insertion without any difference being perceptible.' The author unintentionally ascribed the first application of the diamond to turning steel, to Sir John Barton, whereas it had been used long before by Ramsden in cutting the hardened-steel screw for his rectilinear dividing engine."

These adjustments and corrections, almost perfect as they would seem to be, have been subjected to still further refinement. One of the most beautiful mechanical devices which we have ever met with is described in the subdivision relating to the application of the screw to the *graduation of mathematical scales*.

"One very important application of the screw, is to the graduation of mathematical scales, the screw is then employed to move a platform, which slides very freely, and carries the scale to be graduated; and the swing frame for the knife or diamond point is attached to some fixed part of the framing of the machine. Supposing the screw to be absolutely perfect, and to have fifty threads per inch, successive movements of fifty revolutions, would move the platform and graduate the scale exactly into true inches; but on close examination, some of the graduations will be found to exceed, and others to fall short of the true inch.

"The scales assume, of course, the relative degree of accuracy of the screw employed. No test is more severe; and when these scales are examined by means of two microscopes under a magnifying power of ten or twenty times, the most minute errors become abundantly obvious, from the divisions of the scales failing to intersect the cross wires of the instrument; the result clearly indicates, corresponding irregularities in the coarseness of the screw at the respective parts of its length. An accustomed eye can thus detect, with the microscope, differences not exceeding the one thirty-thousandth part of an inch, the twenty-five-thousandth part being comparatively of easy observation.

* The apparatus was fitted to the second screw-lathe of those described, and the inclined bar was placed on temporary wooden standards.

† Subsequently Sir J. Barton, Comptroller of the Mint, &c.

‡ The microscope had been long used in the process of graduating instruments, but this invaluable mode of employing two microscopes in combination, was first successfully practised by Mr. Troughton.

"From Mr. Donkin's investigation of the subject, he was led to conclude that it is quite impossible to produce a screw which shall be absolutely free from error, when micrometrically proved; and in 1823, he was in consequence led to consider that as Mr. Maudslay's method of the bent lever and inclined *straight* bar, would compensate the error of total length in a nearly perfect screw, a similar mode might be applied to all the intermediate errors, by the employment of a *curve*, experimentally obtained by the method of continual bisection employed in hand dividing.

"It having been explained in reference to the diagram,* that the inclination given to the bar would reduce the effective length of a screw, and the reverse inclination would increase it, Mr. Donkin considered that from the observed fact of one half of the screw (as estimated by counting the number of threads) being generally too coarse, and the other half too fine, the compensation would require the one half of the bar to be inclined to the right, as in the diagram, and the other half to the left; in fact, thus bending the right line into an obtuse angle.

"Extending this mode, upon the presumption that the quarters, eights, or sixteenths of the screw were also dissimilar, the bar would require many flexures instead of the one only, giving to it a more or less zig-zag character, or rather that of a gently undulating line. The undulations being proportioned *experimentally*, to effect such compensations, as should *add* to the movement of the upper platform or supplementary table, where the screw was too fine, and *subtract* from its motion, where the screw was too coarse; so as, from a screw known to be slightly irregular, to produce the divisions of a scale, or the thread of another screw, considerably nearer to equality.

"He carried out this project in 1826, and he has satisfactorily proved the existence of a correctional method, which is within reach of any clever workman who will devote sufficient *patience* to the adjustment of the engine, and which latter will be now briefly explained........To effect the compensation, the platform or table consists of an upper and lower plate, which are capable of a small independent motion. The lower plate carries the fulcrum of the bent lever, whose arms are at right angles and as fifty to one, the lever moves in the vertical plane, so that its longer arm lies by gravity alone on the curvilinear edge of the compensation bar; the upper platform is pressed endlong against the shorter arm of the bent lever, by a spring which always keeps them in close contact.

"The compensating bar, which is of the length of the screw, or 24 inches, has 48 narrow slips of metal placed like the keys of a piano-forte, each having an appropriate adjusting and fixing screw, by which the ends of the pieces may be placed in a continuous line, or any of them may be placed above or below the line, as required in the following mode of compensation. For change of total length and adjustment for temperature, the curved bar is more or less inclined, as in the former example, except that it is placed edgeways or vertically; it is attached to the outside of one of the rails, by a pivot which intersects the one end of its curvilinear edge, and the other end is raised or depressed by a screw, which effects the adjustment for temperature.

"Conceiving the length of the guide-screw divided into 48 equal parts, denoted by the figures 0 to 48, it would be first ascertained by two fixed microscopes, if the halves of the screw, measured from 0 to 24, and from 24 to 48, were absolutely equal quantities; if not, the central slip or finger would be raised or lowered until on repeated trials the due correctional movement was applied to the table. The two halves would be similarly bisected and corrected in the points 12 and 36, and the quarters again bisected in 6, 18, 30, and 42; and the eighths when also bisected, would extend the examination to the points 0, 3, 6, 9, &c., to 48. The easiest method is to compare the path of the slide, with the divisions of a superior scale, fixed upon the slide or platform of the machine.

"It would now be needful to divide the whole into three parts, by the comparison of the spaces from 0 to 16, from 16 to 32, and from 32 to 48, the points 16 and 32 being adjusted until exactly equal, which is the most difficult part of the work; and then these three distances being bisected four times, every point of the 48 would have been examined, and some of them twice over. These adjustments having been repeatedly verified, during which a very frequent recurrence to the total length is imperative the concluding step is to file off the corners of the 48 slips very carefully, so as to convert them into a line with undulations, slight it is true, but which represent fifty-fold the actual errors in the guide-screw; and therefore shift the table simultaneously with its general traverse, so as to apply the exact corrections for inequality, at every point examined and found to be in error.

"But the term *error* must be received in a very restricted sense, as it deserves to be noticed that Mr. Donkin first used a screw made by Mr. Maudslay, and the maximum deflection of the curved edge of the compensation bar from a straight line was very nearly the *eighth* of an inch, indicating the maximum *error* of the screw to have about the 400th part of an inch; and as the curve was nearly limited to a single undulation, or a hill at one end, it may be presumed this minute error was in part attributable to a difference in the material, a source of perplexity from which no care is a sufficient protection. The dividing engine was employed as a traversing lathe in cutting a new screw, and which, although it had the advantage of the compensation, only reduced the error of the new screw to about one-third the quantity of that of the first; as shown by the new curve assumed by the compensation bar, its deflection being $\frac{1}{24}$ of an inch, when re-adjusted in the tedious and anxious method described.

"In the past year, 1842, Mr. Donkin has made a similar but enlarged dividing engine. The length of traverse of the new machine is 42 inches, the screw has 40 threads to the inch, the compensation bar is as 60 to 1, and the value of one single tooth in the counting wheel is equivalent to the 60,000th part of an inch; that of the first machine having been the 30,000th part. It is to be hoped that Mr. Donkin will complete his labours, by publishing a detailed account of these machines, the latter of which, in particular, exhibits throughout its structure a most refined contrivance and execution, of which no adequate idea can possibly be conveyed within the limits of this slender notice, nor without exact drawings of the details, to the arrangement of which great attention has been bestowed."

* Given in the last extract.

The work is in plan one of the most extensive of all those which form the literature of practical science, and forms an invaluable addition to it. We may probably again refer to it. There are two papers by Professor Willis; we should like to know whether they have been originally communicated to this work, or are merely reprinted. They are inserted without any introduction.

The Assistant Engineer's Railway Guide in Boring, &c., preceded by Practical Memoranda on Specifications. Illustrated by 60 woodcuts and plates. By W. Davis Haskoll, Civil Engineer. Williams, Strand, 1846. 8vo. pp. 136.

So many books are now published on various branches of the practice of railway engineers, that we naturally look to the commencement of each new publication to learn the author's specific object, and how his production differs from the rest of its class. The present work has not, however, any preface or introduction: it indicates as far however as may be learned from the title of the book, and an examination of its contents, Mr. Haskoll's object has been to set before the assistant engineer a concise, but at the same time, explicit directions for his guidance, in examining the progress of a railway, and in ascertaining that the contractors' work is satisfactorily performed. The first, and one of the most useful chapters, gives an abstract of the clauses which ought to be contained in a specification for the construction of a railway, and the general conditions of contracts. The next chapter treats of railway borings, and about one-fifth of the whole work is occupied by a full account of the tools and operations requisite in boring to ascertain the nature of the strata which a railway traverses; this chapter concludes with an account of the economic properties of various kinds of English building stones. The third chapter treats of the methods of setting out the centre line and curves of a railway. This is followed by minute directions for setting out slopes, making land plans, &c. The fifth chapter explains the method of setting out foundations, and affords some hints which will be very valuable to those engaged in over-looking the construction of brick arches and masonry. Mr. Haskoll gives a very bad account of bricklayers. They seem a slippery set of fellows, and require as much watching as horse-dealers.

The general directions for securing firm foundations are good in themselves, but not perhaps sufficiently extended: instead of referring to other works, such as Hughes's papers on Foundations, Godwin on Concrete, Vicat on Cements, and papers in the "Civil Engineer and Architect's Journal," the author might have furnished a useful collation of information from those sources. At the end of the book are a table of gradients, and that most valuable appendage—a good index. The arrangement of the book is very clever; the paragraphs are numbered and reference to them is greatly facilitated by the frequent marginal references which occur on every page. The author has saved the student much trouble by bringing together a great deal of information, scattered about different publications, and his task is performed in a successful manner.

The following is, with some omissions, the abstract of the clauses which, ought to be contained in a specification drawn up on the part of railway company, for the direction of contractors. For precedents of the general conditions of contracts, the author refers to those of Stephenson, Brunel and other engineers, in Brees' Railway Practice. The perusal of the extract below will give to the student a good general idea of the practice of railway construction, and of the points to be attended to in overlooking the progress of the works.

"Strong general clauses in a specification are unjust and arbitrary towards a contractor, where they are only intended to shelter an engineer from neglectful omissions, and from due responsibility, and where full and particular explanations and instructions are not given, for the construction of the various works, as they occur along the different contracts. But where they refer to the manner of the work, general workmanship, to the kinds and qualities of materials, unless otherwise specified in particular place, they cannot be objectionable. General conditions to contracts should be added to protect companies from trouble and annoyance, resulting from the depredations and reckless conduct of workmen, times of payment, restrictions from neighbouring lands, and also for the protection of the workmen from fraud and tyranny; power to increase number of men, or to remove objectionable parties.

"The permanent fencing may consist of a brick wall, of which materials, dimensions, footings should be given, by drawings figured; and whether set in mortar or cement, or in part. Or it may consist of a rubble wall, set in mortar, with half hammer dressed coping, according to drawings and dimensions. Where thorough stones or borders are to be introduced, it should be mentioned, and the size of the stones limited, both for the walling and coping. Permanent fencing may also consist of a good set fence and ditch, with a row of posts and railing fixed on the outside, according to dimensions to be given. The posts and railing to be good oak or larch; the posts to be 6 inches square, or 6 by 3½ inches, 3 feet 6 inches out of the ground, and 1 foot 6 inches in the ground; that part below the ground to be well charred, and the posts to be from 7 to 9 feet apart.

"The soil underneath the cop must be carefully trenched over 12 inches deep, previously to the cop being formed; the cop must then be formed by a ramparting of sods on each side, and the intervening space filled with good vegetable soil; the cop must be planted in the months of October or November, February or March, with good white-thorn plants four years old, having been transplanted from the seed bed three years.

"The ditch to be 4 feet wide at the top, and 2 feet at the bottom, and 1 foot 6 inches deep; the depth of the ditch must be varied, so as to carry off all the water flowing from the embankments or adjoining lands, and proper communications must be made with each intersected drain, so as effectually to attain the desired object, and drains must be formed under the cop, at such intervals as may be requisite to carry of all the water from the foot of the embankments.

"If the engineer should deem it necessary to increase the width of the excavations or embankments, or to flatten the slopes, the contractor will be paid extra for increased quantities, unless it happen that there is excess of excavation, which would otherwise have to go to spoil, in which case the engineer may direct the embankment to be increased without the contractor being paid any extra sum, or, unless side-cutting be required, in which case the engineer may direct the excavation to be increased, and the contractor shall have no claim for so doing.

"At the proper season the slopes must be sown with rye grass or white clover seeds, at the rate of 2 bushels of the former to 6 pounds of the latter per statute acre.

"Whenever any change is made in the inclination of any of the slopes, it must be done gradually, and in not less than 25 yards in length, unless it occur at a bridge, in which case the inclination of the slopes may be different at each side of the bridge.

"During the progress of execution, great care must be taken to prevent water from settling in the excavations and embankments, and any means deemed fit by the engineer, must be resorted to in order to prevent it. A ditch or channel, 12 inches wide and 6 inches deep, must be formed along each side of the excavation, at the foot of the slope, to carry off the water; and if, in the opinion of the engineer, it should become necessary or advisable, in any one case, to put open drains, formed with rubble pitching and side walls, as shewn on drawing, the contractor shall be paid extra for such increase of work, according to the prices set forth in the schedule.

"In the event of any soaks, springs or streams of water appearing from the face of the slopes or otherwise, the contractor must, at his own expense, effectually drain the same, by means of drains or water courses, of rubble or brushwood, put in such manner, and to such extent, as the engineer shall deem expedient from time to time, to prevent such soak, spring, or stream, from injuring the works during progress, and the whole of such water shall be conveyed into proper drains.

"Whenever the seat of an embankment occurs on side-long ground, the same must be cut out in steps, sloping inwards towards the embankment, and the material punned so as to prevent the embankment from slipping. Should the seat of the embankment be peat or other soft material, deemed by the engineer unfit to bear the weight, the contractor shall, at his own cost, and according to instructions from the engineer, remove the same, or cut out a trench, 10 feet wide, entirely through the peat, under the foot of each slope, and fill up the same with good dry material, to be approved of, carrying it 6 feet above the surface of the ground previously to the embankment being tipped on it.

"In bringing an embankment over any bridge, or culvert, the greatest care must be taken to prevent any unequal loading; and any damage caused by neglecting this precaution must be made good by the contractor at his own cost. In the case of culverts with side walls, a space of 10 feet on each side, and over the top, must be punned to a height of 8 feet above the culverts, and no greater height of embankment must, in any case, be allowed to be tipped against or upon the culverts than the height already laid upon the culverts. In the case of crossing of bridges in embankments, the earth must be punned in each case, for such a space as the engineer may deem requisite, in no case being for a less space than 10 feet from the abutment or wing wall, and the material must be conveyed across the bridge by means of baulks of timber laid so as to enable each side to be embanked equally at the same time.

"Where the building of bridges may interfere with the traffic of roads, and previous to any bridge works being commenced, a proper well-made temporary road shall be prepared and made, which must be sufficient for the free passage of carriages of all descriptions. The contractor must take every precaution during the alteration, to erect proper fencing, fix lights, and have a night watchman to prevent accidents, as the company will not be liable for any injury arising from any neglect of these precautions on the part of the contractor.

"The bricks made use of shall be hard, sound, well shapen, thoroughly burnt, and of uniform size, and unless made a year before they are used, must be well saturated with water. No broken bricks will be allowed, except where required as closers; and, in case of backing, the whole must be flushed up perfectly solid with mortar, for which purpose, after the outside course is set, the mortar must be laid on the interior space, and water being poured on must be worked about until every joint is filled perfectly solid. The whole must be built in old English bond, that is, in alternate courses of headers and stretchers, and in case of thick walls, every third and fourth course of the interior, must be laid a "Herringbone;" the face work must all be neatly jointed with a trowel, and struck with a straitedge. No face work will be allowed to be built over-handed; no four courses with three joints, must exceed in thickness, when built, three-quarters of an inch more than the same bricks measure when piled on each other without mortar.

"No brick work or stone work shall be set in frosty weather.

"All the stone used in the work should be sound, hard stone, free from shakes, clay holes, beds, or flaws of any description: if desirable, describe the quarry; it must be approved of by the engineer. No stone either in the inside or outside work should break joint less than 18 inches; the stones in the interior work should bond well with each other, and each course well grouted with lime.

"The ashler work shall lay in courses, not less than 12 inches thick, and with stones, not less than 4 feet by 2 on the bed, and laid alternately as headers and stretchers; all joints must overlap at least 12 inches. In all cases where the engineer may deem it advisable, the whole must be dowelled together with dove-tailed hard stone dowells, or cramped with iron.*

"The block in course shall be of stone laid in courses, not less than 7 inches thick, and each stone shall not be less than 12 inches by 18 inches on the bed, laid alternately as header and stretcher; and one-fourth the length of each course shall consist of stones not less than 30 inches in length, measuring from the face of the work to the interior, laid as nearly equidistant as possible so as to effect a perfect bond with the rubble backing.

"The rubble backing must consist of flat hedded stones, as large as can be obtained. The whole must be carefully pinned and made solid, laid in mortar, and cut to a level surface at every course of the face work; and after the next course of the face stones is laid, the interstices must be completely filled with thin mortar, the mortar being mixed with water, and worked about until every crevice is filled perfectly solid.

"When rubble is used for the entire work, both on the face and in the interior, the stones must be laid with great care so as to be perfectly bonded together; no stone must contain less than a cubic foot except when used only for pinning.

"Pier points will consist of flat bedded stones, cut into uniform sizes, not being less than 10 inches by 5 inches on the bed, and 3 inches thick; they will be used for turning the smaller arches.

"Where desired by the engineer in foundations, in parts below the surface of the ground, or under water, or parts exposed to wet, to any height desired, the mortar shall be made with hydraulic lime, of a quality that shall meet with the approbation of the engineer. No mortar which has set, or become hard, will be allowed to be used.

"The cement used shall be patent Lithige, or Earle's cement, or any other desired, but whichever be used shall be of the best quality, and shall be approved of by the engineer; it must not have more than one part of clean sharp sand to two parts of cement, and these proportions shall be accurately measured; the mixture shall be wetted only as required for use, and none shall be used that has set or hardened.

"The concrete must be composed of good coarse gravel, or broken stones, either being approved of by the engineer, with an admixture of good sharp sand. The gravel and sand must be mixed with lime, in the proportion of one part of the latter to six parts of the former.

"Stone arches will be of ashler, block in course, or pier points. The beds and joints of the stones must be worked to accurate planes, and the beds in the direction of the radii of the arch. The greatest care must be taken to cut the stone in the spandrils, so as to fit close on the extrados of the arch.

"In all cases where the arches are built askew, the courses must be in spiral lines, at right angles to the face of the arch.

"Pierpoint arches will be laid similarly to brick arches.

"Counterforts must be worked into the body of the arch, and the courses below the springing of the arch must all be parallel to the radius of the arch at the springing line.

"As soon as the weather will permit, or when the engineer may direct, the arch and backing shall be covered with coal tar. Or asphalte, properly prepared and approved of by the engineer, may be used for this purpose, which is to prevent water from sinking into the arch; and the contractor shall be held responsible that the arches, backing, and spandrils shall be made thus impervious.

"Above this coating of tar or asphalte, and, when ordered by the engineer, a coating of sand to the depth of 6 inches shall be laid, and above this, the space must be filled with shivers of stone laid with a regular sur-

* Though iron cramps are often used, they should not be resorted to without much consideration, as the corrosion of the iron is sure to rend the stone sooner or later, and where the iron is much exposed to atmospheric influence this will soon occur.

face, and lastly, a good road metalling, of a kind approved, of 8 inches thick, shall be laid, and the stones properly broken.

"Where stone imposts or springers are used, they must be equal to the full thickness of the arch, besides allowing for the projection, and no stone shall be less than 30 inches in length; where there is more than one arch, at least four stones on every pier shall extend across the whole breadth of the pier. In cases of skew arches, the skew back must be worked out, to suit the oblique direction of the courses.

"Openings must be left through the lower parts of all abutments, wing walls, and retaining walls, and dry rubble drains carried up at the back, in order effectually to prevent any water lodging behind the brick work or masonry.

"The abutments and wing walls shall be filled into and backed with chipping of stone, as far as they can be procured, clean dry gravel, or suitable material approved of by the engineer, and to be procured in the neighbourhood; as they are carried up, the filling and backing shall be well rammed with punning malts, in courses not exceeding eighteen inches thick.

"Culverts, under three feet in length, must be carried to the outside of the fencing. Culverts must be built to the necessary angle, and each culvert shall be so placed as to give a free and uninterrupted passage to the water; and whenever the position or direction of a culvert does not coincide with that of the existing course of stream, the course shall be altered to such extent as may be considered requisite by the engineer, to adapt it to the position of the culvert, by the contractor, at his own cost. They shall be built of materials to be approved of by the engineer, and such as will stand well in water, and shall be set in good hydraulic lime mortar. The site of culverts may be varied by the engineer.

"The foundations of viaducts, bridges, culverts, walls, and other works, must be excavated to such depth as the engineer may deem requisite, and no masonry or concrete must be put in until they have been examined and approved of by the engineer. All the water must be effectually kept out during the execution of the works by means of coffer-dams or pumps, or both, and the coffer-dam or pumps, or other machinery, to be provided by the contractor, and approved of by the engineer. If it is required to carry the foundations lower than shown on drawings, the contractor must execute such additional masonry, brick work or concrete, or piling and planking, according to the schedule of prices, being paid only for such additional work so put in.

"The piles to be of red pine timber, 10 inches square, each pile shod with a wrought iron shoe, weighing at least 18 lb.; the piles to be driven well home, and at least 2 feet into a solid material, with waling pieces, 12 inches by 10, bolted to them by wrought iron bolts, to which 3 inch planking shall be firmly spiked.

"The whole of the timber used in the bridges shall be of the best St. John's red pine or Baltic timber, and the deals from Dantzig, of such lengths as may be required, free from heart shakes, sap, dead knots, dry rot, or any other defects whatsoever, and thoroughly seasoned, having been felled at least two years, and six months out of water. All the trenails used in the bridges shall be of sound English oak. It must be stacked as soon as brought on the ground, and preserved from wet until used. All the timber must be painted with three coats of good oil paint, at such times as the engineer may direct. In measuring timber, no allowance to be made for mortices, tenons, &c., but only the net measurement taken; and the workmanship throughout to be good, sound, and firm, and such as shall be approved of by the engineer.

"All castings shall be moulded of a true form, and free from air holes or other defects, and shall be of correct measured dimensions when ready to be fitted in place. All cast iron shall be of the best No. 2 iron, re-melted in the furnace, and shall be of a quality approved by the engineer; no hot blast iron will be allowed.

"Girders shall be subject to be proved by the hydraulic press, under the inspection of the engineer, and at the expense of the contractor, according to what the substance and form are calculated to bear, and each girder shall be tested by at least one half the calculated breaking weight. Or the iron shall be of such strength, that an inch square bar, of 36 inches in length, between supports, shall bear a weight of 500 lb. suspended in the centre. And, should any castings be injured by testing, or prove unequal to the test, others, that shall be satisfactory to the engineer, shall be provided by the contractor.

"All joints shall be made to fit perfectly close and tight, and no cement stopping or plugging shall be introduced; and in all cases where iron rests upon stone, a milled pad must intervene, and the whole must be put together in the best and most workmanlike manner.

"Wrought iron must be of the best scrap, or No. 3 bar iron, approved of by the engineer, and of sufficient strength to bear, without injury, 15 tons per square inch of sectional area.

"No wrought iron straps, bolts, or other work, must on any account be hammered when cold, without being afterwards annealed. The bolts to be made so as to fit the holes correctly, after they are seasoned to receive them. All iron work must be painted with three coats of good oil paint, without being allowed to rust.

Engineer's Manual of Mineralogy and Geology. By Mrs. Varley. London: Weale. 1846.

This is a very clever little work, well written, lucid in its descriptions, and we think fully carries out the intention of its talented authoress. Mineralogy is a subject of growing interest, both as a pure science, and in its applications to the arts; and a work, divested of technicalities, and the intricacies of nomenclature, is a desideratum. No science has undergone more revolutions in this respect, as we find many minerals have no less than four or five names in different books. A knowledge of the laws, and the relations of crystalline forms, which obtain in the mineral kingdom is valuable, not only as a subject of philosophic speculation, but also in its applications to geology, chemistry, and especially to engineering pursuits. Few men have more frequent opportunities of studying practically the sciences of geology and mineralogy than engineers; for at the present time, when railways are being carried on, and the surface of the earth penetrated in almost every direction, the different strata, and the mineralogical character of the country must be constantly under their notice, and in the words of our authoress, "They ought in such operations to compare and combine an accurate observation of whatever comes under their cognizance with facts already established; and every new incident however trifling it may at first appear, if recorded with precision, will become valuable as an addition to the geological knowledge we already possess."

As an illustration of the necessity of paying due attention to the internal structure of the materials used in machinery, and more particularly to those parts which are subject to a long continuous vibration, we may instance the alterationof structure to which the iron axles of railway carriages are liable from the perpetual vibrations to which they are exposed. The toughest and most fibrous wrought iron is always selected for the construction of these axles, and from this continuous vibration the particles assume a new crystalline arrangement, assimilating to the construction of cast iron, and eventually becoming brittle. We understand this important point is under careful examination. Some very interesting specimens of iron axles which have undergone the molecular changes in question, may be seen at the Museum of Economic Geology.

We will now give a brief sketch of the subjects in the work, and the manner in which they are handled. The first 42 pages give a short account of the rocks of Devon and Cornwall; the unstratified rocks, granite, syenite, greenstone, basalt, porphyry; all of which belong to the trap formation with the exception of granite; also the places at which they most abundantly occur: then follow the stratified rocks, gneiss, mica-slate, clay-slate, the old and new red sandstone formations, carboniferous and oolitic systems, cretaceous and tertiary systems, with the minerals which are found in them—with a short account of the analysis of them, by that invaluable little instrument, the blow-pipe. Although we agree with the authoress that "in the greater number of cases, if a specimen of ore be characteristic, an accurate observation of its external character will enable us to recognise it without having recourse to chemical process;" yet we would strongly recommend students who wish to acquire a knowledge of mineralogical science, first to obtain some acquaintance with chemical analysis. A few tests or re-agents, combined with the application of the blow pipe, will enable them to perform a qualitative analysis of an ore, and thereby obtain a much more intimate knowledge of the composition and nature of the ore than could possibly be acquired by the simple observance of its external characters: again, according to Mitscherlich's law of isomorphism, there are minerals whose crystalline forms are identical, but whose chemical composition is different.

The different ores of gold, silver, copper, iron, &c. are next brought under consideration, their characters are succinctly given, and the richest ores for smelting stated. The tables of analysis of silver and copper ores are valuable, as showing the amount of metal which can be extracted from each one: we should have liked to have seen the same carried out for some of the other metals. The next part of the work treats of the mineral rocks and earths, and closes with the physical characters of minerals, embracing a brief account of the doctrines of crystallography. We would notice the only error which we have observed while perusing the work, and that for the purpose of having it corrected in a subsequent edition. It is stated, page 46, that gold is soluble in hydrochloric acid, which is a mixture of nitric and muriatic acids; now, hydrochloric acid is the new name for muriatic acid, and as such, gold is insoluble in it. Gold is not dissolved in any of the pure acids; its best solvents are chlorine and nitro-hydrochloric acid, and the latter only when it gives rise to the formation of chlorine. We might observe that fluorine also combines directly with gold. In every other respect the work merits our most cordial approbation, and our thanks are due to the lady who has produced a book which we feel assured will be useful.

The NEWLEAFE DISCOURSES *on Fine Art Architecture. An attempt to talk rationally on the subject.* By ROBERT KERR, Architect. Weale, 12mo. pp. 208. [No date.]

The author of this book ought to be condemned to write his own review of it: his principles are so indefinite, and are expressed in such diffuse language that no one but himself could give a fair analysis of them.

Trusting to the table of contents more than to an examination of the book itself, we may state that the subjects considered are mainly these:— The definition of architecture, considered as a fine art, comes first. Then follows a contrast between an orthodox, well-fed, alderman-architect, distinguished principally by a sedulous regard for the main chance, and a heterodox, visionary, artist-architect, distinguished (as we should say) by having, as times go, no chance at all. Next, the several pursuits of two such architects are distinguished, and are illustrated, moreover, by some stories which are meant to be very funny, and are in fact very puerile. Archæology, the history of architecture, Ecclesiolog*ism*, architectural study, &c., are subsequently considered. The concluding topic is the Royal Institute of British Architects.

We quite agree with the opinion published by Candidus last month (*ante* p. 328), that the book is clever and entertaining, and the doctrine (what little there is of it) excellent. We think also that the writer has displayed a generous courage in defence of his art by boldly—and without respect of persons—denouncing all attempts to degrade it. But what we chiefly object to in these Discourses is, that they are overladen with verbiage. The reader plods on—and on—and on—page after page, expecting every moment to arrive at the gist of the argument, but never reaching it till he be fairly tired out. You are perpetually reminded of eating *omelette soufflé;* or quote mentally Polonius's question to Hamlet, with the reply—

> "What do you read, my lord?"
> "Words, words, words."

The question of Precedent, which occupies our author a good deal, seems capable of being so easily stated, as to be scarcely worth discussing. Antiquity affords a presumptive, but not a final, proof of excellence. There are precedents for error as well as for truth, for bad architecture as well as for good; but still we may presume that, on the whole, good architecture would be the most carefully preserved. The noblest monuments of ancient art are old because they are good—not good because they are old. That is to say, their long preservation is the effect, not the cause, of their excellence.

Both good and bad precedents have their value, however: the former teach us what to emulate (not imitate), the latter what to avoid. It is well enough to say that all art must be ultimately criticised by the principles of beauty observed in nature; but this canon, invaluable as it is as a fundamental truth, is of that abstract nature, that its full value can be learned only from its examples. Two architects may both agree as to its accuracy and importance, and differ *toto cœlo* as to the methods of *applying* it. The right-thinking student, therefore, will not refuse to benefit himself by the efforts of his predecessors, which enable him to compare actual examples of these different methods.

Or, to view the subject a little more metaphysically, is it not clear that the principles of beauty observed in nature, are *applied* in nature in a manner in which they cannot be applied in art? What the architect wants to avail himself of are, not so much natural forms as natural principles. Now the process of separating the one from the other is too difficult to be effected by a single trial—it must be tentative. It is only after many trials and many failures that we shall be able to combine masses of masonry into forms useful for artificial purposes, and yet strictly restrained by "the modesty of nature." That a man may have sufficient genius to do this at once is possible, though not probable; but for men of ordinarily constituted minds the bare knowledge of principles is insufficient; expertness in the correct use of them is the result of actual practice. An accurate knowledge of hydrostatics, for example, does not necessarily lead to dexterity in the art of swimming; and a man may be thoroughly versed in the theoretic rules of horsemanship, and yet break his neck in the first attempt to apply them.

The attack upon the Archæologists and Camdenists is ingenious enough, but not sufficiently discriminating. Archæologists no doubt have their follies like other people, and are especially apt to consider that the most estimable parts of antiquity are its dust and rust. Still the Archæologists are our fellow labourers, and useful in their way. They have often preserved or discovered monuments of the Beautiful which had else been lost —and the Beautiful is ever to be venerated whatever be its date or the designation of its guardians. The Camdenists are a still more valuable body, for they openly avow the doctrine of progression. It is true that they are slightly touched on the subject of symbols, and are apt to wander and talk wildly when the topic is introduced. They display also a most lady-like punctiliousness on the subject of dress. But take them from their idiosyncracies and they show an honest generous enthusiasm for artistic architecture—talk like men who observe diligently, and yet are capable of reasoning for themselves; reason for themselves, and yet are not above confirming their judgment by observation.

The strictures upon the Institute of British Architects are, we fear, too correct. It were difficult to say what the Institute has done, since its foundation to advance the art which it professes. It is clear that the collection of editions of Vitruvius and prize essays on slates does not forward architecture a single step. Can the most zealous member of the Institute inform us of any one fact or opinion elucidated during the last sessions which will tend to the advancement of architecture? We know of none—except it be the ingenious investigation by Mr. Penrose,* tending to show that the Greeks observed in their works one of the sources of beauty which has been overlooked by the moderns. There were discussions *usque ad nauseam* about plaster imitations of stone, and the Five Orders, and prizes for architectural designs in which the canons of constructive fidelity were systematically violated. But efforts such as these are not progressive, but retrograde.

The truth is that the Institute is too orthodox—too big-wigged—too *donnish*, to use a Cambridge word. The individual members have, we believe, a sincere love of architecture, and are actuated by the best intentions; but they are infirm of purpose, fear to speak unless they can quote chapter and verse for their authority, and shut their eyes to the fact that the whole system of architecture has grown debased by the lapse of time, and wants reforming.

Mr. Kerr's talents are certainly above mediocrity, and his denunciations are courageous, if not the most prudent. At all events he shall not have cause to complain that we are opponents of his efforts to purify architecture. We are among the malcontents ourselves. The reform of abuses which Pugin advocated in the Pointed style *must* in spite of opposition be extended to all styles, and if Mr. Kerr will but write a little less diffusely, and lay down more definite and tangible principles, he may become an invaluable labourer in the good cause.

We had nearly forgotten to state that a considerable part of these Discourses is a republication of letters addressed to *The Builder*. This fact, in courtesy to our contemporary, ought to have been stated in the present volume. The pervading fault seems to be an over-anxiety to be facetious. We do not mean to say that there is no real original wit in the book, but simply that we have been too dull to perceive it.

A Manual of Gothic Architecture. By F. PALEY, M.A., with nearly seventy illustrations. London: Van Voorst, 1846. 12mo. pp. 304.

An instructor should always know more than he teaches. It might appear at first sight that the writer of an elementary treatise need possess no more than elementary knowledge; yet it is a matter of experience that those who have not advanced beyond first principles cannot teach first principles correctly. Profound erudition has never been more worthily displayed than in smoothing the paths which lead to the gate of knowledge.

Architecture is at present in a state of transition from a crude code of dogmas to a systematic science. Some of the simplest principles are at this moment the subjects of warm controversy, and until those principles have been definitely agreed upon, it is evidently impossible to write a complete elementary treatise upon architecture. Such a work may fitly teach all that has been strictly ascertained, but the debated points must be reserved for those who are competent for the discussion.

It follows from these considerations that there are two qualifications requisite in a Manual of Gothic Architecture—profound knowledge on the part of the author, and the exclusion of uncertain speculations. The first of these requisites is perfectly, the second generally, satisfied in the work before us. The object professed is simply to teach the uninitiated to distinguish and classify architectural details, but many of those who deem their knowledge sufficient to qualify them for the practice of the art would find their errors tacitly demonstrated in this unpretending treatise. Mr. Paley however considers the present imperfect state of church architecture neither acrimoniously nor ungenerously: he sets out by acknowledging

* See ante, p. 97.

that "we are all too ready to disparage unjustly the works of modern architects, who more frequently want the means than the power to produce Gothic works equal to those of antiquity. It is next to impossible to judge of modern designs with strict impartiality; and critics are seldom fully aware, or disposed to admit, how much their judgment is warped and biassed by that utterly false and unjust notion, that every mediæval work is good, and every modern imitative design is a failure."

The first chapter traces in general terms the history of church architecture from the fall of the Roman empire to the present time. Respecting the word *Gothic* it is observed that "the term is in itself absurd and calumnious; but it has now become so general that it avails little to endeavour to supersede it by another." We cannot assent to this conclusion. The word *Pointed* is now popularly understood to refer to all styles in which the arch is angular at its vertex, and has been so generally adopted by architectural writers that the revival of the word *Gothic* seems like a retrograde step. Moreover, Mr. Paley does not adhere consistently to his own argument, for he proposes to disturb the present terminology of English Pointed architecture and to substitute new appellations for those which at present are used without inconvenience, and being descriptive are easily remembered. The term "Third Pointed" would confound the Perpendicular of England with an altogether different style—the Flamboyant of France: a similar objection applies to the term "First Pointed." On the other hand the term "Early British," or "Anglo Saxon,"—the first on Mr. Paley's list—refers to our own architecture exclusively. His nomenclature seems therefore unsystematic; in one case his desire of generalizing leads him to overlook national peculiarities of style; in another he disregards his own generalization.

The second chapter treats principally of round-arch architecture. In the following extract, the first statement is contrary to known mechanical principles, and appears sufficiently refuted by what follows it.

"The pressure of Norman vaulting is straight downwards on the walls, that of Pointed vaulting oblique, or lateral (See Hope, p. 312). Yet, from bad construction, or other causes, Norman vaults have a great tendency to push outwards the supporting walls. The aisle of St. Sepulchre's, Cambridge, actually fell down from this cause just before its late restoration. Thus some resistance has been proved by the result to be wanting, though the want might not be known or suspected at the time."

In the third chapter the successive development of the three Pointed styles is admirably treated, and the engraved illustration possesses singular beauty.

A subsequent chapter is devoted to "the uniformity and progressive character of the Gothic styles." The following extract is a long one, but the subject is so interesting, that we have made but few omissions.

"No architect of the present day is fettered by any other rules or conditions than those imposed by his employers, in regard to the choice of a style. He may copy that of any nation and any period, and he may alter, combine, detract from, or add to it, as he pleases. Indeed he must do so more or less, because no one recognised and distinctive national architecture, either ecclesiastical or secular, exists at the present day. It is all copied, and none of it is, properly speaking, original or self-developed. It has ceased to be inventive, at least in any favourable sense.

"But the case was very different in the Middle Ages, when freemasonry was a craft in the hands of a corporate ecclesiastical confraternity, the members of which seem to have been bound down to certain rules, and yet to have had almost unlimited license in carrying those rules into effect; precisely in the same way as if the alphabet of a language were given to any one, and he were allowed to combine the letters into words as he pleased, but not to introduce any new forms or symbols. This seems exactly to illustrate the position in which the ancient freemasons stood. They had certain *kinds* of mouldings, foliage, window tracery, &c, which were, with comparatively trifling modifications and exceptions, repeated in all buildings of the same era, only very arbitrarily combined, arranged, or applied. For example, in the age of the Complete Gothic or Flowing-Decorated, all window tracery was designed on one fixed principle; it was neither geometric, nor rigidly vertical, as in the next style; but it was, with surprisingly few exceptions, of wavy and curved lines. Yet each architect seems to have had full liberty to adapt this principle to his own taste; and thus we find thousands of different patterns. Again in mouldings; some ten or a dozen forms being employed by all with inflexible exactitude, their *grouping*, or positions in relation to each other, as well as their application, seems to have been the result of individual caprice (See Hope's Essay, p. 213). And herein is the glory of the Gothic styles, that they attained by these means *perfect uniformity combined with almost infinite variety.* There is no monotony, no wearisome repetition; every detail has some freshness; yet all are strictly subjected to certain laws of composition. Hence that charm of never-ceasing interest created by perpetual novelty; for this in reality is a much more enduring gratification than either the magnificent effect or the exceeding aggregate beauty of some buildings, both which impressions are rather those of first sight, while the minute detail of any one building might engage the attention for months, or even years.

"Little or nothing has ever transpired of the secret system which the freemasons adopted in building, nor of the organisation of their body, except that it was ecclesiastical, and under the jurisdiction and benediction of the Pope. It is certain that they were a very numerous, energetic, and talented class, whose genius was chastened and ennobled by all the enthusiasm of a grand religion, and whose efforts were aided by the supply of almost unlimited resources. They must have had the entire monopoly of both domestic and ecclesiastical architecture; though perhaps the distinction is vain, for everything in the Middle Ages was ecclesiastical. ....Constant communication must have been kept up between all the members of this numerous and widely-extended body. For if we consider the immense number of churches built in every reign from the Conquest to the overthrow of the ancient religion, and the perfect uniformity of style in all of the same period, we shall perceive how complete the intercourse must of necessity have been. Perhaps the following is a plausible scheme of their constitution. Those whom we now call architects seem to have been designated 'Masters,' as we read that 'the Master' did so and so, in ancient accounts, where it is clearly equivalent to 'the Architect.' These 'Masters' must have been trained in one and the same school, just as our clergy are trained in the universities, and they seem either to have been sent about to different stations, or to have been attached to some mother church or cathedral, or even to have taken up their permanent residence in certain localities, since we often find several churches in a particular neighbourhood which clearly exhibit the same hand in their design.

"Though we may in most of the arts attribute a good deal to mere fashion, which might formerly (it may be said) admit of as little variety in architecture as it now does in the shapes and materials of costume, still this is quite insufficient to account for the positive *identity* of coëval capitals, bases, foliage, windows, &c., in the two opposite extremities of the kingdom. We suppose therefore there was either some central school whence all such details emanated, or, which is the same thing, the Masters went about as so many missionaries, disseminating what they had learnt or developed together. How this adherence to rule for a long period can be reconciled with the phenomena of sudden changes in, and eventually complete revolutions of, style, or who had the boldness to suggest, or the authority to enforce, novelties in the masonic art, must be matters of mere conjecture. In England, indeed, the employment of foreign artists will account for many new introductions; but the question remains the same,—whence did these foreign artists themselves derive them? However such changes were first introduced, they were quickly adopted *semper, ubique, et ab omnibus*.

"William of Sens is the first known master mason whose works are extant. The masons were not *incorporated* in England till the thirteenth century; yet there is at least as much uniformity of detail observable in the Norman and (as before observed) even in the Saxon styles. An oath of secrecy is said to have been tendered to all novitiates.[1] They appear to have been convened and held secret meetings at certain times and places. The name *Free-masons* is a corruption of *Frères maçons*, or fraternity.[2] A presumptive proof how exclusively the details of the art were in their keeping may be derived from the blundering attempts at drawing them, which are always found in MSS., stained glass, brasses, and fresco paintings. The master masons were generally foreigners, incorporated by royal authority. When a large building was contemplated, the masons removed in great numbers to the spot; hence they have been well described as a kind of 'nomade race.'[3] How they were paid, or how maintained during their sojourn, is not certainly known. Perhaps the masters did not so much design, as carry out the designs of powerful and munificent ecclesiastics.[4] A good deal, too, of actual handy-work was done by the ecclesiastics[5] themselves, which will account for any of those touches of the satirical in the way of droll portraits, which seem so pointedly directed against rival clerics.[6] But when we read of repairs and buildings executed by abbats, bishops, or monks, we must generally understand the expression to mean that they promoted them, but that masons were employed in carrying them out.[7]

"'The old builders possessed nothing but the sound intelligence of sensible men, and an aptness in practice exercised from earliest youth. They lived more at the building place than at home; thought of little else and did little else; and thus they evidently succeeded much better than our well-grounded sages, who often bring into the world their left-handed productions, or tamely written pamphlets, and would fain superintend the erection of buildings from their writing-desk.'"[8]

"One thing is quite clear, and admitted by all; that the masons of the time being were absolutely restricted to *one style*. They never thought of going backwards, under any circumstances whatever, and seem to have contemned the very idea of copying older work, however incongruous

would be the result of the new, in additions to, or alterations of, a pre-existing edifice. In fact, they thought they could improve upon it. Of this principle many of the most interesting illustrations might very easily be adduced, did space allow their insertion. Scarcely ever did they compose a single detail even with a view of *suiting* the older work; for in truth they had a thorough contempt for uniformity. They placed traceried windows of many lights in juxta-position with single lancets, pointed with semicircular arches, and complex Gothic columns with plain and heavy Romanesque piers........It is very possible that the masons themselves, in always using the style of their day, desired to stamp an imperishable evidence of date upon the works they were executing........In altering churches, the parts most generally preserved were doorways, nave piers and arches, north-west aisle windows (for some unexplained reason), sedilia, piscinæ, fonts. The parts most commonly innovated were windows, aisle walls, clerestories, roofs, porches, chantry chapels.

"It is very singular to observe how even the slightest changes and turnings of style were regularly adopted in the progress of such large buildings as required a great number of years for their completion. For example, the west elevation of York Cathedral exhibits early Middle Pointed work in its lower part, while the belfry windows, battlements, and pinnacles are finished of pure Third Pointed detail.* These changes we may attribute to the succession of new master masons, each of whom could or would design only in the details of his day.

"Every master mason must have been able at all times to command the services of workmen well acquainted with and accustomed to the working. Perhaps these operatives (*confrères*) accompanied him from place to place; certainly they must generally have devoted their lives to the work; for the exquisite chiselling of the boss, and floriated capital, or the statuary and canopy work of such a place as the Lady Chapel at Ely, could never have been attained without intense and zealous application, aided by great taste and artistic feeling, and long practice. Probably the few modern architects to whose lot it has fallen to carry out work of this description, would verify this from their own experience. It is one thing to design, another to find workmen capable of executing accurately the more minute and difficult details. That such workmen did anciently exist, and in great numbers too, is proved by the works they have left behind them as monuments of their skill. It is probable that they worked by drawings, as at present; or the plans were laid out for them by the master's hand, as occasion required; of which perhaps the diagrams and geometric marks sometimes found on the stones of disjointed buildings may be taken as examples. Yet there are parts occasionally to be met with which must be called 'botches,' and which are clearly the results of extemporary constructive ingenuity without any pre-arranged plan..........There must have been, for centuries previous to the change of religion, a constant, untiring, incessant zeal for church building, a zeal which is more striking, when contrasted with the dead apathy, or at least the almost exclusive plundering and demolishing, which from first to last has characterised the new system. Only let the reader contemplate the vast quantity of ancient ecclesiastical work we still have left, taking into account the *enormous* destruction of the sixteenth and seventeenth centuries, and the unceasing havoc of the combined causes of neglect, avarice, and profanation, which have been in active operation for three hundred years! When we think of some towns having anciently had forty or fifty great churches, where not more than ten or a dozen now appear, all the rest having long ago been razed to their very foundations; of a thousand abbeys and religious houses, of which scarcely one hundred shattered ruins now remain, though some of them were fully as large and splendid as our first-rate Cathedrals, —Glastonbury, Reading, Bury St. Edmund's; when we know fully what we have lost, in comparison with what we have left,—we shall be indeed amazed at the almost superhuman efforts of the mediæval church! It has been computed that each one of these vast Cathedrals or conventual edifices would cost, in our times and with our much greater facilities, from five to eight hundred thousand pounds. A million of money must have been expended on the fabric of some of our greatest churches; and if we may credit the accounts of the vast wealth stolen by Henry VIII. from Canterbury and Lincoln Cathedrals, and include all the vestments, plate, and other furnitures, the stained glass, pictures, tombs, silver statues, and shrines, we are justified in doubling that sum. How inadequate a notion do our present bare, dilapidated, and rifled structures afford, of the amount which religion once bestowed on the Church, and which irreligion has sacrilegiously taken from her!"

There are many other parts of the work from which we should like to make extracts, but our limits prevent us from extending them. We must therefore refer the reader to the work itself: we cannot however omit the following quotation in which the ancient and modern principles of church building are happily contrasted.

"Let us now observe how completely every one of these principles has been INVERTED in modern practice, and we shall have obtained some clue in tracing the causes of modern failures.

"Modern principles are:

"1. To make buildings uniform by equal and similar wings, corresponding doorways, windows of the same size and kind, level and regular elevations, not broken up into parts of greater or less prominence and height. Every Gothic new building in Cambridge exhibits these faults, which are the certain result of the same hand composing in two contradictory styles, Classic and Gothic.

"2. To add unnecessary and unmeaning ornament in conspicuous positions to attract the eye and produce a showy appearance, leaving the less exposed parts bare and naked in the contrast.

"3. To place effect before utility, as by building an inconvenient or unnecessary feature because it is supposed to look well. Hence we have doors which afford no entrance, turrets with no available interior, and chimneys which do not emit smoke.

"4. To erect buildings whose primary idea is that of a large unbroken area, without columns and arches, with wide roofs, and without distinct component parts. Such *were* the great majority of the modern churches, which often had neither buttress, nor string-course, nor arch in the whole design; in short, nothing Gothic about them except the minor details.

"5. To use *usque ad nauseam* a few hackneyed Gothic details, copied from celebrated churches or cathedrals, or borrowed from books; and to apply these without sufficient regard to difference in the *kinds* and character of buildings.

"6. To sacrifice solidity and strength to unnecessary and adventitious ornament, and to impoverish the fabric to obtain the greatest possible amount of conspicuous but needless decoration.

"7. To arrange exterior elevations without regard to the nature of the interior, or to force the latter to suit the former; as to give the outward appearance of nave and aisles where there are no columns or arches inside; of three gabled roofs where there is but one flat ceiling within; of pinnacles or gable-crosses which are but chimneys. Hence the custom of building *masks* either to hide necessary parts which do exist, or to give the idea of those which do not.

"8. To be satisfied with actual weakness without even apparent lightness, as by the use of plaistered timber to imitate stone, and by the omission of essential constructive details, such as shafts, mouldings, and the visible resistances of lateral thrusts.

"All might be summed up in a very few words. The ancient churchmen built for God, not for man; for the church, not for private interest; for religion, not for fame; for endurance, not by contract; for devotion, not in a spirit of economy; *pro salute animæ, non pro crumena.*"

There are of course many opinions incidentally expressed by our author, which might be disputed—such as the indiscriminate intolerance of Classic architecture, &c., but it is not necessary to discuss here topics which have been fully treated in other parts of this Journal. The student who desires to learn the elements of Christian architecture accurately, may be confidently referred to this work. Our criticism however relates exclusively to the architectural information: respecting the religious dogmas which the author briefly propounds, or rather alludes to, it is not within our province to offer an opinion, beyond an expression of regret that Mr. Paley has suffered his name to be involved in the religious dissensions which unhappily exist in our Universities. These disputes are in any case deplorable, but the evil of them is greatly increased when they tend to diminish the public esteem of our academic institutions as "seminaries of sound learning and religious education."

STEAM NAVIGATION.—GUN STEAMERS.

(With Engravings, Plate XIX.)

We are indebted for the following judicious remarks on a better adaptation of the light classes of steamers to the objects of the naval service, to a letter from Mr. REDFIELD to the Navy Commissioners of the United States, published in the *Franklin Journal*. It is a sequel to the report given in this Journal in September last, p. 207.

1st. The proportion of length to breadth in these steamers should never be less than the average of class C—the length being equal to *nine breadths* or *diameters*; and, if extended to nine and a half, or even ten diameters, this will perhaps be within the limits of maximum advantage. These ratios of length are especially required for objects yet to be noticed. The proportion of *depth*, however, may be slightly increased, if sufficient care be taken to restrict the top weight.

2nd. The extreme horizontal outline of the deck and guards should be brought *within* an angle of fourteen degrees from the midship line at the bow and stern; in order not only to ease of motion, but to favour the deflection of the shot of an enemy from the hull when engaged *head or stern on*. The bow and stern angles at the water line will necessarily be much finer—say within the semi-angle of eight or ten degrees. The stem and stern post should be nearly vertical, and the floor frames, or at least their rudimentary forms, should be extended forward and aft to the joinings of the stem and stern post; dispensing altogether with the common "dead wood" of the stern. Suitable provision should also be made for steering in opposite directions, with either stem or stern foremost.

3rd. The deck frame should consist of plank-sawed and deep-moulded scantlings, one to each frame of the vessel, and screw-bolted to the same in crossing to the guard or fender line. The common deck knees should

* Exeter Cathedral was, however, carried out on a uniform plan for fifty years by Bishop Quivil.

be dispensed with, and snug knees of hackmatack be applied externally, at proper intervals, where the projection of the guards will permit.

4th. There should be a very light hurricane-deck over the central portions of the hull, and extending to a length equal to two or three diameters of the vessel. All the constructions above deck should be of the very lightest description, and be comprised, if possible, within the same limit. Thus the forward and after ends, each to the extent of about three diameters of the vessel, would be left free of incumbrances; excepting the gun-fixtures and other indispensable attachments.

5th. The engine should be so placed below deck as to act directly upon the cranks, as in the steam frigate Missouri, if the midship body of the vessel will allow of this arrangement; otherwise, a half beam arrangement may be resorted to. The paddle-wheels should spread less on the shaft than is common in American steamers, and the paddle be extended to a point at its centre in a trapezoidal or triangular form. This form will admit of a greater immersion, and thus obtain a better resistance, than the common paddles, especially in a sea-way. The crank and chimney openings in the deck should be comprised in a narrow enclosure, with upright sides, extending fore-and-aft-wise to a point, so as to present an acute angle of deflection, for the protection of the crank and lower part of the chimney from shot when *end on* with an enemy. The main shafts, which must be above the deck, should also be protected by *deflecting planes*, covered with iron and slightly inclined from horizontal.

Much apprehension has been sometimes manifested for the safety of the wheels and paddles when under fire; but those who have employed steamers day after day, for successive seasons, in encountering ice from four to fourteen inches in thickness, and who have witnessed the speed of a steam vessel when one half or more of the wheel arms and paddles have been disabled in this service, will think more lightly of this hazard; to avoid which, almost every quality valuable for a war steamer has sometimes been sacrificed.

6th. To sustain the guns, the scantlings beneath them should be somewhat enlarged in thickness, and securely stanchioned and screw bolted. The gun pivots should be of strong timber, adequately secured to the deck-frame, and extending to the keelsons. The deck, where exposed to the action of the guns, should be strongly sheathed, and the whole be secured, if needful, by transverse bars, strongly bolted or clamped to the deck-frame; and, if necessary, connected by vertical bolts and stanchions with the floor-timber. When about to engage, sand bags, or other equivalent weights, may also be used for covering that portion of the deck exposed to injury from the explosion of the guns.

To illustrate my views of the proper form of construction of these vessels, I annex an approximate sketch of the deck plan and guards. This outline has, for its base, the elongated rhomb *a a*, *b b*, (fig. 1, Plate XIX.) and presents at the deck a guard line of the bow and stern, *a a*, the maximum semi-angle of fourteen degrees; which is only equal to that which has been already adopted in some well-proportioned steamers for coast service. It also contemplates a length which is equal to nine diameters of the vessel; each of these diameters being visibly set off on the plan, fig.

It will be found, practically, that this proportion of length is sufficiently limited; for the engine, if placed as proposed, will require much length, and the necessary weight must, also, for a light draft, be extensively distributed. Moreover, the first diameter at each extremity, the flotation of which can properly support little more than itself, may be viewed as substituted for the cutwater, bowsprit and other fixture, which is commonly attached to heavy steamers and sailing vessels; while the second diameter thus set off, answers practically to the usual bow and stern in other vessels; thus leaving five diameters for the proper body of the vessel and the necessary machinery and storage.

7th. The armament of each steamer, I apprehend, should consist of *six traversing guns*. Two of these, of ten inches calibre, should be worked each on a strong pivot, placed on the line of the keel, at the distance severally of about one and a half or two diameters of the vessel from the stem and stern post. The four remaining guns, each of eight inches calibre, may be worked on like pivots, placed near the sides of the vessel, and as much nearer to the main shafts as will avoid interference with the two larger guns. When engaged with an enemy, *the line of fire should always, when practicable, be in the line of the keel.* The above mentioned ordnance constitutes the armament of the recently constructed war steamers of England; and, so far as I can perceive, is the most appropriate and effective for a steam vessel: the peculiar vocation and advantages of which ought to be rapid motion and effective fire.

Perhaps some persons may entertain apprehensions of the inability of these light steam vessels to carry and sustain the action of the guns above mentioned. But these apprehensions are without any just foundations, as will appear from the following facts and considerations:—(1.) The points at which the guns are placed, require an access of weight equal to this armament, in order properly to equalise the load throughout the body of the vessel. (2.) The weight merely of these guns is no more formidable or destructive to a vessel than a like concentrated weight of other heavy articles, of which vastly greater amounts are safely carried in all weathers on lighter decks than I propose for these vessels. (3.) Owing to their large capacity, and their great superficial bearing upon the water, these vessels are better able to bear the addition of the above weight than any vessels now in the naval service.

This may appear from the following facts: First, the average load-line area, or bearing superficies, of class C is nearly *three-fifths* of that of the Brandywine frigate; while, if we allow 50,000 lb. for the guns and carriages of the steam vessel, and 48,000 lb. for the ammunition and other accessaries, it will then equal but *one-fifth* of the weight of the armament and its accessories of the Brandywine; and will require to sustain it only a draft of 4½ inches from the light load-line. Again, this average superficial bearing of the steam vessels is more than *four-ninths* that of the Ohio ship of the line: while the above weight of guns, ammunition, &c., is less than *one-eleventh* the weight of the military outfit of the Ohio. Once more, the average height of the *decks* of these steamers above the water at midships, exceeds *six feet*, with an average bearing surface of near 7¼ feet per ton of the vessel and its contents; while the height of the port-sills of the Brandywine and Ohio are but 5½ feet above water, with an average bearing superficies of nearly 2¼ feet per ton. This shows an immense proportion in favour of these steamers, in the ability to carry accessory weight. Hence, this class of steamers may not only carry this armament, but, in addition, may also transport, when occasion requires, from five to eight hundred troops.

It may be well to notice here the apparent chances of this class of steam vessels when opposed to heavy war ships of the rates above mentioned.

1. *The choice of action* and position will always belong to the steamers. This is important when opposed to any force whatever; for the most favorable time and circumstances for combat may thus be commanded, or, if it should be proper and advantageous, the action may for the time be easily avoided. While, on the other hand, an equal or inferior force need not be allowed to escape.

2. *The target surface* presented by the Ohio when in chase, below the hammock rails, is probably equal to 1450 square feet; and in broadside about 5000 square feet. The cross area of the Brandywine presented in chase is probably equal to 940 feet, and that of her broadside area near 3800 feet; while the average cross area of the hulls of the steamers of class C exposed above water, to a height of seven feet above the deck, is only 340 feet. Now, as the steamers will probably engage chiefly at long shot, and *end on*, we may here perceive how great will be the advantage for the steamers, with equal skill in gunnery, whether or not a sufficient number of steamers to match the broadsides in weight, be taken into the account.

I say nothing here of the extraneous exposure of the wheels and smoke-pipes on one hand, nor of the spars and rigging of the ships on the other: believing that these chances, with proper precautions, are not unfavourable to the steamers.

From the great stability and superior steadiness of these steamers when in motion, particularly on the line of the keel, and from the accuracy with which they may be made to bead *on or off* an object, by means of a marking point subtended above the bow, to guide the helmsman, they will afford to skilful gunners greater accuracy of fire than is usually obtained in ships, unless the latter be lying in smooth water.

In comparing the weight of metal opposed, if we reckon to the steamers the full weight which is due to the increased calibre of their guns (and considering the greater destructiveness of shells to a ship, this appears not improper), we shall find that four of these steamers, each with three guns engaged, will exceed, at each round, the weight of shot thrown by the broadside of the Brandywine; and that the fire of seven steamers will equal, in like manner, the broadside of the Ohio. While, in chase, there would be an overwhelming advantage in favour of the steamers. In these estimates the weight of shot thrown by the broadside of the Ohio is taken at 1600 lb., and that of the Brandywine at 804 lb., as by advisement; and the shot of the eight and ten inch guns at 68 lb. and 98 lb., respectively.

As regards the relative power of endurance, if shells are used, as they doubtless will be, this power in a vessel cannot be in proportion to the weight and massiveness of the structure; and may prove quite the contrary. But, if the form of model and position in action, which is here recommended, can be made efficacious in some degree for the protection of the engine and boilers below deck, which seems practicable, the steamers, with equal gunnery, must clearly have greater advantages for the endurance of fire in the aggregate than will belong to the ships. Besides, if we may estimate the aggregate power of endurance to be in proportion to the bearing area or superficial extent of the vessels, as appears not wholly improper, this advantage will be proportionally in favour of the steamers. Moreover, in shell-firing a single shot may prove fatal to a ship; while even a like result to one or more of its alert antagonists need not cause a discontinuance of the combat.

However important it may be to maintain a powerful and well ordered navy, consisting of ships of the established classes, it can hardly be in our power, or within the scope of our policy, to maintain a numerical superiority as against England, even on our own coasts. And without such superiority, or at least a near equality, effectual blockades may not hereafter be prevented; to say nothing here of the chances of losing our ships and naval arsenals, by the onset of a powerful and well appointed expedition, supported by a numerous fleet of ships and war steamers.

With the aid of her numerous and heavy armed steam ships, England might effectually blockade not only our ships, but our war steamers of the heavy and medium classes. For our steamers of these classes could hardly put to sea, or return to port, in the face of a superior force of the same character; and it would be quite in vain to attempt gaining a superiority of this force by new constructions of like kind, for the present means of England, both mechanical and financial, are sufficient to outdo us in this effort, more than three to one. It is therefore indispensable to our superiority, that we should be prepared *with faster steamers, of lighter draft*, *and equal weight of metal, with those of England.* These steamers, being of the classes which I propose, could never be blockaded in our ports by the existing naval means of any country. Moreover, if maintained in sufficient numbers, so as to be readily assembled in large squadrons at the points where the exigencies or demands of the service might require, the most powerful fleets would be unable to maintain a blockade, or to carry out with success a military expedition against our shores.

The same classes of steamers are also of essential importance on our frontier lakes, where armed steamers of the heavy classes and draft of water hitherto adopted, would be of greatly inferior value; and where all the strategetical advantages will be in favour of the classes proposed.

The greater value and adaptation of light built steam vessels, tenaciously constructed—not less in length and size, nor exceeding in weight and draft, the average of the classes C and D, may be now reviewed, or more summarily considered.*

I. Their facility of movement and surpassing speed, exceeding that of existing war steamers from three to six miles an hour, must necessarily afford, as above mentioned, the choice of action and position; and excepting accidents, no enemy can either escape or overtake them, except at the will of their commanders.

II. Owing to the light draft of water and greater speed of these vessels, they may shelter themselves from a superior force in shoal positions, or attack and annoy the enemy from such positions on a vast extent of coast and inner waters, where heavy ships or steamers cannot approach. When the elaborate survey of our coast, now in progress, shall have been completed, and our officers shall also have become familiar with these shallow grounds by active coast service, in proper steam vessels, these facilities may become of great value.

By this means, not only may the exposed positions at Key West and other points be maintained in war, and made available for the annoyance of an enemy, but the strait of Florida, if not the other outlets of the Caribbean Sea and Gulf of Mexico, may be effectually and securely blockaded by squadrons of these steamers.

By means of these active steam vessels, and a suitable and skilful force of marines and marine artillery, trained for both land and sea service, which, I trust, may shortly be provided, an enemy's colonial posts may be captured, and his military resources laid under contribution. By like means, in case of a war with England, might the coal furnishing ports, and other outposts near our eastern frontier, be taken into our possession, and retained, or abandoned, as occasion might require.

It is chiefly by these means that we may expect to command, in such emergency, the more hazardous coasts of Maine, Nova Scotia, and the Gulf of St. Lawrence; thus cutting off the communication and military supplies of an enemy, and virtually blockading his American colonies. On these rocky coasts, as elsewhere, any general degree of safety which might be supposed to result from solid built bottoms and heavy structures, may be far more than compensated by lightness of draft and tenacity of structure, and facility of movement; while in security against attack from a superior steam force, the heavy built steam vessels could maintain no equality with the light footed classes. The coast of Maine affords all necessary shelter and resources for this service; and this description of force, if matured by timely preparation, and put forth in our strength, might generally command the coasts and shores, from Quebec to Nantucket. Two or three vessels of the proposed class would doubtless prove more than a match for one of the heaviest English steam ships; and, for reasons already noted, the latter might find it difficult to escape.

By proper arrangements, and, if needful, with the associated aid of one of the steam frigates, these lighter built steamers may be sent to any part of the world, where their services may be desired, and where friendly or neutral ports can be found to afford the necessary shelter and supplies of fuel. Their great speed and efficiency might thus be employed with great effect on an enemy's commerce and resources.

I have been led, by the request of the commissioners, thus to explain, to some extent, my views on this essential branch of public defence, and to urge the adoption of a class of measures on which I consider the future safety of the country may largely depend; being fully persuaded that it is not so much on the *magnitude*, as on the *available qualities* of our naval force, that we must rely for success in any future conflict with the great mistress of the seas.

* I consider the Gladiator as being the proper type of the class D; except as being slightly deficient in length, which would be better at 200 feet.

EXPANSION OF STEAM.

Observations on the effect of using Steam expansively under different pressures, and when cut off at different points. Reported in the American *Journal of the Franklin Institute.*

I was led to the following calculations respecting steam, by a notice published some time since in the *Franklin Journal*, of the operation of the Cornish Engines. The writer of that notice intimates, that the "duty," said to be performed by the engines, is greater than the calculated power, to be derived from the fuel, and that a new theory has been proposed to account for it, by the "momentum" of the percussion of the steam upon the piston. He states that in some of the engines the steam is let into the cylinder at a pressure of 45 lb. to the inch, and "cut off" at one fourteenth of the stroke. As I could find no table showing the effect of the expansion of steam when carried so far, I prepared the following:—

Steam let on during the	Effect produced by expansion.	Total effect of the steam used.	Average effect throughout the cylinder.
Full Stroke.	0·000000	1·000000	1·000000
$\frac{1}{2}$ do.	0·693151	1·693151	·846575
$\frac{1}{3}$ do.	1·098616	2 098616	·699538
$\frac{1}{4}$ do.	1·386303	2·386303	·596575

From the above table it appears that one per cent. of a cylinder full of steam, if suffered to expand, will give an average pressure throughout the cylinder equal to 5·6 per cent. of the pressure it exerted when entering the cylinder; or that the same quantity of steam, if suffered to expand to 100 times its volume, will do 5·6 times as much work as if used, without expansion, through the whole stroke of the cylinder. And when cut off at $\frac{1}{14}$ of the stroke, as in the Cornish engines, the average pressure will be more than one fourth of what it would have been, if fourteen times as much steam of the same pressure had been used. This sufficiently explains the cause of the superiority of the "duty" performed by the Cornish engines over those in which expansion is not carried to so great an extent; for it requires less water to be raised into steam to work expansively than would be required to work with steam of the same average pressure, and full cylinders. In the case of the Cornish engine the steam was used at 45 lb. pressure for $\frac{1}{14}$ of the stroke, giving an average pressure, agreeably to the table, of $·259219 \times 45$ lb. $= 11·665$ lb., and to perform the same work, with the full stroke, would have required steam of at least this average pressure. Now to determine the quantity of water required. Dalton says that steam obeys the same law as the gases with respect to pressure, and *they* have expansive force in the ratio in which they are compressed. Then steam of double pressure should contain a double quantity of water. The published tables of the specific gravities of steam give an addition of weight of only about 87 per cent. to steam of double pressure, which would contradict Dalton's position. Supposing, however, that Dalton's law is correct, and that atmospheric steam contains 253 grains of water to the cubic foot, then steam having the above pressure of 11·665 lb. would contain 435 grains; and steam of 45 lb. pressure would contain 1012 grains of water per cubic foot. But, with this last, it requires but $\frac{1}{14}$ of the quantity, or $(\frac{1012}{14} =)$ 72 grains to give the same average power, when used expansively, as the 435 grains on the full cylinder plan. The fuel required should be in proportion to the water to be evaporated. Watts's experiment with the open and closed boiler, each subjected for an equal time to an equal heat, showed that the same quantity of water had escaped, in steam, from the open boiler, as flew off from the close one, upon opening the valve at the end of the operation; thus proving that equal weights of water require equal quantities of heat to raise them into steam, irrespective of pressure. On this principle, then, the Cornish engine should require but $\frac{72}{435}$ or about $\frac{1}{6}$ of the fuel that would have been required to work them on full steam, which very nearly corresponds with the "duty" performed by the present Cornish engines compared with that done by the engines formerly constructed by Bolton and Watt in the same locality.

Another principle comes in play, in working expansively, which is lost sight of when working with equal steam throughout the stroke—viz., that matter in motion would never cease to move unless retarded by external causes, and would require, to stop it, a power equal to its weight multiplied by its velocity. Now, in working expansively, the steam is applied at a pressure sufficient to start the load at a certain velocity, to continue which, it is only necessary that the additional quantities of power should equal the retarding forces of gravity, friction, and resistance of air, until the commencement of the next stroke. Now, in the Cornish engine, where the steam is cut of at $\frac{1}{14}$ of the stroke, the increments of power beyond that point, or that portion of the power gained by expansion, amount to nearly 2·64 times the direct power of the steam applied, and which gives the original velocity. This velocity must therefore be continued until the gravity, friction, and resistance of air, amount to 2 64 times the original power, applied before cutting off the steam. The whole weight of the machinery and load thus operates, on the fly-wheel principle, to continue the motion, as the velocity given to them forms one of the factors of their momentum, which is counteracted only by the other factor, the gravity.

It is thus readily seen that the weight of the load raised by an engine working expansively, may exceed the average pressure of the steam on the piston, for it only requires the steam to be at a high initial pressure, so as to give the necessary velocity, and of course momentum, to the load at the commencement of the stroke; it may then expand so as to bring down the average pressure and leave sufficient power, to be derived from the momentum and the expansion, to carry forward the work. This reserved power will of course be applied in a decreasing progression, while the retarding powers would be constant. It will be a useful exercise of the skill of some of your mathematical friends to calculate how far the load may exceed the average pressure upon the piston.

It appears from the table that the advantage to be derived from expansion, increases with the expansion. It becomes therefore important to ascertain the extent to which it may be carried. I noticed that in the Cornish engine they use a "steam jacket" to their cylinder to prevent condensation. This led me to inquire into the heat of the steam, and how it would be affected by its expansion. Will steam expand in a cylinder from any given pressure down to that of the atmosphere? Pressure or condensation of air produces heat, and the release of it from pressure, cold. If steam be affected in the same way, and you suffer it to expand to 100 times its bulk, will not its heat be divided by 100, and be reduced below the freezing point? The cut-off steam can take up no heat from the boiler, and its inherent heat is stated to be about 1212° divided into portions, sensible and latent, according to its pressure. As each particle of steam must be supposed to contain an equal portion of heat, the heat must necessarily be divided with the expansion of the steam. Then if it contain but 1212°, and this be divided by the expansion, it is evident that before the steam can have expanded 40 times, its heat would be reduced below the freezing point, even if the latent heat all became sensible, unless it could take up heat from the cylinder, which is not of a nature to conduct it with sufficient rapidity. That the heat is divided by the expansion, any one may satisfy himself by placing his hand in the steam issuing from a high-pressure boiler. He will in the same way be convinced that steam is not frozen by expanding from 150 lb. to the pressure of the atmosphere. Now it is impossible that in this case it should take up from the atmosphere sufficient heat to prevent freezing, if the heat, originally in it, did not exceed 1212°, as indicated by our books. To account for the phenomenon, I suppose we may assume that the heat in atmospheric steam is correctly stated at 1212°, of which 212° are sensible, and 1000° latent—a second volume of water, rising in the form of steam in the boiler, takes up an additional 1212° of heat; and now the steam contains twice as much water, and twice as much heat, as atmospheric steam, shows 15 lb. pressure by the mercurial gauge, and about 242° of heat by thermometer, the remaining 2182° being latent; and so, for each individual 15 lb. of pressure, another volume of atmospheric steam would be compressed into the original space, a less portion of its heat each time becoming latent. On this theory, steam of 150 lb. pressure will contain 11 times as much water as atmospheric steam, and 13332° of heat, while the thermometer would show but about 360°. And the temperature of such steam, when expanded to the atmosphere, should be 88°. It would therefore rush into the air and immediately assume the form of water, which, judging merely from the sensation, is near the fact. The advantage of the "steam jacket," therefore, is obvious. It is also obvious, that steam of any pressure may be used, on the plan of expansion, in a condensing engine, as the heat may always be reduced, by expansion, to the point at which it may be condensed. The following calculations seem to show, that the most economical engine would be built upon this plan.

Steam at 180 lb. pressure, cut off at $\frac{1}{100}$ of the stroke, by the table, will give an average pressure of 10 lb. to the whole cylinder, and, by adding the vacuum and air pump, 10 lb. more may readily be obtained. Such an engine would therefore give a power equal to two of Bolton and Watt's, of the same size, worked with atmospheric steam. Proceeding on the data, that equal quantities of water are to be evaporated for each lb. pressure of steam, at the same expense of fuel, on both plans, we have two cylinders-full of atmospheric steam, weighing 253 grains per cubic foot on the Bolton and Watt plan, and only $\frac{1}{100}$ of one cylinder-full of steam at 180 lb., weighing 3289 grains per cubic foot, in the other. The water to be evaporated to produce the same power in both will then compare as 253 to $\frac{3289}{253}$, or, the Bolton and Watt engine will require $15\frac{1}{2}$ times as much water to be evaporated as the other, and fuel and boiler in the same proportion. The 180 lb. steam, by the theory, would contain 15626° of heat, which, divided by the expansion 100, would be reduced to 156°, while in the atmospheric steam, there would be 1212°, or nearly 8 times as much. Of course, the condenser, air-pump, and condensing water, need only be $\frac{1}{16}$ of what the two Bolton and Watt cylinders would require for the condensing process.

If Dalton be correct in the opinion that steam, like gas, has expansive power in proportion to its compression or density, we have data to calculate the maximum power of steam. Water is found to expand nearly 1800 times into steam of atmospheric pressure, or 15 lb. to the inch. Then, by compressing such steam to $\frac{1}{1800}$ of its bulk, we should get it back into water, and multiply its elastic force in the same degree, $1800 \times 15 = 27000$ lb. per square inch, the maximum.* In following the same law of elastic power in proportion to density, we find, that each expansion of steam to twice its volume, in a steam cylinder, gives precisely the same increment of power to the piston, which must move each time double the distance. Thus the distances moved by the piston for each expansion, form the series 1, 2, 4, 8, &c., and the increment of power for each distance is ·693151 of the power applied before the steam is cut off.

ERSKINE HAZARD.

Philadelphia, July 20, 1846.

* Steam thus compressed into water, would instantly give out all its heat, and produce a temperature, according to the theory, of 212° x 1800 + 1000° 382600°.

REGISTER OF NEW PATENTS.

If additional information be required respecting any patent, it may be obtained at the office of this Journal.

MANUFACTURE OF IRON.

George Hinton Bovill, of Mill-wall, Poplar, Middlesex, engineer, for "*Improvements in the manufacture of Iron.*"—Granted Jan. 31; Enrolled July 31, 1846. (*With Engravings, Plate XIX.*) Reported in the *Repertory*.

The improvements relate, 1st, to an arrangement of apparatus for heating the blast from the flames passing off from the top or funnel head of blast furnaces; 2nd, to an improved mode of heating the air or blast, by blowing the same partly through and partly over a fire in a closed retort or fire-proof chamber; 3rd, to the working of blast furnaces by exhaustion or suction, in contra-distinction to the present method of blowing air into them at a greater pressure than the atmosphere: 4th, to the introduction of steam above the boshes of blast furnaces; 5th, to an improved method of puddling iron by the application of the water furnace, commonly known as Kymer and Leighton's furnace, the same being worked by air blown into a closed ash pit, and the introduction of air over the fire to consume the gases generated; 6th, to a preparation to assist the working of iron in the puddling furnace, and its further application to facilitate the combination of steel with iron; 7th, to a mode of calcining iron ore by combining the use of furnaces with heaps of ore; 8th, to a mode of constructing furnaces for heating or re-heating iron.

Plate XIX., fig. 1 is a side elevation, fig. 2 a section, and fig. 3 a plan of apparatus placed at the top of a blast furnace, the cold air from the blast main passing through the same, and being heated by the gaseous flame passing off from the furnace top, is blown in at the tuyeres of the furnace in the ordinary manner. *a* is the top or stage of a blast furnace; *b* the brick tunnel head of the furnace, showing the doorway *c*, through which the furnace is charged, and to which doors are hung, confining the gaseous flame to pass through the heating cells; *d* the cold air main and branches from the blowing engine connected to the three chambers *e*, provided with doors or bonnets *f*, secured by bolts and nuts, air tight: the object of these doors is to get access to the socket joints, by which the connection is made with *g*, flat cells or chambers (shown in enlarged section, fig. 4), extending across the tunnel head *b*, and connected, as above-mentioned, to the cold air chambers *e* on one side, and to *h*, three similar chambers, on the other side, from which the heated air is conveyed by the three pipes *i*, to their respective tuyeres and blown in at the bottom of the furnace. *j*, spaces between the air-cells, *g*, through which all the gaseous flames from the furnace ascend, the cold air being divided into thin currents, absorbs heat in its passage through the cells *g*, from the flame of the furnace, and obtains sufficient temperature to be blown into the furnace. By this arrangement the air, being divided into thin currents, is brought into contact with greater heating surface, and consequently absorbs the heat therefrom more rapidly than when pipes of considerable diameter are employed: it is important to keep the heating cells for each tuyere distinct, and by the arrangement here shown, it is clear either of the sections may be repaired without any interference or stoppage of the others; the arrows indicate the direction of the currents. The great object of this part of the invention is to use apparatus at the tunnel head of a blast furnace of such a description, that the heated compartments through which the air passes shall offer considerable depth as compared with the width, and so that the air may be said to be in a series of very thin sheets or currents of considerable depth.

Fig. 5 is a section of an improved hot air stove for heating the air used for the blast. *h* a tight iron case, lined with fire-brick, and provided with a Kymer and Leighton's patent water grate, *i*, supplied with fuel by means of a hopper, *j*, provided with a horizontal sliding door at the end near the furnace, and at the opposite end with a piston door, *l*, that will move freely along the hopper; *m* ash pit, closed by the door *n*, and supplied with air from the blowing engine; *o* air pipe, furnished with a valve to regulate the quantity of air to be admited from the cold air main *p*, to which also is applied the nozzles *q*, to admit the cold air into the space above the fire on the water grate, where it mixes with the products of combustion and vapour of water, supplied from the water troughs of the fire-bars, and passes away through the pipes *r*, to the tuyeres of the furnace; the admission of air and consequent regulation of heat of the blast are governed by the slide valve *s*. The mode of applying the blast possesses a great advantage in giving a command over the working of the furnace: when the cinder from the furnace has a glassy appearance, indicating the presence of unreduced oxide of iron, the admission of air over the fire should be reduced or the quantity through the fire increased; on the other hand, should the furnace be working sluggishly, the quantity of air over the fire should be increased; by the application of the Kymer and Leighton's water grate, the fire bars of the furnace are preserved.

Fig. 6 represents a blast furnace, with a double hopper, *a*, the slides of which, *b*, are worked by gear from the handles *c*, on the top of the furnace; the furnace is charged by the furnace man opening the top slide and filling the hopper, which, when closed, and the lower one being opened, the charge descends into the furnace. *d*, suction pipe from furnace connected to the exhausting engine, by which is worked the furnace, instead of blowing or forcing air into furnaces at a greater pressure than the atmosphere, by which means is obtained a more perfect distribution and circulation of air through the red hot mass of materials in the body of the furnace with a smaller exertion of power; the unconsumed gases drawn off from the furnace may be profitably applied to various purposes connected with the manufacture of iron; either hot or cold blast may be used with this as well as the system at present adopted; if the former, the air may be heated by the plan already described, or otherwise. It is well known iron is frequently much injured by the presence of sulphur in the materials in the blast furnace (of which the fuel contains the largest portion), at the point of fusion this enters into combination with the iron. The object therefore for that purpose, is to apply an injection of steam and distribute it through the mass of materials in the furnace, above the point where any fusion takes place, at the upper part or above the boshes of the furnace.

Fig. 7 represents a puddling furnace, with one of Kymer and Leighton's patent water grates (fig. 2 is one of the water troughs and a bar, in large section); *a* hearth of furnace; *b* patent water furnace; *c* double fire door; *d* air pipe through which the air is blown from a blowing machine between the plates of the fire door, and distributed over the furnace combining with the gases of the furnace, more particularly produced from the decomposition of the water, and producing an intensely hot flame; *e* ash pit, with closed door *g*, and air valve *f*, for regulating the supply of air from the blast pipe through the fire. In commencing the operation of puddling, it is preferred to introduce a portion of some carbonaceous substance mixed with the iron.

The sixth part of the improvements has for its object the preparation of what the patentee calls a cinder, to be used in the puddling furnace, when puddling iron and also when piling iron, or iron and steel, in order to facilitate and improve the welding of these matters. In preparing this cinder, take Cumberland ore, or oxide of iron, such as hammer scale from the iron forge, and charge the same into a cupola or other blast furnace, with the slack of anthracite coal or other suitable fuel, and cause the same to be melted by the blast, and tap the furnace from time to time, and allow the melted cinder to run out and become cold, or it may be used by being conveyed at once to the puddling furnace. In charging the furnace, the Cumberland ore or other rich oxide of iron is first mixed with a like quantity of the slack or culm of anthracite coal, and the charge is continued as it descends into the furnace. The cinder for puddling is to be broken into small lumps; and when the iron has been brought to the metallic state in the puddling furnace, is to be stirred in about 20 per cent. by weight of the cinder to the iron in the furnace, and then the balling process is to be completed as usual. In using the cinder when piling iron, or iron and steel, the cinder is reduced to powder, and dusted over and amongst the surfaces to be welded, by which the process will be facilitated and improved.

The seventh part of the invention consists of a mode of calcining iron ore, by combining the use of furnaces with heaps of ore, in place of combining the ore and fuel in heaps and igniting the whole mass. Fig. 8 shows a section of a furnace and a heap of ore; and fig. 9 a front view thereof. The furnace is so arranged that a blast of air may be applied below the fire bars as well as over the ignited fuel above, the ashpit being closed. The flame and products of combustion are thus forced through the heap of ore, and the same becomes calcined by the passage of the products from the furnace.

The eighth part of the invention relates to a mode of constructing furnaces for heating or re-heating iron, and the improvements consist of so forming a reverberatory furnace, that, in place of the flame and heat passing off at the end of the furnace, it is caused to descend through the bed of the furnace, which is made open for that purpose. Fig. 10 represents a section of the furnace. The general construction is similar to an ordinary reverberatory furnace, and is provided with a passage at the end into the chimney, for the purpose, when first lighting the fire, to get up the heat to allow the working to take place in the same way as if it were an ordinary reverberatory furnace; but on the slide being closed, the bottom of the furnace is so openly formed, that the heat and flame pass through the bed into the chimney. The bottom of the furnace is preferred to be constructed of a series of brick arches, *a*, leaving a space of about two inches between the neighbouring arches, or, instead of the brick arches, a water grate may be used as the hearth; and to facilitate the draft of the chimney, a steam jet is applied at *b*, or other convenient means may be used. In working with this furnace, the bottom is covered with coal or coke of such size, that it will not pass through, and on such bed is placed the iron to be heated. By such construction of furnace it will be found that the reheating of iron will be facilitated and the cost reduced.

STEAM ENGINE CONDENSERS.

Thomas Howard, of King and Queen Iron Works, Rotherhithe, Surrey, engineer, for "*Improvements in steam engine condensers.*"—Granted March 25; Enrolled September 25, 1846. (*With Engravings, Plate XIX.*)

This invention applies to such condensing steam-engines as have their boilers supplied with water of condensation, and wherein the steam is condensed by injecting water properly cooled down. A tank *a*, is placed in any convenient situation, and supplied with cold water by pumps or otherwise at *b*, and which having its course governed by plates *c*, *c*, within the tank, escapes at *d*, as further shown by the arrows. The ends of the tank are closed by plates which are recommended to be of brass, *e*, *e*, pierced with holes, in which are secured, water tight, the ends of tubes of copper or other appropriate metal, *f*, *f*, *f*, a section of one row in height only being shown in the drawing, but which extend through the breadth of the tank. Bonnets *g*, *g*, are fixed over the plates and open ends of the tubes, (and so as to be removeable if access be required to the tubes,) and are divided into compartments, which in either bonnet alternate in position with those in the opposite one at the other end of the tubes, as shown in the drawing. A nozzle, *h*, on one bonnet is connected by a pipe or otherwise with the hot cistern, and a nozzle *i*, on the other is connected with the injection cock of the steam-engine. Within the nozzle *h*, is a plate *h'*, perforated with small holes. A quantity of water being introduced into the hot cistern (by first starting the engine with the ordinary injection, which it is recommended to be attached or otherwise) sufficient to fill the tubes, and properly effect the circulation, the injection cock connected with the nozzle, at *i*, is opened, when the warm water in the hot cistern will pass by the atmospheric pressure through the opposite nozzle at *h*, and to and fro along each series of tubes determined by the divisions in each bonnet (and as shown by small arrows), and will be reduced to nearly the same temperature as the external water, supplied at *b*, and will, after passing through the nozzle *i*, and effecting the condensation by its injection, be withdrawn by the air-pump of the engine in the ordinary way into the hot cistern, from whence it will again circulate, through the tubes, being cooled and reinjected continually, as before described. Any waste which takes place is made good by the ordinary injection, which the inventor prefers to the use of stills; but the latter may be employed upon any ordinary plan if required. He does not confine himself to the precise arrangements hereinbefore described.

The injection water and the external refrigerating water may be made to change positions, the former to pass without and the latter within the tubes. The cold water may be supplied by any known means. It is recommended that the refrigerating surface be about ten square feet per nominal horse power, when the steam is so employed as to leave the cylinder of the engines at 10 lb. per square inch pressure, irrespective of the atmosphere, and be more or less accordingly, and that the supply of external or cold water be not less than twice the quantity of the injection water.

The inventor states that patents were granted to him, dated 13th October 1825, and 30th November, 1832, in both of which was included a process of condensation by the reinjection of the same water or other liquid, which he does not hereby claim.

But he claims the so arranging apparatus, that the water for condensation shall be subdivided into many streams in its progress to be cooled and used as injection water, as herein described.

RAILWAY LIFTING APPARATUS.

Thomas Pope, of Kidbroke, Kent, gentleman, for "*Improvements in apparatus for moving railway carriages on to railways, and in machinery for lifting and moving heavy bodies.*"—Granted March 25; Enrolled September 25, 1846. With Engravings, Plate XIX.

The invention relates firstly, to an apparatus for moving railway carriages on to or from a line of railway in case of accidents or otherwise; and, secondly, to apparatus for lifting and moving heavy bodies. Fig. 1, Plate XIX. shows a side view of the apparatus for moving railway carriages; *a* is a frame with a screw shaft *b*, turning in bearings at each end; on one end of the shaft is fixed a pinion *c*, which takes into another pinion *d*, with a winch handle *e*, and on the shaft is a female screw with a travelling nut *f*, with a pin that passes through the groove or opening in the top of the frame *a*, and secured in a hole to the plate *g*; the two plates *g*, *g'*, carry portions of two rails *h h*, and the plates are connected together by the rod *i* and rest on friction rollers *j*, which run on the frame *a*. When the apparatus is to be used, the carriage, supposing it to be off the rails, is raised at one end by a screw-jack or lever, then the apparatus is placed under the carriage with the rails *h h* under the wheels, and if the carriage be not far off the rails, one end of the frame *a* is placed on the line, and then by turning the handle, the end of the carriage is gradually brought over the line or part of the way, then it is either lowered on the rails or allowed to rest, and the apparatus applied to the other end of the carriage and shifted, and so on shifting the apparatus from end to end until the carriage is correctly over the line, or in place of one apparatus two may be used to shift both ends at once.

The rod *i* is made moveable so as to adopt the apparatus to different gauges of railway, and instead of the pinions on the shaft *b*, the shaft may be made to revolve by a screw wheel taking into a screw wheel *b*. The inventor does not confine himself to the apparatus, he says in some cases a simple ratchet-wheel may be placed on one of the rollers taking into a rack on the frame *a*, as shown in fig. 2. The frame *a* may be dispensed with, and any planks of wood used to form a bed for the plates *i* to run upon.

The second improvement is for an apparatus for lifting purposes, consisting of a case with a screw inside, and a female screw working up or down with a bracket thereon, and passing through the side of the case. On the top of the screw shaft is fixed a toothed wheel which takes in and is driven by a worm wheel turned by a handle.

STAINING AND ETCHING GLASS.

Isaac Hawker Bedford, of Birmingham, for "*Improvements in the manufacture of window and other glass.*"—Granted June 12; Enrolled September 12, 1846.—(Partly invented and partly communicated from abroad.)

The improvements relate to staining and etching glass. The staining is effected by the use of copper to produce a red colour either before or after cutting and polishing the glass, and the whole or any part of the surface may be stained; the invention is most successfully performed with glass made without the use of soda. The glass is to be well cleaned, and treated in the following manner:—take one part by weight of sulphuret of copper; two parts of the scales of iron from a smith's forge; three parts of sulphate of copper burned to whiteness; and four parts of calcined yellow ochre, all ground as fine as possible with the essence of turpentine, which has become rather thick by exposure to the atmosphere. The mixture being of the consistency of cream is laid on the surface of the glass to be stained by a brush, and allowed to dry; the glass is then placed in a stainer's muffle and heated to as high a degree of heat as it will allow without melting. The fire is then drawn off, and the glass allowed to cool down slowly, and washed when cold, when the appearance of the glass should, on looking in a direction edgewise of the glass, offer a greenish yellow if lead has been used in the making of the glass; the colour obtained will, however, differ according to the composition of the glass. The glass is again placed in a muffle, and heated as before; when the fire is withdrawn a quantity of small coal is introduced into the lower part of the muffle; (4 lb. of coal is the quantity for a muffle 24 inches in diameter and 30 inches in length). The muffle is then completely closed and luted, by which the products of the coal will be prevented escaping. The muffle and the glass are to be allowed to cool down, and when the glass is taken out, it will generally be found to offer a brownish-red colour. Those articles which offer such colour are then to be placed in another muffle which has been lime-washed, and again heated and cooled down as before.

The second part of the invention relates to ornamenting of glass by a peculiar process of etching. For ornamenting window glass take five parts of puce-coloured oxide of lead (peroxide) to one part of flux, (the flux employed is 17 parts of glass of borax and 13 parts of red lead fused together); the oxide of lead and the flux is ground with turpentine, and with this composition the artist paints the desired devices or designs on the surface of glass to be etched: when coloured glass is to be etched, acetate of lead is preferred in place of the oxide of lead; the same are then allowed to dry, and the articles are to be fired in the same manner as when gilding on glass, and allowed to cool; and when cold they are dipped in a weak solution of nitric acid in water, and the surfaces cleansed by rubbing off the preparation above mentioned.—The claim is firstly, for the manufacturing stained window or other glass, by applying copper for producing a red colour for staining the same on the surfaces, as herein explained; and, secondly, for the mode of manufacturing window and other glass, by etching on the surfaces thereof by means of lead acted on by acid.

STEAM ENGINES.

Mark Rollinson, of Brierly Hill, near Dudley, engineer, for "*Improvements in steam engines.*"—Granted May 7; Enrolled November 7, 1846.

The improvements relate to obtaining additional power by admitting steam in the upper part of the air pump of steam engines during the down stroke, simultaneously with the admission of steam in the steam cylinder. The air pump has a solid packed piston, and valves and passages communicating with the condenser.

COKING ARTIFICIAL FUEL.

Ferdinand Charles Warlich, of Deptford, Kent, gentleman, for "*Improvements in the manufacture of fuel.*"—Granted April 7; Enrolled Oct. 7, 1846.

The improvements relate to the subjecting of moulded fuel to the process of coking; for this purpose the patentee prefers the manufactured fuel, consisting of the small of anthracite coal, of free burning coal, and of bituminous coal, mixed with pitch or bituminous matter moulded into bricks; to be heated in retorts or ovens to drive off the volatile products (as described in a patent granted October 5, 1843, to the present patentee). The bricks are then placed one upon another with a small space between the sides, in a coke oven, (a square one is preferred), when they are converted into coke by the ordinary process.

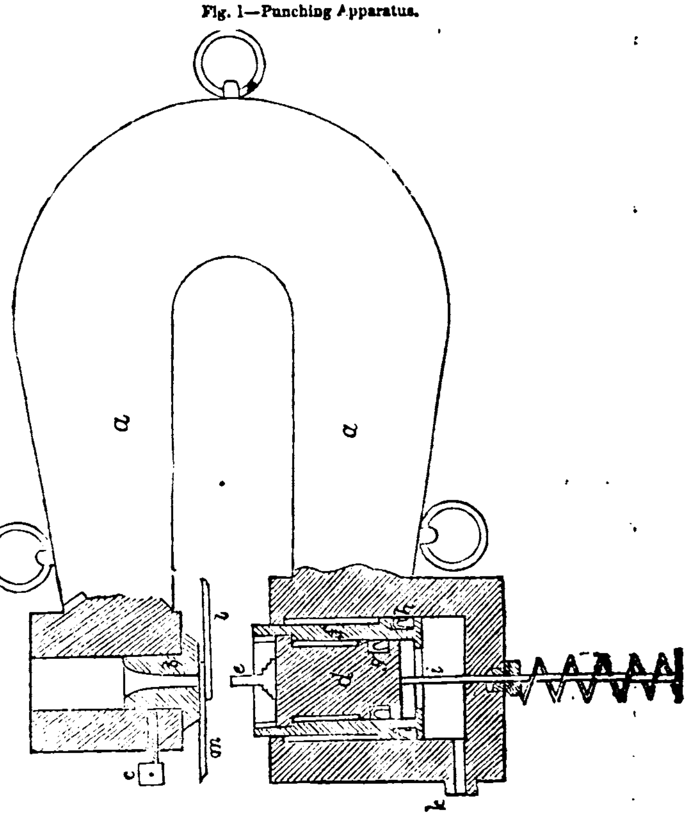
PUNCHING AND SHEARING.

Charles May, of Ipswich, Suffolk, civil engineer, for "*Improvements in machinery for punching, rivetting, and shearing metal plates.*"—Granted April 15; Enrolled October 15, 1846. (Reported in the *Patent Journal.*)

This invention consists of the application of different modifications of the principle of the hydrostatic press.

It consists first in its application to the punching of metals, used for boat building, boiler making, &c. Fig. 1 represents a side view of this improved machine, which is partly exhibited in section. It is a strong iron frame *a*, in the shape of a horse shoe, the upper arm of which is furnished with a die *b*, the size of the hole in which corresponds with the size of the hole desired to be perforated in the plate or plates of metal; it is affixed to the arm by means of a pinching screw *c*, which admits of its being changed for a new one, or one of a different size. The extremity of the lower arm is cast hollow and fitted with a ram or cylinder *d*, similar to the ram of a hydraulic press; this ram *d*, carries the punch *e*, used to force out the hole in the metal plates. It is placed directly opposite the hole in the die *b*, into which it is received when forced upwards. Another external or annular cylinder *f*, which is bored to suit the external diameter of the ram *d*, and the exterior is turned to fit the hollow in the arm; both these cylinders have cap-leathers *g h*, placed in recesses turned to receive them, which prevent the water escaping between the surfaces of the cylinders when the pressure is applied. Attached to the centre cylinder is a rod *i*, which passes through a stuffing box in the bottom, and has attached to the other end a spiral spring, which withdraws the punch from the plates after the hole is punched. *k* is the aperture to which the tube is attached to form the connection between the pumps and the press.

Fig. 1—Punching Apparatus.



The frame *a* may be of any other convenient form, but the patentee prefers the foregoing, as it may be easily suspended by the rings from a traversing crane, and moved about in any direction where it may be required; the pumps being placed on the platform of the crane, and connected by means of a flexible tube, the best for which purpose being of metal, and coiled round in the shape of a spiral, having a sufficient number of turns to give it the requisite flexibility.

The action of this apparatus is as follows:—The plates *l*, *m*, having been introduced between the punch and die, water is forced in below the rams by means of pumps, one of which should be considerably larger than the other, in order to take up the slack, and the small one to produce the pressure. The water being thus forced in, will raise both cylinders *d* and *f*, until they meet with some resistance from the plates; the external cylinder *f* forcing them close together, and the pressure being continued, the internal cylinder or ram will rise still further, and force the punch *e* through the plates; and on the water being allowed to escape, the cylinders will be withdrawn by the action of the spiral spring, both of which cylinders are furnished with suitable collars, so as to prevent either of them being forced or depressed beyond a proper range.

The second part of this invention relates to the rivetting together plates of metal by the same means as before described for punching; the only difference in the machine being, that rivet sets are adjusted in the same position as the punch and die; to receive and form the rivet heads, it is not necessary that it should be furnished with a double ram or cylinder.

The third part relates to the shearing and cutting of metal plates, the machines for which, are modifications of that already described, one being exactly similar to the common form of Bramah's press, but furnished with a double ram. The patentee proposes to use this for cutting such articles as railway axle guards. A punch, of the shape of the article desired to be cut, is fixed on the head of the ram, and a corresponding die in the cross head; the ram, on being forced up by the means already explained, will cut the metal plate the shape required.

Fig. 2—Cutting Shears.

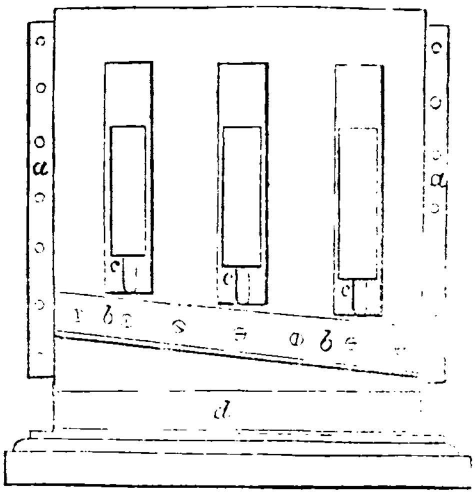


Fig. 2, represents a front elevation of a machine of shearing; *a*, *a*, is a strong iron frame, supported in a vertical position by means of dovetail guides, in which it moves freely up and down; *b*, *b*, is a knife or shear, attached to the frame *a*; *c*, *c*, *c*, are a series of hydraulic rams, by which pressure is applied directly on the knife or cutting shear; the corresponding shear *d*, is stationary, and a fixture to the frame of the machine.

Having described the manner of applying the invention to the different purposes for which it is intended, the patentee wishes it to be understood, that he lays no claim to the details as herein described and carried out, nor to the application of water for the same purposes; but claims, first, the application of the pressure of a fluid, caused by means of pumps, for the punching of metals. Second, the application of the pressure of a fluid, caused by means of a pump or pumps, for the rivetting together plates of metal, as hereinbefore described. Third, the arrangement of a series of hydraulic rams, for the purposes of shearing metal plates, as hereinbefore described.

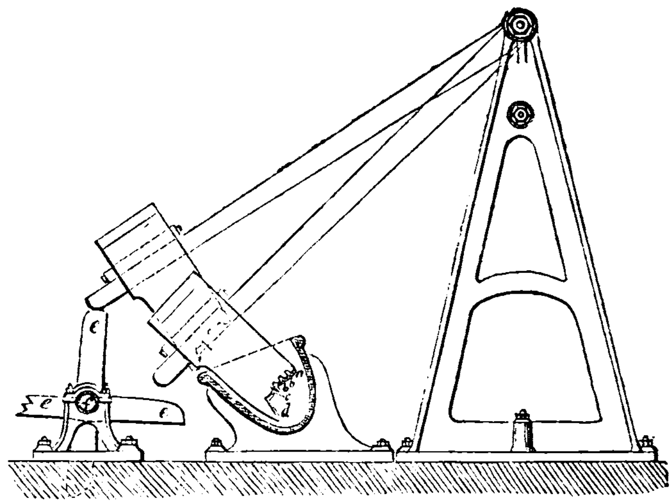
APPARATUS FOR PREPARING FIBROUS MATERIALS.

William Newton, of Chancery Lane, Middlesex, civil engineer, for "*Improved modifications and novel application of known machinery and process to the purpose of cleaning, softening, dividing and preparing flax, hemp, and other vegetable fibrous materials.*" (Being a communication.)—Granted August 14, 1845; Enrolled February 14, 1846.

The invention relates to the employment of an apparatus similar to the ordinary fulling-stock, for beating, breaking, or operating upon textile plants of all descriptions, and for constructing the beaters and trough or bed of the stocks in the manner hereinafter described.

Fig. 1 is a vertical section, and fig. 2 a plan of the apparatus; the bed or trough may be made of cast iron, copper, or other suitable metal, the internal surface is formed of three curves; the first curve is the front of a radius of 10 feet and 2 feet in length, which is the length of the arms of the beaters; the bottom curve is 10 inches in length and 10 inches radius, and the back curve 19 inches in length and 24 inches radius; the trough is about 24 inches wide on the top. The wooden beaters are of equal size, and lifted by rotary tappets *e*, falling alternately on the substances in the trough, they are about 400 lb. in weight, and have a fall of 2 feet, (the weights and fall may be varied according to the degree of hardness and resistance of the plant). The beaters have 5 teeth, the front tooth is 2½ in. thick, and projects half an inch beyond the two following or intermediate teeth *b b*, which are 2 inches thick, forming an arc of an inch radius, and the fourth tooth *c* is 1¼ inch thick, and 2½ inches longer than the first, and the fifth and last tooth *d* is 4½ inches thick, and projects nearly 7 inches; a space of 2½ inches is left between the 4th and 5th tooth. The upper surface of the beater is perpendicular to the first tooth, and curved to the shape of the trough. The teeth are covered with sheet copper, and the arms of the beaters are mounted so as to vibrate in an arc concentric with the front curve of the trough.

Fig. 1.



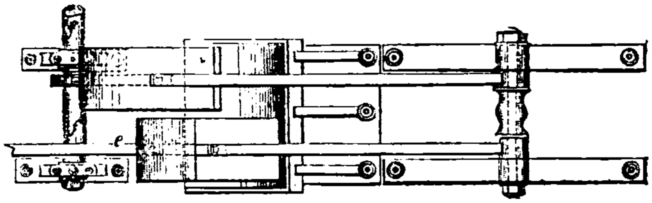


Fig. 2.

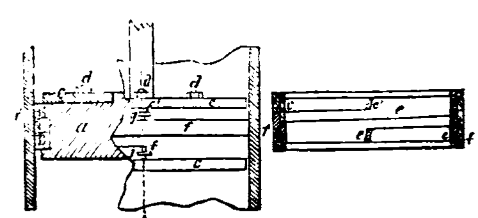
The operation is performed in the following manner:—the plants are firmly twisted together in bundles of about a pound each, and then cleansed and deprived of all gummy and other extraneous matters, and softened by being beaten or pressed. About 80 lb. of the plant is then laid on the trough and submitted to the action of the two beaters, acting alternately for about four hours.

This alternate action of the beaters turns the plant over and over, in a regular and uniform manner, compressing it forcibly against the sides of the bed, and causing the fibres to rub against each other at every stroke of the beaters. The outer covering or woody portion of the plant is first broken and then removed by the peculiar shape of the teeth of the beaters. After a time the outer covering and ligneous matter being broken off, the filaments are separated and the plant gently heated, which facilitates the removal of the gummy matters, and all the parts become softened. After this operation, and a cleansing in water, the fibres are operated upon in the ordinary matter.

METALLIC PISTONS.

William Mather and Colin Mather, of Salford, near Manchester, millwrights and engineers, for "*Improvements in metallic pistons.*"—Granted April 28; Enrolled October 21, 1846.



The improvements relate to the mode of packing pistons by a combination of two helical springs, one within the other, as shown in the annexed figure, one-half of which shows the outer spring *a*, and the other half the inner one *b*, which surround a groove or channel formed round the body of the piston *e*; they are compressed and held in their places by the top plate or cover *d* of the piston when fixed down by three screws *e*; at the two ends of the outer spring, there are filling or stopping bits *f*, placed across the two openings in recesses formed in the outer spring in order to stop the steam passing down or up through the splits.

The two springs *a* and *b* are made by first forming a cylinder by casting and then cutting out a portion of the metal in an inclined direction, a vertical cut being made at the points *a'*, *a'*: when the springs are put together, the two ends of the outer spring are made to come at the opposite side of the piston to the two ends of the inner spring. The outer spring *a* is formed with an inner flange, and the inner spring *b* comes between the flanges, and causes by its elastic force, to open out and press the top and bottom surfaces of the outer spring *a*, against the top and bottom plates of the piston. As the two springs require to be compressed when the piston is introduced into the cylinder, they will when in exert an expansive force and fill up the cylinder in which it is working, notwithstanding any wear either in the cylinder or the packing.

The claim is for packing of pistons by the use of helical springs *a* in combination with spring *b*.

MARINE ELECTRIC TELEGRAPH.

Arthur Philip Perceval, of East Horsley, Surrey, Clerk, for "*Improvements in communicating between places separated by water.*"—Granted April 23; Enrolled October 23, 1846.

These improvements consist—First, when the electric wires have been effectually secured from water, by thread and gum or caoutchouc, they are to be enclosed in a "necklace of iron rings in contact with each other, or of iron sockets dove-tailing one into the other. Coil it on the deck like any other cable, and throw it overboard in transit." Secondly, where this means of communication is unavailable, transfer a semaphore apparatus on land, to hulls, fixed at proper distances and secured by anchors, sufficiently spacious for the accommodation of men to work the signals.

AMERICAN PATENTS.

Granted in August, 1845, reported in the American Franklin Journal.

For "*an Improved method of making matrices for casting printers' type.*" Thos. W. Starr, Philadelphia.

This is for forming matrices on types by the electrotype process, which afterwards are properly fitted up to give the necessary strength and durability. Claim.—"Having thus fully described my method of forming matrices for casting the face of printers' type, and other articles therein, what I claim as new, and desire to secure by letters patent, is the manner of forming the same by means of a common type or cut, and a metallic plate with an opening, with slanting sides, the two arranged and prepared in the manner described, and placed in a solution of sulphate of copper, and connected with the pole of a galvanic battery, in the same manner usually practised in electrotyping; and after receiving a sufficient deposit of copper, to be fitted up for use, in the manner set forth."

For "*an Improved method of lessening friction in clocks, &c.* Eli Terry, Plymouth, Connecticut.

The claim is for "the employment of a suspension piece, arranged and operating substantially in the manner of that which I have denominated the friction-preventor, for sustaining the weight of the balance wheel and its arbor. The arbor of the balance wheel is supported by a stirrup which vibrates as the balance rotates, so as to relieve the journals or pivots from the friction due to the weight of the balance."

For "*a composition of matter for removing acids from cloth, &c.* Solomon Guess, Boston.

This compound consists of 4 lb. of fucus vesiculosus (sea or bladder wrack) boiled in 3 pints of water until reduced to one, mixed with one quart ox gall, 1 lb. of carbonate of ammonia, ½ lb. of alum, and 24 lb. of common white soap; the whole is properly melted and mixed together.

For "*an Improvement in the propeller.*" John Ericsson, New York City, N. Y.

The claim is for constructing the hub with perforated projections, and the combination of the same with elliptic braces, for the purpose of sustaining and strengthening spiral propeller blades. The projections from the hub to which the blades are attached are made hollow for the passage of the water in the direction of the plane of the face to which the blade is attached. And the elliptic braces are segments of hoops made oblique to the axis, and therefore elliptical—they are used to brace together the blades about midway between the hub and tips.

Machine for folding sheet metal. Henry A. Roe, Erie, Pennsylvania.

The patentee says:—"The nature of my invention consists, first, in attaching what I term the folding plate, that is to say, a plate which gripes the edge of the sheet of metal, and on which the folding is effected by the folder, to a bed placed below it and hinged to the bed of the machine, so that the sheet of metal can be folded entirely over, instead of griping the sheet by a square jaw extending above and forming a stock above the plane of the bed of the machine, as heretofore, which prevents the sheet from being folded entirely over, and therefore requiring a secondary operation to complete the folds. Secondly: In supporting the said folding bed, to which the folding plate is attached, in the middle of its length by a joint bolt, the head of which lies in a semicircular recess in the folding bed and as near as practicable in a line with the axis of motion, and secured in the bed of the machine. Thirdly: In the employment of a side plate below the folding bed and back of its journals, provided with inclined planes on which projections from the back of the folding bed rest, so that by the working of the side plate by a lever at the end of the machine, the folding plate can be made to gripe and liberate the sheet of metal."

For "*an Improvement in the propeller.* Leonard Phleger, Wilmington, Delaware.

The invention consists in making the wings of the propeller in the precise form of such a portion of the convex surface of a regular cone as would be cut out by a plane or planes passing through its axis, and comprehending about half of its surface, each wing being attached, along one of its straight edges, to the shaft.

GUN COTTON.

It will be remembered that Dr. Otto, of Brunswick, claims to be considered one of the inventors of gun cotton, and states that he was led to the discovery by a remark published by Pelouze, in the *Journal de Chemie.* M. Pelouze, at the Academy, on the 2nd November, says, on the subject of gun-cotton: "Although M. Schönbein has not published the nature or mode of preparation of his cotton, it is evident that the properties which he assigns to it can only apply to xyloidine. Reasoning on the hypothesis that the *poudre-coton* is nothing else than xyloidine, I may be permitted to say a few words with respect to its history, and of some of its properties. Xyloidine was discovered in 1833 by M. Braconnet, of Nancy. He prepared it by dissolving starch and some other organic substances in nitric acid, and precipitating these solutions in water. In a note inserted in the *Comptes rendus de l'Académie des Sciences,* in 1838, I showed that the xyloidine resulted from the union of the elements of the nitric acid with those of starch, and explained, by this composition, the excessive combustibility of the substance produced. I ascertained—and this I think is a very important result in the history of the applications of xyloidine—that instead of preparing it by dissolving the cellulose, it might be obtained with infinitely greater facility and economy by simply impregnating paper, cotton, and hemp with concentrated nitric acid; and that these organic matters thus treated took fire at 180 degrees, and burnt almost without residuum, and with excessive energy: but I think it right to add, that I never for an instant had an idea of their use as a substitute for gunpowder. The merit of this application belongs entirely to M. Schönbein. Eight years ago, however, I prepared an inflammable paper by plunging into concentrated nitric acid, a sheet of paper known in commerce by the name of *papier ministré.* After leaving it there for twenty minutes, I washed it in a large quantity of water, and dried it in a gentle heat. I have recently tried this paper in a pistol, and with about three grains pierced a plank two centimetres in thickness (about three quarters of an inch), at a distance of twenty-five metres." The results of experiments at Paris, under authority, were communicated to the Academy on the 9th inst. The proved advantages of the gun-cotton appear to be, cleanliness, rapid combustion without solid residue, the absence of bad smell, lightness, no dust possible, and therefore no sifting necessary, an indisputable force, and valued at present as triple that of an equal weight of gunpowder. The disadvantages are—volume, and hence a difficulty in making up, and in the transport of ammunition; and the production of a large quantity of watery vapour within the guns, which is, perhaps, more inconvenient than the dirt of ordinary powder. Of five specimens tried, one fired the fourth time without the gun having been sponged, was projected with the greatest part of the cotton unburnt, and this was so moist that it would not take fire in the open air.

Test of quality.—M. Pelouze announced an important discovery by two of his laboratory pupils; it is, that when xyloidine has reached its greatest degree of explosive power, then it is completely soluble in ether. Hence a test of quality, and a proof of the best make.

At a meeting of the Chemical Society of London, the same day, a paper was read *On the Gun Cotton,* by Mr. E. F. Teschemacher. The author stated that he entered on this subject with a view of obtaining some data as to how far the possible introduction of this substance in the place of gunpowder was likely to affect the consumption of saltpetre and nitrate of soda. The gun cotton examined was made by Mr. Taylor's process. Fifty grains of South American cotton were dried over a water-bath, and lost 3·40 grains. It was steeped in the mixed acids, washed, dried, and found to have increased to 79 grains. The acids used were then examined, by saturating with carbonate of soda, and it was found that the cotton had taken acid equivalent to 28½ grains of soda; or 48 grains of dry nitric acid had combined with the 46·60 grains of cotton, forming the 79 grains of gun cotton. The synthetical composition was stated as

46·60 cotton, less
15·60 water taken away by the sulphuric and nitric acids, leaving

31·00 cotton deprived of a portion of its constituent water,
35·55 oxygen } equal to 48 nitric acid.
12·45 nitrogen }

79 parts, or
39·25 cotton deprived of a portion of water,
45·00 oxygen } equal to 60·75 nitric acid.
15·75 nitrogen }

100 parts.

Thus it would require 114·75 parts of saltpetre, or 99·10 parts of nitrate of soda, to form 100 parts of gun cotton. Mr. Teschemacher directed attention to the large quantity of oxygen—viz., 45 parts in every 100—which must be derived for combination with the cotton. He stated that he had also experimented upon other vegetable substances, such as flax, sawdust, &c. He found 50 grains of flax to increase in weight to 72 grains, but that the combustion of this substance was less perfect and less rapid than that of gun cotton.

The gun cotton does not ignite when violently struck. It may occasionally be made to *decrepitate*—not explode—by percussion. The King of Prussia has issued a decree extending all the safeguards for the manufacture, keeping, and selling of gunpowder to this new explosive material.

Professor Schönbein, in a letter to the *Times*, denies the identity of the xyloidine of M. Pelouze with his gun cotton, as believed by some chemists and as stated in the Academy of Sciences at Paris. The difference between them, he says, will be made known at the proper time. Until then, also, we may here remark, the several experiments and their results that have been made public can be received only as the performances and effects of certain explosive materials, concocted by sundry individuals, and not as proofs of the properties or capabilities of *the* gun cotton.

WESTMINSTER BRIDGE.

Our attention has been drawn to the following announcement in the daily journals:—

"Demolition of Westminster Bridge and Construction of a New One.—It is definitively arranged by the Westminster Bridge Commissioners, that the present bridge shall be removed. It is intended to apply next session for an act to pull down the old bridge and erect a new bridge, from the eastern end of Whitehall-place, to Sutton-street, in the York-road, Lambeth. Powers are to be taken in the act to allow the commissioners to make the following new streets in connexion with the bridge:—1st. A new street from the south side of Charing-cross by the south-west side of Northumberland-house to the north bank of the Thames, near the end of Whitehall-place, passing over Angel-court, Craigs-court, the eastern ends of Great Scotland-yard. and Whitehall-place. On the Surrey side of the bridge there will be a new street in a direct line to the east side of the Westminster-road, to Mason-street, Lambeth. On each side of the bridge it is intended to construct large and commodious piers for the use of the steamers plying on the river. The bridge will, it is said, be constructed of granite."

We fear the construction of this new bridge will be most detrimental to existing interests, and cause the greatest inconvenience to the inhabitants of Westminster. It will not only destroy the direct line of thoroughfare from Pimlico through the Park and Great George-street, over Westminster-bridge to the Elephant and Castle and the Surrey roads, but it will be the cause of increasing the traffic through the already over-crowded thoroughfares from Charing-cross to the City, as it is now far nearer and quicker to go from the Law Courts and Parliament-street over Westminster-bridge to the City, the Brighton and Dover Railways, and ultimately to the new station of the South-Western Railway; and consequently this traffic, if this new bridge be constructed, will be directed along the Strand; and besides, there will be a distance of a mile through Westminster from Vauxhall-bridge to the site of the proposed new bridge that will be entirely cut off from the Surrey side, excepting by the circuitous route over those two bridges. By a reference to the map of London, it will be seen that if this new bridge be carried over the river at right angles to the shore at Whitehall-place, the end on the Surrey side will almost come in contact with the foot of Hungerford-bridge! Surely the direct communication from Charing-cross over this last bridge is ample accommodation for the public, without intruding another within a stone's throw.

Why the new bridge should be removed from the present site of Westminster-bridge we cannot devise. A new bridge might be constructed on the eastern side of the present bridge, and the latter pulled down when the new one is erected, as was done with Old London Bridge. By removing Westminster-bridge, the only land-view from which a perspective view can be obtained of the new Houses of Parliament will be lost, and, as we before stated, all the elaborate and minute sculpture and decorations will not be seen. To get a view of the grand facade, we shall be obliged to go in one of the river steamers, and catch a transient glimpse as the vessel passes along.

Can it be supposed that Parliament will sanction such a scheme, to the destruction and despoilation of all the valuable interests connected with the trade and property in Westminster and Lambeth? and ultimately cause another bridge to be constructed, at the expense of the public, somewhere above the new Parliament Houses, which must follow if Westminster-bridge be removed from the present site.

MACHINE FOR PRINTING TWELVE THOUSAND SHEETS PER HOUR.

We have been shown the model of a printing machine, which we have little hesitation in designating a stride in the already wonderful progress that has been made in the printing art during the last five and twenty years. The steam press by which the *Daily News* is printed is, we believe, the fastest—because the newest, and, consequently, provided with the latest improvements—at present in existence; yet the average number of copies it produces within the hour is 5,000. The improved machine is calculated to print 12,000 per hour; and after a careful examination of the model, we have every reason to believe that the calculation is correct. To persons unacquainted with the details of printing machinery it will be next to impossible to convey a complete idea of the improvement, simple as is the principle on which it has been effected: a general notion may, however, be given. For the benefit of the uninitiated, we must premise that the present printing machines consist of two principal parts; first, of a sliding table, the middle of which is occupied by the type, each end having a surface on which the ink is distributed, and from which it is taken up by soft elastic rollers, and imparted to the type, secondly, of cylinders constantly revolving, to which the sheets are conveyed by tapes, impressed by the periodical sinking of the cylinders upon the type, and conveyed away again by the tapes. By the present plan, as the impressing cylinders revolve in one direction, an impression can only be taken at each forward transit of the type; the cylinders being lifted, to clear the type as it travels back again. In other words, the type passes under each cylinder *twice* to produce *one* impression. The new, or, as it is aptly termed, "The Double-action Machine," takes advantage of *both* passages of the type under its cylinder, printing a sheet as the type passes backward as well as when it goes forward. This is managed by reversing the revolutions of the cylinders at each stroke, simply by means of straight racks placed upon the long edges of the table, in which work cog-wheels attached to the axles of the cylinders. In this double action resides the main feature of improvement. It not only allows of two sheets being printed for one, but—by disencumbering the steam-press of the machinery necessary for lifting the cylinders that they may clear the table at each return—admits of the introduction of eight cylinders into the machine instead of four, the present maximum number. By this accession seven sheets are printed in the time of four—the natural supposition would be eight sheets; but a peculiarity it would be impossible to explain in this paragraph prevents the double action being imparted to the two outside cylinders, which constantly revolve as of old, in the same direction, and which reduces the ratio of production one sheet per stroke of the machine. There are many minor advantages derived from the application of the new principle, that would, if described, involve the general reader in a maze of technicalities which would not be, to him, very interesting. The inventor and patentee is Mr. William Little, publisher of the *Illustrated London News*. We are told that his first draught of the invention was so correct, that in making the model not the minutest alteration was found necessary—a proof of the soundness of the mechanical principle from which he started.—*Daily News*.

PROCEEDINGS OF SCIENTIFIC SOCIETIES.

ROYAL INSTITUTE OF BRITISH ARCHITECTS.

Nov. 2.—The President, Earl De Grey, in the Chair.

Mr. G. Allen and Mr. C. Mayhew were elected Fellows, and Mr. C. Barry, jun., an Associate.

A paper was read by Mr. Mair, "*On an Ancient Structure existing at Al Hather, in Mesopotamia, and on some Antiquities recently discovered by* A. H. Layard, Esq., *at Nimroud*;"—the description and drawings having been forwarded by that gentleman. Of the building at Al Hather, which appears to have been both a palace and a temple, considerable remains still exist. They were visited by Mr. Ross, the surgeon to the British Residency at Bagdad, in the year 1837; and again by Messrs. Ainsworth, Mitford, and Layard, in 1840,—when the latter gentleman took the dimensions and made the drawings exhibited by Mr. Mair. As to the precise date of the origin of this building, there is a difference of opinion; but Mr. Layard conceives that it owes its origin to the Sassanian dynasty of Persian kings. At the time of Jovian's retreat, the city was deserted; but, as the character of the ruins in question is that of a later date, it is probable that, after the treaty of Dura, the Persians, seeing the importance of Hatra or Al Hather, rebuilt and strongly fortified it. By an inscription repeated more than once upon the walls of the palace, it appears that that building was restored in the year of the Hejira 586 (A.D. 1190). The period of its final desertion is not known. The resemblance of these ruins to those at Ctesiphon is striking. To this day, the mode of construction adopted by the Sassanian Kings of Persia has been preserved in most parts of that country:—the centre of the edifice being usually occupied by a hall of large dimensions, which extends the whole depth of the building, and is open only at one end. It is called the Aiwam; and is flanked by a number of smaller rooms, generally forming two stories. The whole structure usually stands in the midst of a large court-yard, ornamented with gardens, fountains, and reservoirs. The palace at Al Hather has three aiwams (two of which are 98 feet long by 48 feet wide); but in other respects it closely resembles, in arrangements of the apartments, the modern houses of Shuster and Dizful, in Western Persia. The arches over the entrances are richly adorned with human busts; the head-dresses of which are extremely varied and peculiar,—but generally resemble those found in Persia on monuments of the Sassanian dynasty. The stone of which the building is composed is a very fossiliferous limestone. The blocks are well cut, neatly fitted, and firmly united by a fine and tenaceous cement. On each of them is found a peculiar mark, to which some have ascribed a mysterious meaning; but Layard appears convinced of their having been used solely in connexion with building purposes—as they occur also on those stones which could not have been exposed when the building was perfect. Mr. Mair then read a letter from Mr. Layard, respecting his discoveries at Nimroud. The mode of construction is described as peculiar. Slabs of marble, highly sculptured, are placed against intervening walls of sun-baked bricks. The roof was, probably, flat, and constructed entirely of timber. Ornaments and rings of ivory, copper, and porcelain are found among the ruins. The rooms are paved with either slabs of marble, layers of bitumen, or bricks. In some parts of the building, glazed and *painted* bricks occur;—the ornaments of which are extremely elegant, and the colours very brilliant. They are still in perfect preservation. Mr. Mair exhibited to the meeting drawings of one of the *bas-reliefs* representing chariots and warriors, and of one of the winged human-*headed* lions,—which excited considerable attention and curiosity.—It was stated that Government had lent its aid in promoting these researches; and that eight *bas-reliefs* and other sculptured fragments were on their way to this country.

Nov. 16.—S. ANGELL, Esq. V.P., in the Chair.

John Haviland, Esq., of Philadelphia, was elected as honorary and corresponding member.

The following paper was read:—"*Remarks on the Art of the Marbles from Halicarnassus*," by CHARLES NEWTON, Esq., M.A. (of the British Museum); and Drawings of the Bas-Reliefs, by JOSEPH BONOMI, Esq., were exhibited to the Meeting.

Mr. NEWTON proposed to consider whether these marbles really formed part of the celebrated Mausoleum of Artemesia. He stated that the description of Halicarnassus left by Vitruvius is far more minute than that of most cities of antiquity; but unfortunately the interpretation of some expresions made use of by that author are so doubtful as to leave the question of the site of the principal buildings mentioned by him still open to much difference of opinion. Mr. Newton then explained, by reference to an enlarged copy of an Admiralty chart of that part of the coast, his arrangement of the various buildings surrounding the port—which was only a partial adoption of Vitruvius's description, and would make the spot now occupied by the fortress the site of the *palace* of Mausolus; while that of the mausoleum itself would appear to have been situated where the modern street of the town now exists. Still, there are no remains which would justify any positive conclusion on this point. Adopting, however, this arrangement, the marbles in question must then either have formed part of the palace, and have been used in the construction of the fort as materials lying "in situ,"—or, if fragments of the mausoleum, they must have been brought for that purpose from the higher ground.

Mr. Newton then proceeded to consider whether the style of these sculptured fragments is that of the period at which the celebrated mausoleum was constructed (B C. 350); and whether they are worthy of the great reputation of the artists employed in the adornment of that monument. With respect to the subject represented—a Combat between Amazons and Greek Warriors—Mr. Newton entered at some length into its connexion with the mythical history of Caria, or of the house of Mausolus. These figures appear on the coins of several cities of Caria, and other parts of Asia Minor; and the myth was, without doubt, sufficiently national to account for its being chosen as the subject for the decoration of so important a monument as the mausoleum.

Lastly, Mr. Newton referred to the structure of this monument itself,—giving interisting extracts from Pliny, from the Comte de Caylus, and from several ancient MSS. Few of the conjectural restorations of the monument estirely agree: the data—particularly the dimensions on which they have been made—being slender and equivocal; the question of the relative size and position of the substructure or basement, and the consequent arrangement of the steps, being doubtful. The description given by Pliny is too doubtful to enable us to adjust the measurement of the frieze to any of his dimensions. In default, then, of more direct evidence of the site which these marbles originally occupied, their dimensions considered architecturally, or the character of their execution and subject, we must remain contented with the positive declaration of Fontanus—that the fortress of the Knights of Rhodes was built out of the ruins of the sepulchre of Mausolus; and, on the faith of this declaration, consider that in these marbles we possess fragments of one of the seven wonders of the world.

Professor DONALDSON offered some remarks on the Design of the Mausoleum erected at Halicarnassus by Artemesia, and read some extracts from his journal, in illustration of the description given by Vitruvius of the site of the ancient city; and in describing the existing antiquities there, alluded to many fragments of the Ionic order, lying about the modern town, now called Boodroom. Mr. Donaldson exhibited his restoration of the Mausoleum, and also drawings of the details of a Doric temple and other antiquities, from measurements taken by himself on the spot.

Professor COCKERELL, R.A., stated his intention of devoting two Lectures, in January next, at the Royal Academy, to the subject of this and other similar Mausolea, and invited the attendance of such Members as felt interested in the subject.

The following resolution of the Council respecting the Halicarnassian marbles was announced:—

"That the circumstance of the opening to public view, in the British Museum, during the vacation of the Institute, the sculptured marbles recently obtained from Boodroom (the ancient Halicarnassus), demands special notice and record; and the Council therefore avail themselves of the opportunity afforded them by this, the first meeting of the session, to express the gratification they feel, that these important and interesting relics of antiquity are now secured for the general advantage of artists, and for the promotion of art, in this kingdom.—The Council reflect with satisfaction, that the acquisition of these valuable monuments of ancient art has been effected through the suggestions offered to her Majesty's Government, by the architects of this country, in the year 1841, and they desire to express the acknowledgments of the Members of the Institute for the courteous attention given to the representations then made to her Majesty's principal Secretary of State for Foreign Affairs, the Viscount Palmerston, through whose instrumentality so desirable an addition has been made to the National Collection.

The CHAIRMAN announced, that since the last meeting, an application on the part of her Majesty's government had been made to the Council, for their opinion relative to the position of the equestrian statue of the Duke of Wellington, on the arch at the entrance to the Green Park; in consequence of which, a report had been prepared and forwarded to Lord Morpeth, and the Council had reason to believe that the recommendations therein would be adopted by her Majesty's Government. The report was read as follows:—

"That the effect of the equestrian statue of the Duke of Wellington, on the top of the arch at the entrance to the Green Park, is unsatisfactory, and its position there most objectionable.

"The Council in the first place deem it proper to observe, that the following opinions are given as those of the Council only, there not being time sufficient to submit the question to a general meeting of the Institute; but a well grounded impression prevails, that few, if any dissentient voices would be found among the members to the judgment of the Council in this matter.

"The Council next refer to the strong opinion expressed by the architect who designed the arch, and who has supported his objections with much of sound and excellent reasoning; and they consider it a recognized principle amongst artists, that the architect who designs a successful work is by far the most competent authority upon a question as to the propriety, size, and character of any sculptural adjuncts or decorations proposed to be applied to his own design.

"Independently of the valuable opinion referred to, the Council feel, that the statue is by far too large for the mass it was intended to decorate, and discordant with that harmony of proportion which is indispensable between the structure and its sculptural embellishments. The size of the arch is apparently diminished by the colossal dimensions of the statue; the elegant screen of columns towards Hyde Park, and indeed all the contiguous buildings are alike affected, and the grandeur and importance of the principal approach to the metropolis is thus lessened by the false scale produced by the colossal size of the statue.

"The most celebrated statues of colossal or heroic size were all placed on suitable plinths or pedestals on the ground, and not applied as crowning ornaments to buildings. The Jupiter at Elis, the Minerva at Athens, the Marcus Aurelius in the Roman Capitol, and the Group on the Quirinal, may be cited among many other ancient statues; and of modern times, the statues in the Square and Loggia at Florence, of San Carlo Borromeo at Arona, Peter the Great at St. Petersburg, and George the Third in the Long Walk at Windsor, may be instanced.

"In conclusion, the Council feel, that if the statue were removed to an approved site, and the arch enriched with appropriate sculptural decoration, under the superintendence of its architect, such decorations being accessorial and subordinate, it would then no longer be subject to the severe criticism of artists, foreign visitors, and persons of acknowledged taste."

NOTES OF THE MONTH.

A correspondent of the *Athenæum* writes from Freiburg, that in the architecture and internal decorations of almost all the buildings lately erected, we see the most gratifying displays of taste and skill in adaptation. Some of the new railway stations exhibit extraordinary elegance in design and fertility of invention. I would particularly refer to all the buildings erected in connexion with the line of railway extending from Mannheim to Freiburg, under the direction of the architect of the Grand Duke. From the policeman's cottage to the grand central station, all have been designed with a view to utility and ornament. The smaller buildings have a good deal the style of Swiss cottages, with overhanging roofs, quaintly carved. The central stations are distinguished by a clock tower, and have something of an Elizabethan character. A great deal of ornament is expended in the roofs of the sheds over the platforms. An arched portico, the ceiling of white and red brick, covers the approach to the pay windows and post office. At each extremity of the building devoted to waiting rooms, clerks, offices, &c., rise two pavilions, or square turrets, inhabited by the superintending officers of the railway. It is easy to imagine that, with such arrangements, a very imposing façade may be produced. In its construction, white bricks with stone dressings have been employed, and a profusion of carved wood; the roofs, which are steep and visible from all sides, are composed of tiles of three colours, light brown, dark brown, and green, arranged in diagonal patterns. The internal decorations of the waiting rooms and the flower frescoes of the walls and ceiling are all designed by the architect. A good effect is produced on the platforms by red and white tiles laid in ornamental patterns.

Burnettizing Timber and Marine Insects.—Sir W. Burnett, the head of the Naval Medical Department, paid his annual official visit to Sheerness, on Saturday, 7th November last. About 18 months ago a series of small logs of ash, elm, pine, teak, "condie," or New Zealand fir, beech, and oak, after having been duly immersed in his solution, were deposited at neap tide at the mouth of the harbour, with another series of the same kinds of wood in their natural state. On being taken up and laid out for inspection on Saturday, externally Sir William's series exhibited the smoothest surface; but, on being split open, with certain exceptions like the series which had not been immersed in his solution, they exhibited one living mass of "pholades," the generic name, we believe, of the worm in question, encased, where not broken, in their testaceous coverings. The Malabar teak, in both cases, was riddled like a sieve, as were the ash, the elm, and the beech; the pine was in rather better condition; the oak was not much affected; the "condie" was as perfect as when at first laid down, with the exception of one single worm, who had found his way into one of the extremities of the log which had not been immersed in the solution. The exterior of all the kinds of wood was considerably injured by a smaller insect, particularly the pine and the teak. As has been stated, the exterior of Sir William's series was not so much decayed, but, as to the interior, there was little difference from that of the other. Some of the worms inhabiting the interior were 8 or 9 inches long, while few were shorter than 2 inches; all were about the circumference of a medium-sized quill, and each possessed a testaceous covering and cell for itself. Deriving its sustenance through the pin-head opening in the exterior of the wood, it keeps the smaller extremity constantly there, while with the other, gradually enlarging, it bores for itself with its treble-shelled proboscis a cavity in many instances sufficiently large to admit the little finger.

Another Bridge over the Thames.—Parliamentary notices have been given to apply to Parliament in the next session to bring in a bill for constructing a bridge across the river Thames, from near Essex-street, Strand, to the opposite shore, near to Dowson's-wharf, in the Marsh and Wall liberty. Also for making and maintaining a market, at the south end of the proposed bridge.

Railway Station at London Bridge.—The London and Brighton and South Coast and South Eastern Railway Companies are making preparations for the erection of a large and elegant station, to supersede the present incommodious building. It is designed to extend from Joiner-street and New-street on the west, Maze-pond and Wells-street on the south and south-west, to the London and Greenwich Railway on the North of Crucifix-lane. The streets at present passing under the station are to be blocked up.

Metropolitan Improvements.—It is reported that the following extensive improvements in the vicinity of Leicester-square are to be made. The whole of Upper St. Martin's-lane is to be demolished, and a street, 101 feet wide to be formed, to be ultimately carried through the heart of the Seven Dials to Tottenham-court-road. A new street, to be formed at the junction of St. Martin's-lane, Cranbourn-street, Newport-street, and Long-acre, in a line through to King-street, Covent Garden, and the Strand, the south end of St. Martin's-lane, near the church, will also be widened by throwing back the houses at the corner of Hemming's-row, and a communication opened between Coventry-street and Oxford-street, by throwing down the pile of buildings separating Rupert-street and Berwick-street. The cost of these undertakings will, it is stated, be 120,000*l.*

The Birkenhead Docks are now progressing very rapidly, and it is expected that one of them will be ready to be opened for business at the beginning of the new year.

St. James's Chapel, Morpeth, is built of stone, in the Norman style; the architect is Mr. Terry, of London.

Liverpool.—In consequence of the great increase of traffic on the North Western line, the company contemplate pulling down the present terminus at Lime-street, with all its appendages, and erecting another upon a scale of magnitude equal to the requirements of this leviathan establishment. To effect this object it has become requisite to remove about 450 feet of the Edge-hill tunnel, at the extremity adjoining the station, and to excavate the solid rock for a considerable distance at either side. Even the space thus cleared has proved inadequate; and it is contemplated to remove the church near Rupert-street, London-road, and on its site erect carriage-sheds, and other appropriate buildings. The church, which is a handsome edifice of recent construction, will be replaced by another to be built at the expense of the company, in the most suitable position that can be found for the purpose. The architect of the company has been requested to furnish plans and estimates for the new station, with a view to the immediate prosecution of the works upon the necessary act having obtained the sanction of parliament. It is supposed that upwards of two years must elapse before the works can be completed, and that the cost will exceed 300,000*l.* It is also proposed to construct a tunnel from Lime-street to Wapping, for the purpose of conveying goods from the docks.

It is reported that the Wellington Statue will be placed in the open space between the Horse Guards and the enclosure in St. James's-park.

The Great Britain.—The attempt to construct a breakwater to defend this vessel have totally failed, and she has recently suffered such additional injuries that the engines and masts are at length about to be taken out.

Sewers.—It is stated that there are 50 miles of sewerage in London.

Electric Telegraphs in London.—Pipes containing wires, communicating with the Southampton Railway telegraph, are in the course of being laid down in the Kennington-road. These pipes are put about 18 inches below ground, and run beside the foot pavement. They will be continued to Charing-cross and the Royal Exchange.

Brighton.—A new infirmary has been erected at Brighton, for diseases of the eye. The architect appears to have been afflicted with an opthalmic disease himself, or else to have been desirous of bringing custom to the institution. The architecture (!) follows the approved fashion of sticking the imitation of the portico of a Greek temple on to the front of a modern square-built dwelling-house.

Sherborne Abbey Church is to be restored under the superintendence of Mr. Farey, who proposes to remove the galleries, &c.

Croydon Atmospheric Railway.—A correspondent of *Heparath's Railway Journal* states that this railway will be converted into an entirely locomotive line.

South Devon Line.—It is said that the repairs of the breaches made by the sea, and the defences against future injuries, will cost £100,000.

The North British Line has again been seriously injured by the sea. An embankment at Lamberton, within a few yards of the sea, has fallen.

On the Chester and Holyhead line also great injury has been done by the sea; a great part of the sea-wall at Penmaenmawr has been washed away. Why *are* railways built close to the sea? The engineer must have somewhat of King Lear's madness, who

> "Contending with the fretful elements,
> Bids the wind blow the earth into the sea."

The Barrentin Viaduct of the Rouen and Havre Railway has been rebuilt in a substantial manner. It is 100 feet high, and 1,500 feet long, and has been completed in the short space of six months.

Glasgow Cathedral.—It is very gratifying to learn that this edifice is being restored. The Scotch possess so little good architecture that they should take care of what they have.

According to the *Edinburgh Register*, a corps of surveyors is now engaged in the trigonometrical survey on Ben Nevis in Scotland, where they have a theodolite, constructed by Ramsden, 3 feet in diameter, with 8 microscopes, reading to tenths of seconds; and by which, with the aid of sun mirrors on distant mountain tops, it is expected that observations may be taken at a distance of 120 to 150 miles.

Eton College Chapel.—The great east window is being filled with stained glass. The Marchioness of Lothian has contributed the glass for one compartment, and the boys for three other compartments.

The Cambridge Botanic Gardens.—The vice-chancellor planted the first tree on the 2nd ultimo. The *Cambridge Chronicle* says: "Twenty men are actively engaged in deeply trenching and leveling about seven acres of the ground, intended for the immediate reception of as many of the principal groups of the larger descriptions of trees as can be procured before winter. The curator, who is zealously superintending the work, has found both the depth add quality of the soil much superior to what he had anticipated: and he considers even the poorest portions, towards the south-west angle, perfectly suitable to certain tribes. The gentle undulations over the whole twenty acres, and the introduction of a large sheet of water, where the depression is greatest, will tend greatly to break whatever of formality it may be necessary to observe in the scientific grouping of the various objects that are cultivated in a botanic garden."

Covent Garden Theatre.—The whole of the interior of this theatre before the curtain, from the ceiling to the foundations is to be taken down, and the area of the pit considerably enlarged, consequently a larger number of boxes will be obtained, of which there will be five tier, the greater part of them being private. The stage will also be advanced considerably before the curtain; there will likewise be several other alterations for the convenience and comfort of the public who patronise the Italian Opera, one will be to make a carriage drive under the grand portico in Bow-street. When finished the interior will have a magnificent appearance. These extensive alterations are entrusted to the directions of Benedict Albano, Esq.

NOTES ON FOREIGN WORKS.

The Royal Foundry and Machine Manufactory of Munich.—Amongst the great works executed of late at this establishment, are the statues for the great fountain on the Freiung-square, at Vienna. The middle part of the fountain, constructed of large-grained granite, will be surrounded by five statues, 8 feet high,—the Danube, represented by a female, which, with a far-reaching look and placid countenance, seems to contemplate the expanse of that river; the Po, as the guardian of Italy, is represented with a key in her hand; the Elbe, and the Vistula. On the summit of the work appears the figure of Austria, a proud, sublime, stately figure, but unfortunately represented with the attributes of strife and contention—the spear and shield.—The four statues for the Jubilee column at Stuttgart, representing allegorically the four estates of empires—warriors, teachers, traders, and producers, have been cast from the models of Professor Wagner, at Stuttgard, whose thoughtful and delicate style is generally admired.—The Huskisson statue at Liverpool, and that of Charles John, King of Sweden, for Norkorseing, have given general satisfaction. The prepartions for the casting of another portion of the statue of "Bavaria" causes great excitement; it is the largest ever executed in ancient or modern times. The upper part is already cast.—The plaster of Paris model of the statue of Bavaria, for the triumphal arch in the Ludwig Strasse, is now exhibited in the royal foundry, previous to being cast. With flowing garments and an onward look, she firmly grasps the reins of the four lions which draw the quadriga. This work was designed by M. de Wagner at Rome, by whom, assisted by his pupils, the model has been made. Beside the royal establishment, the iron foundry and machine manufactory of M. Maffei is next to be adverted to. Here, on a most extensive scale, the forging and casting of large works of art and utility are carried on, amongst which, some huge staircases and sepulchral monuments of Gothic style are conspicuous. The ornamented pieces for the inner roof-work of the round arches of the Munich *campo santo* (cemetery) are also cast here.

The Munich Art Union seems to have fallen into an egregious error. As many persons of the middle classes have joined it lately, the committee, thinking, probably, to do them a piece of courtesy, have made the subject of the members' plate, as general and every-day a thing as possible. It is not the aim of Art Unions to keep art continually on the same level, still less to debase it; on the contrary, it is the elevation of art and public taste which is their chief and legitimate province. So, after all, the above may be considered anything but a compliment, for which, at least, it seems to have been intended. The subject, therefore, for next year's prize plate is yet under contention.

Mountain-Relievo Exhibition at Munich.—The well-known engineer and geographer, M. Stoltz, has lately exhibited his relievo of Hohenschwangau in the conservatorium of the Topographical Bureau. It renders one of the most interesting parts of the mountains of South Bavaria with a correctness, which only repeated barometical admeasurements and the surveying of every detail could effect. The relievo of Tegernsee made by M. Stoltz previously, and on a larger scale, is equally interesting to the geographer and geologist.

Restoration of Ancient Canals in Russian-Caucasia.—The Russian Government have very praiseworthily begun the restoration of those canals of irrigation, which furrow the whole south-eastern portion of the trans-Caucasian provinces. Most of these canals were constructed by the kings of Armenia, and subsequently by the shahs of Persia and the sirdars of Erivan. The origin of some is even ascribed to the great historical monarch of ancient Asia, Semiramis, amongst which is one called Shamiram. What must have been the fertility of these countries—of which, however, history has preserved no record—may be guessed from the fact, that in one district of Eriven alone, there are to be seen 148 canals of great extent, which were the source for the further finding of 384 secondary branches. But the greatest part, and amongst them the very largest, present but a heap of ruins: which, however, by their stupendous development, attest the fertility and population of these now almost deserted *steppes*. All this, war, rebellion, and oppression, have swept away. Governor-General Prince Woronzoff is said to consider the re-construction of these ancient canals as a favourite idea, which would do an immense good to the inhabitants of Russian-Caucasia.

The new Haven of Swinemünde on the Baltic.—The Prussian Government is using great exertions for making this the "Havre of the North." The Oder has been corrected and regulated, and the harbour laid out and enlarged with great judgment, and at a great expense. The situation is very felicitous, as Berlin can now be reached in 9 hours, Copenhagen in 18, and St. Petersburg in 48. The number of vessels frequenting the harbour has increased during the last year to 1500, mostly English, with coals, &c.

Ancient Roman Canals.—The ingenuity and sucess of the Romans, not only in works of art, but also in objects of general utility, has lately become more apparent by the discovery of some canals in the famous Pontine swamps, used in ancient times for the drainage of this now unhealthy and barren country. According to the opinion of experienced engineers, it will require but little trouble to put them in complete repair, and make them again available for the purpose which they served 2000 years ago.

The Coal Mines of Hungary.—Coal has lately risen into great importance in Hungary, by the introduction of extensive steam communication in that country. The quality of coal in the Banat is said to be equal to the best English. For the purpose of properly opening the coal mines of Oravitz, Gerlistz, &c., an under-shaft is to be constructed, which will extend to the great length of 2,600 fathoms. For ensuring a proper ventilation, this tunnel will be 18 feet high, and occasion an expense of half-a-million of florins: but, when finished, will yield a yearly produce of two millions of chaldrons of coal. But for ascertaining positively, whether the seams of coal retain their size and quality down to the required depth, gigantic pits will be sunk in the Stewendorf mine, and coal and rock raised by steam engines of proportionate magnitude. For obtaining an easy outlet for such a mass of mineral, a railway will be constructed from Oravitz to the Danube. The iron works in these distant parts of Eastern Europe will receive a great impulse, as an astonishing number of rails is now in demand. Forges and tilt-hammers on a large scale will enliven those hitherto inactive and unproductive countries.

Restoration of the Harbour of Marsala, Sicily.—This harbour, one of the finest and best situated in that island, is to undergo a thorough restoration, by the voluntary contributions of the inhabitants of Marsala and some of the English houses engaged in the wine trade. An engineer has lately arrived to make the necessary surveys. The harbour is so fine, that the Arabs called it *Mars-Allah* (God's-haven), but John of Austria had it filled up after the battle of Lepanto. These obstructions removed, Marsala will double its commerce.

New System of Bridge Construction.—At the late Exhibition of French Industry, at Paris, M. Neville's model of a bridge, upon a new system, attracted much attention. The Belgian government has since taken up the subject, and experiments were made on the North Line. Two locomotives and their tenders were placed at the disposal of M. Neville, of the enormous weight of from 30,000 to 32,000 kilogrammes. They were made to pass the bridge, side by side, first at a slow and then at a rapid speed. The experiments, several times repeated, afforded the greatest satisfaction, as these heavy masses produced very little flexion in this comparatively slight structure; indeed, the flexions of the bridge, with an opening of 72 feet, did not exceed, even at the greatest speed of the engines, more than ⅜ inch in the middle. M. Van Esschen, engineer of the government railways, was under the bridge, to measure the flexion; and the persons on the bridge stated that the vibrations during the speediest transit were nearly imperceptible.

Steamers on the Caspian Sea.—Since July last, two iron steamers, of 100 horse power each, perform twice a month the journey between Astrachan and Baka, which occupies only two days. Thus, a person may now go from the Caspian to St Petersburg in 15 days. A railway, only for horse power, has also been opened between the Don and the Wolga.

Castle Wartburg, Saxe Gotha.—This castle, once the abode of Martin Luther, is undergoing a thorough renovation by order of the hereditary grand duke of Saxe Weimar. It is, after all, no easy task to restore such a huge building, erected at various periods of remote date—to pitch at the right ideas of the original builders, to omit nothing essential, and to produce a harmonic whole. This difficult task has been confided to M. de Quant, architect to the court of Prussia. For the sake of obtaining a correct idea of all the structures which have existed on the spot, the various foundations and walls have been laid open by extensive excavations. What has been already found is of great value and beauty. The middle façade of the court or square of the castle presents three stories of arcades, in the Byzantine style. A large quantity of rubbish and ashes of former conflagrations has also been removed, and several rows of Byzantine columns of good proportions, have been discovered on the eastern wing, and which will, when restored, exhibit a finer appearance than the more modern ones, as they are higher and of more slender modules. All the buildings which surround the large court are now exposed, and present a very different front and position than has been hitherto supposed. A staircase, hewn in the main rock, has also been discovered, leading to the baths of the ancient landgraves. The apartments of the landgravines appear to have been under ground, but are of large and fine proportions, each supported in the middle by a column, with a very fantastic capital, like those in the Remter, at Mareinburg. Some parts of the castle still appear as they did in olden times, as, for instance, the banqueting hall, which is adorned with portraits of former markgraves and landgraves. Close to it is the armoury, filled with figures of knights, on foot and on horseback. It is to be remarked, that permission has been given to inspect the castle at all times, so that visitors are even occasionally admitted to the rooms which the hereditary grand duke and his guests occupy—a liberality, after all, only possible in a small and not over-crowded town of Germany.

Kaulbach's Cartoon for the Berlin Museum.—This latest work of the great master has been exhibited at Munich, and is of the size of the picture of the Destruction of Jerusalem, by the same artist; but the work itself will be still larger. It is the first of a series of six pictures for the same royal establishment, and represents the "Division of nations at the building of the Tower of Babel." German periodicals expatiate much on the coincidence of the ideas of the artist with those of the modern German school of philosophy, and quote Schilling to prove the beauty of a cartoon. So far English art-criticism has not yet provided, and we can merely state that Kaulbach has represented Nimrod as failing in his over-reaching tendencies, that the people are driven forth from their unholy occupation—the tribes of Shem, Ham, and Japeth each powerfully and originally characterised by a splendid force of the crayon. Besides this force of the composition, that particular *naiveté* and sweetness of Kaulbach's works is also diffused over the whole cartoon—making the beholder long after the coluor-execution of such sublime thought.

The Earthquake in Italy.—This phenomenon has now ceased to exert its ravages, terminating with a few slight shocks. According to all experience, such undulations of the soil following a great earthquake, are the last throbbings of the volcaic powers, acting at an astounding depth. Tuscany had been, for ages past, free from such awful catastrophes as have lately visited it, and those formerly perceived were only the last eradications of the earthquakes of Sicily or Calabria, whose effects are always felt at great distances. The *Gazetta di Firenze* has given, of late, an accurate account of this phenomenon, by which it appears that the centre of the movement was the Colline, where it extended over a space of about 100 square leagues. In the former locality, the large villages of Lorcazana and Orciano resemble places demolished by the battering of cannon. The opinion generally received by geologists since the times of Dolomieu and Bertrand, that earthquakes and volcanic eruptions are contingent on very rainy seasons—the waters penetrating to the lower parts of the earth's strata, being there converted into steam—has not been confirmed in this case, the season having been a very dry one.

Academy of Sciences of Paris.—M. Lerebour the younger, one of the principal mathematical instrument makers of France, has forwarded to the Academy a volume, "On the chemical and apparent area of the objectives of the Dauguerreotype." M. L. states that he has succeeded in making these two areas coincide, and that the instruments which he has invented completely obviate the hitherto definitive coincidence. The Academy considered this a great improvement of the Dauguerreotype.—M. Faye, astronomer of the Paris Observatory, has also sent a memoir, entitled "Determination of the parallax or distance of the Argelander (the star 1,830 of Groombridge's catalogue) from the earth. In this fine essay, M. Faye has well combined theory and practice, and united elevation of mind with minutiæ of detail and correctness of observation. The result of his observations makes this star of the magnitude of 1″ 06, and at a distance from the sun of 190,000 middle distances of the earth from the sun; and, at the rate of 75,000 leagues per second, the light would require three years to arrive from the Argelander to us.

Diffusion of Sulphur over the Surface of the Globe.—M. Dumas mentioned in his memoir, the cascade which the Rio Vinagre forms not far from the volcano of Pareci, in Popanja. The observations of Humboldt and Boussingault have proved that this water contains free sulphuric and hydrochloric acids. An analogous phenomenon are the Lagoni of Tuscany—those open spiracles of the ground, where aqueous vapours constantly issue, and which contains, besides boracic acid, a considerable portion of sulphuretted hydrogen. Other phenomena of the kind are to be met with all over the globe. Sulphur also holds a great importance in the formation of all nitrogenous substances, animal and vegetable—constituting about the $\frac{1}{100}$th part of their weight. Thus 10 kilogrammes of dried nitrogen matter (which is about the weight of an ordinary sized person) contain 100 grammes. The quantity of sulphur, therefore, which is scattered over the globe, be it in a mineral or organic form, is very great. Messrs. Belfield—Lefevre, and Foucault have presented to the Academy an essay on their improvements of the Dauguererotype. "Hitherto—they say—the merely iodized plates have not been efficient whenever the diverse portions of the object to be represented possess notably different intensities of illumination; and thus, by the process hitherto pursued, the different portions of the plate could not appear with the tone corresponding to the respective intensity of illumination." The process consists in polishing and iodizing the plate as usual, and then to make it absorb vapours of bromine, three times the amount which has been hitherto considered the maximum of the susceptibility of the plate.

NEW CHURCHES.

St. Thomas, Winchester.—This church is nearly completed externally on a scale of great magnificence. The style is Decorated, and the eastern elevation exhibits a chancel and chancel aisles under separa-e gables. The new church has been built upon high ground, and its spire will have a very striking effect. The old church of St. Thomas having been found inadequate for the wants of the parishioners, the new edifice is to supply its place.

Christ Church, Portswood, Southampton.—Messrs. Brandon are the architects of this church, which is in the Decorated style, and consists of a chancel without aisles, and a nave with aisles, and a clerestory of quatrefoil windows.

St. Mark's, Swindon.—The Great Western Railway Company have built and endowed a handsome new Church. The architects are Messrs. Scott and Moffatt. It is gratifying to find a work like this entrusted to architects, who, we know, generally prefer real to showy architecture, and are incapable of using *papier machè*, or stucco, in the decoration of churches. The present edifice consists of a chancel and sacristy on its south side, a nave with aisles, a porch on the south side, and a tower and a tower and spire on the opposite side.

Wallingford.—The Chapel of St. John the Evangelist has been consecrated by the Bishop of Oxford.

Seer-Green, Bucks.—The recently consecrated church has been built by Mr. Deerson, in the early English style. The extreme length including the chancel, is 80 feet, the bell-turret is 60 feet high. The church is fitted with open seats throughout, and will accommodate 200 persons.

Chantrey, Somerset.—The Church of the Holy Trinity is another of the works of Messrs. Scott and Moffat, and comprises a nave with a porch on its south side, a chancel, sacristy, and bell-tower. The style is decorated All the windows are glazed with painted glass, by Mr. Wailes. Th seats are of oak, uncontaminated by varnish, the pulpit is of stone, the chancel is paved with ornamental tiles. There are stalls erected, not merely for ornament, but for actual use by the choir. This church ha been built at tne cost of a benefactor recently deceased.

St. Edmund's, Vobstor, Wells, is built by Mr. Ferrey in the Decorated style, and consists of nave, chancel, and sacristy, with lean-to roof. There will be neither galleries nor pews in this chapel.

St. Michael, Bissage, Gloucestershire, is a small structure built by Mr. Harrison in the Decorated style. The western tower will hereafter be crowned by a spire. The chancel is paved with encaustic tiles, and contains returned stalls. The pulpit is of stone and stands in the nave.

Darweston, Blandford.—Mr. Hardwick has rebuilt the church here at the expense of Lord Portman. There is a spacious chancel with an elaborate timber roof: the pulpit is of carved oak.

Stert Church having been almost rebuilt has been opened by the Bishop of Salisbury.

St. Mary's Flint. We regret to learn that this very ancient church is to be pulled down to make way for a modern structure.

St. Giles, Petworth is being rebuilt from designs by Mr. Billing in the early English style. The total length including the chancel is 90 feet. Over the porch is the south aisle is a low tower, the roofs internally are open.

St. Mary's Torquay a very fine Church, by Mr. Salvin. The nave has aisles and clerestory, and the chancel is terminated by an apse. On the south side of the nave is a tower. The effect of the interior is very imposing, and is not marred by an ostentatious redundancy of ornament. The west window consists of five lancets of which two only are pierced all the glass will be stained.

St. Paul, Alnwick is another spacious structure, by Mr. Salvin, and is built and endowed by the Duke Northumberland. The style is decorated. The plan comprises a lofty nave with clerestory and aisles, a chancel with aisles, and a high tower on west side. The east window i filled with flowing Decorated tracery. The stalls in the chancel scarcely deserve their name as they are not appropriated to their apparent use, but are simply superior pews for the Duke of Northumberland's family. When will dukes doff their dignities and privileges at the church-doors?

There appear to be about 400 churches in progress throughout the country, and almost every one is built in the style of our national architecture.

STEAM NAVIGATION.

The Oriental and Peninsular Steam Navigation Company.—The two new vessels which have been lately added to the Fleet of this Company, the Pottinger and the Ripon, have been fitted with steam engines on the oscillating principle, the largest we believe that have been as yet constructed; they are 76 inches diameter and 7 ft. stroke. Letters from the captain and engineer of the Pottinger have been received, the one from Gibraltar, the other from Malta: they speak in high terms of the performance of the engines, she passed through some very bad weather between England and Gibraltar. The Ripon went to sea without any trial of the engines, and although exposed to the most adverse circumstances for new engines, and having had her rudder-head washed off in the late heavy gales, there is not under all the trying circumstances to which they have been exposed, any fault to be found with her machinery, for, with the ship labouring in an unmanageable state in the trough of a heavy sea for some hours, the engines were never brought up, and continued to do their work all the time admirably. These satisfactory results prove that oscillating engines of any power may be used for marine navigation, by which there will be a saving in space and weight.

The Capri and the Vesuvius.—These two new steamers have been built for the Neapolitan Steam Navigation Company, by Messrs. Ditchburn and Mare; they are constructed of iron, and are 189 feet long, and feet beam, and 600 tons burthen, with steam-engines of 220 horse-power—double cylinder by Messrs. Maudslay and Field. At the trial of the Capri down the river Thames, at Long Reach, it is stated that she attained a speed of 17 miles per hour. The vessel is elegantly fitted up, and promises to be a clipper.

The Sphynx Steam Frigate.—This war steamer is a vessel of 1200 tons, fitted with a pair of oscillating steam engines of 500 horse power, by Messrs. Penn and Co.; the cylinders are 82¼ inches diameter, and 6 feet stroke, and fitted with double slide valves. When she made her experimental trial down the river Thames last month she was laden with 350 tons of coal, and all her stores for 12 months, and provisions for 3 months; her draught of water was 14 feet 1 inch forward, and 15 feet 1 inch aft. It is stated that she ran an average speed of 13 miles an hour, and made 14½ revolutions per minute, with the floats of the paddle-wheels deeply immersed. The great success which those engines have attained, as well as those of the Pottinger and Ripon, also fitted with oscillating engines, by Messrs. Miller and Ravenhill, and of about the same power as the Sphynx, clearly show that oscillating engines of any power may be as easily constructed and adopted for marine purposes as fixed cylinders.

New Holyhead Packets.—The Admiralty have contracted for four new steam packets for the Holyhead station. One to be built by Messrs. Ditchburn and Mare, it is understood, on the lines of the Surveyor of the Navy, engines by Messrs. Seaward and Co.; one of wood, on the lines of Mr. O. W. Lang, with Penn's engines; one, engines and vessel by Messrs. Miller and Co.; and one vessel by J. Laird, the engines by Forester, of Liverpool. They are to be called the Caradoc, Llewellyn, the Kathleen, and the Banshee.

The *Janus*, steam-sloop, Lord Dundonald, will be ready by the beginning of the year to make a final trial, the Admiralty having granted 1000*l*. to make the necessary alterations.

The *Medea*, steam-sloop, on the 6th ult., proceeded down the River Thames to test the engines, at the mile in Long Reach. Her speed on the first trial was 8·889 knots against the tide, and 13·094 with it, giving an average of 10·991, but on subsequent trials she made more than eleven knots. She had on board about 190 tons of coal. Her draught of water was 13 feet forward, and 13 feet 5 inches aft. Her engines, which were supplied by Messrs. Maudslay and Field, were in excellent working order, and made 24 revolutions a minute.

Screw Propeller.—A series of interesting experiments on the powers of the various screw-propellers, and the best mode of fixing them in steamers, have been carried on and are still in progress with the Dwarf, steamer, which has been set apart for these experiments. The first trial was made with the common Archimedian screw (Smith's patent), and the results were as favourable as those exhibited by any subsequent invention. The next trial was made with Rennie's screw, but the results, in this instance, were not so satisfactory. A third trial was made with Hodgson's parabolic propeller, and, up to the present time (for this invention is to be again tested) the success was equal to that of the common propeller. A fourth trial will soon be made with Woodcroft's patent, constructed upon a new plan of shifting the angles of the screw to the most favourable position, with the view of determining the best angle of impingement. Some trials have also been made by altering the dead wood of the Dwarf, so as to resemble the square sterns of the old block ships; but in this case it was found that the screw could scarcely give the vessel tideway.

The *Teazer*, a small iron steamer, with engines of 100 horse power, and fitted with the screw-propeller, was tried again on Nov. 16, at the mile in Long Reach; her engines, which are on the vibrating principle, by Miller and Ravenhill, attained a maximum number of nearly sixty revolutions, but she did not make very rapid progress, the stern of the Teazer being square, which is apparently the worst form for the action of the screw propeller.

It is the intention of the Lords Commissioners of the Admiralty that, in future, the engineers in steamers shall be considered as ward-room officers. The alteration is most creditable to the board.

The Effects of Shot on Iron Vessels.—The information received from the officers of the Gorgon steam vessel, which has lately arrived from La Plata, gives a very alarming account of the effect produced on the hulls of the Harpy and Lizard iron steam vessels by the shot from the batteries of Rosas. It was expected, from the nature of the material, that any breach made by shot would leave a clean fracture, merely curling up the lips of the orifice, as is usual when fractures are caused in iron by the application of an ordinary force. The results, however, are quite different. Instead of a clean fracture, large splinters of iron flew about in all directions on the hull being struck, rendering the danger from this cause tenfold more imminent than that produced by the shot itself. Several splinters of this kind, struck from the hull of the Harpy, have been brought home by the officers of the Gorgon, and, amongst the rest, the splinter from the angle iron which caused the death of poor Mr. Barnes, the clerk in charge, proving that the tendency to splinter is not confined to the thin sheet iron of the hull, but to the heavier masses which compose the vessel. These results are in accordance with those observed in the experimental trials on board the Excellent, and they constitute a sad drawback against the general use of iron as a material for vessels of war. Whether the iron in question is not so malleable as it ought to be, or might be if better wrought, is another question; for the present, however, the men are alarmed, and those who have witnessed the effects produced on board the Harpy, declare that they will never go to sea in an iron vessel.

LIST OF NEW PATENTS.

GRANTED IN ENGLAND FROM OCTOBER 22, 1846, TO NOVEMBER 21, 1846.

Six Months allowed for Enrolment, unless otherwise expressed.

Etienne Abraham Maccaud, of No. 1, Place de la Madeleine, Paris, mechanician, for "Improvements in lamp and gas burners."—Sealed Oct. 22.

John James Alexander Maccarshy, of Sidney-terrace, Brompton, gentleman, for "certain Improvements in anchors and fids for masts of vessels."—Oct. 22.

William Anderson, of Clitheroe, Lancaster, for "certain Improvements in machinery or apparatus, for preparing and spinning cotton, and other fibrous substances."—Oct. 22.

John Paterson Reid, of the city of Glasgow, and Thomas Johnson, mechanic, for "certain Improvements in machinery for weaving, and for producing patterns in weaving, as also in machinery, for finishing certain woven fabrics."—Oct. 22.

James Thomas Jullion, of Stratford, chemist, for "Improvements in the manufacture of certain acids, also improvements in decomposing certain acids, and applying the products resulting therefrom, to the production of certain chemical compounds."—October 22.

James Lysander Hale, of Hackney, Middlesex, civil engineer, for "certain Improvements in sewerage and drainage, and apparatus connected therewith, parts of which are applicable to steam engines."—Oct. 22.

John Hutton, of Commercial-road, East, chronometer-maker, for "certain Improvements in chronometers and other time keepers."—Oct. 22.

Henry Mapple, of Child's-hill, Hendon, Middlesex, machinist, for "Improvements in apparatus for transmitting electricity between distant places, and in electric telegraphs."—Oct. 27.

William Crane Wilkins, of Long Acre, Middlesex, for "certain Improvements in lamps, and apparatus connected therewith, parts of which are also applicable to the raising of water."—Oct. 29.

William Reid, of Saint Pancras, Middlesex, engineer, for "Improvements in the manufacture of wire."—Oct. 29.

Noel Etienne Aime Paret, of Lyons, in the kingdom of France, gentleman, for "Improvements in finishing silk, cotton, and other fabrics, and in heating apartments."—November 2.

Henry Headley Parish, of Chesham-street, Middlesex, Esq., and Samuel Rootsey, of Portland-square, Bristol, Esq., F.L.S., for "Improvements in supplying and purifying water."—November 3.

George W. Eddy, of Waterford, in the State of New York, of the United States of America, for "an Improvement in the manufacture of cast metal wheels for railway and various other carriages."—November 3.

Baron Charles Wetterstedt, of Rhodes Well Road, Limehouse, Middlesex, for "Improvements in the manufacture of sheet metal, for sheathing and other purposes, in preventing the corrosion of metal, and in the preservation of wood and other materials."—November 3.

William Exall, of Reading, in the county of Berks, engineer, for "Improvements in the construction of wheels, and in certain implements or tools employed therein, and in the mode of forming and manufacturing the tyres of wheels, which mode is applicable to making metallic rings, bands, hoops, cylinders, and other similar articles."—Nov. 3.

Alfred Vincent Newton, of Chancery-lane, mechanical draughtsman, for "certain Improvements in the manufacture of driving bands, part of which improvements are also applicable to the manufacture of other fabrics." (A communication.)—November 3.

Gaetan Bonelli, of Milan, engineer, for "Improvements in bridges, viaducts, aqueducts, and other similar erections."—November 3.

Matthew Lealny, of Great George-street, Westminster, civil engineer, for "certain Improvements in steam engines."—November 5.

Robert Teagle, of Hammersmith, plasterer, for "Improvements in chimney pots, and in apparatus for cleansing chimneys."—November 5.

David Barnett, of Birmingham, merchant, for "new or improved instruments or machines, for effecting or facilitating certain arithmetical processes or computations." (A communication.)—November 5.

Frederick Herbert Maberly, of Stowmarket, clerk, Thomas Branwhite, of Eattlesden, millwright, and Dennis Lusher, of Great Tinborough, farmer, for "Improvements in machinery for obtaining and applying, and for accelerating and for retarding motive power, and for giving notice of alarm in expectation of, or in actual danger."—Nov. 5.

Henry Henson, of Hampstead, in the county of Middlesex, gentleman, for "a new fabric suitable for goods, wrappers, wagon covers, and other like purposes, and certain processes in the manufacture of the same."—November 5.

Thomas Yates, of Preston, Lancaster, watchmaker, for "Improvements in time keepers."—November 12.

John McBride, of the firm of McBride and Company, cotton spinners and power loom cloth manufacturers, Albyn Works, Glasgow, for "Improvements in weaving."—November 12.

William Bridges Adams, of Old Ford Lane, in the county of Middlesex, engineer, for "Improvements in the construction of wheel carriages and engines moved or retarded by animal or mechanical agency, parts of which improvements are applicable to other like purposes."—November 12.

Louis Hypolite Piaget, and Phillip Henry Du Bois, of Wynyatt-street, Clerkenwell, for "Improvements in producing ornamental surfaces."—November 12.

George Smith, of Camborne, in the county of Cornwall, safety fuze manufacturer, for "a new safety fuze."—November 12.

Edward Staite, of Peckham, in the county of Surrey, gentleman, for "certain Improvements in lighting."—November 12.

George William Jacob, of Hoxton, in the county of Middlesex, printer, for "a new manufacture of printed, patterned, ornamented, coloured, embossed, and moulded surfaces."—November 12.

John Healey, of Bolton, in the county of Lancaster, machine maker, for "a new and improved woven fabric, and also certain improvements in machinery for producing the same."—November 17.

Thomas Masters, of Upper Charlotte Street, Fitzroy-square, Middlesex, confectioner, for "Improvements in apparatus and means for cooling liquids and matters, and filtering and preventing liquids freezing."—November 17.

Bartholomew Benlowski, of Bow-street, Covent Garden, Middlesex, gentleman, for "certain Improvements in the apparatus for, and process of, printing."—November 17.

William Eaton, of Newington, in the county of Surrey, engineer, for "certain Improvements in obtaining motive power."—November 17.

Robert Brett Schenck, of the city of New York, in the United States of America, gentleman, for "certain Improvements in the preparation of hemp and flax." (A communication.).—November 17.

Christopher Robson, of Newcastle-upon-Tyne, grocer, for "Improvements in machinery for dressing fruit."—November 21.

James Denton, of Greenacres Moor, Oldham, Lancaster, mechanic, for "Improvements in certain parts of machines used in the preparation for the spinning of cotton, wool and other fibrous substances."—November 21.

James Barsham, of Bow, Middlesex, manufacturer, for "Improvements in manufacturing brooms and brushes."—November 21.

William Pidding, of North Crescent, Bedford-square, Middlesex, gentleman, for "Improvements in carriages."—November 21.

TO CORRESPONDENTS.

PYNE on "Perspective," "City, Town, and County Architecture," "Railways for the many—not for the few,"—Received.

"*Six Years' Subscriber.*"—Perhaps the best account of the details of the Steam Engine is to be found in the Treatise of the Artizan Club, but a systematic and satisfactory work on the Steam Engine remains among the desiderata of Engineering Literature.

END OF VOLUME IX.
