THE

CIVIL ENGINEER AND ARCHITECT'S JOURNAL,

INTRODUCTORY NOTE.

In commencing the 100th Part, and a new volume of this work, the conductors of it venture upon a few introductory remarks; the object proposed is not, however, merely to offer the courtesies of salutation, though, were it no more, we might well be excused—at a season of universal greeting and goodwill—for expressing to those who have accompanied us, and those who have assisted us in the prosecution of our task, with how much gratification we arrive at this epoch of it, and commence a new portion of our labours.

In a periodical devoted, not to the general purposes of literature, but to the publication of information on specific subjects, and these of a very extended and frequently complicated nature, the reader has a right to expect that the mode of selecting and communicating information should be guided by certain fixed principles; for it is certain that, were no other rules adopted in conducting such a work as this, than that of setting down whatever appears to possess a passing interest, and that of recording the information just as it is supplied to us, the reader would no longer find what he would most anxiously seek for in these pages, professional information selected for its intrinsic importance, and referred to certain fixed principles as tests of its value and accuracy.

In Engineering, the first branch of our labors, it is by no means difficult to explain the rules here adopted. The theory of the operations of the engineer belongs, fortunately, to a philosophy the most accurate and complete, of all which the range of human thought encompasses—the philosophy of motion and equilibrium; and the application of this philosophy to practical mechanics is founded on a system of experimental knowledge, far exceeding in extent and the uniformity of its results all that has been obtained in other practical arts. For while, on the one hand, none of the operations of nature have been so successfully theorised as the mechanical, and on the other, none have been made so generally the subjects of practical industry.

In examinining, then, the labours of the engineer and mechanist, we have first to see how far their notions accord with the pure theory; secondly, how far the details of their works stand the test of experience. There once prevailed, unfortunately, an idea that the theory and practice of mechanics were inconsistent with each other; but the new and constantly increasing requirements of modern engineering are now fast dissipating the error; for, while the theoretical student finds it impossible to render his knowledge available without actual experience, the practical operator frequently finds, from the rapid advances of modern engineering, that he is placed in circumstances altogether new to him—discovers that his notions of the laws of mechenics picked up here and there, without any system, and generally mixed up with a vast amount of extraneous matter will not always suffice, and that he must frequently submit his judgment, in a measure at least, to that af the theorist.

It is quite true that the actual operations of engineering generally depend on natural laws so complicated as to render direct mathematical investigations, either impossible, or rendered possible only by hypothetical simplifications of the cases examined. It is not, therefore, to the immediate results of mathematics, that we are to look for the most general benefit derivable from pure theory, though even here how much has been done for the assistance of the engineer, labours such as those of Coulomb, Poncelte, De Pambour, Hodgkinson, Moseley, and Professor Willis amply testify. But there is another far more common benefit which the engineer will derive from mathematical knowledge, which, if duly considered, ought to remove from the mind of the practical student all coldness and suspicion respecting the results of theoretical mechanics.

It is not to be expected that an engineer, however high his mathematical attainments, could determine, numerically, the velocity of every engine he constructs, the pressure on every tunnel, or revetement wall which he builds; but this is certain, that his mathematical education will have so *systematised* and *simplified* his mechanical conceptions, that he will examine his works far more critically than he possibly would, were his physical notions derived merely from his own experience or popular treatises. It may be unhesitatingly affirmed that the perspicuous general insight into the laws of mechanics, afforded by the study of mathematics, is not to be obtained by discursive reading and casual experience however extensive or varied in its nature. It were easy enough to give instances of men eminent for their practical labours, who, from lack of systematic knowledge, frequently utter notions the most confused on mechanical subjects; or—to refer to more immediate instances—we might, from our own pages, point out repeated cases of inventors obtaining patents for the supposed attainment of physical impossibilities.

That chief value of the mathematical theory of mechanics to the practical engineer would seem then to be, not so much the prediction of the exact result of his labours, as the general guidance afforded to him in conducting them—the knowledge by which, without the toil of experiment, he distinguishes between what is physically possible and what impossible, and is directed in choosing the mechanical appliances best suitable to effect his objects. Who can estimate how vast an amount of intellectual and experimental labour might have been saved, had those who so long long strove to discover "perpetual motion," and the means of making water raise itself, known that they were, in fact, striving to give to matter laws altogether diverse from those assigned to it in the economy of nature? And yet the same efforts (applied to different objects) are made in our own day. It may, therefore, be safely assumed that we cannot greatly err in recording the progress of engineering, if we constantly refer to pure theory as a test of the accuracy of our judgment—if we apply constantly the principles of mathematical philosophy divested of its language.—The language of symbols is requisite only in determining exact statistical results, but the general principles of pure mechanics are of universal application, and are capable of being expressed in ordinary language with a facility and accuracy far beyond what might be naturally anticipated, had we not eminent proofs that the attempt may be made with success.*

IN ARCHITECTURE the determination of fixed rules of criticism is not so easy a natter. Taste refuses to be fettered by the strict laws of natural philosophy, and the canons of the fine arts are seldom demonstrable. Still we have even here some fixed principles which rest on the safe foundation of universal consent, and are susceptible of very extended application. The general law that architectural beauty is dependent on utility was universally recognised by those from whom we borrow the only kinds of architecture adopted by us—the Classic and the Christian—and it is a law which at a time like the present, distinguished by a growing interest in the philosophy of the arts, few will be bold enough to controvert—the simple and indisputable rule that architectural members applied without use, or to wrong use, are deformities *per se*, will of itself frequently be sufficient in determining our judgment.

It is not however to be concluded that this principle is the only one which the Classic and Mediæval architects held in common; and it may here be remarked how little progress has been made in discovering the *abstract principles* by which these masters were guided. Of the actual *forms* adopted by them there has been no lack of study. The lines and dimensions exhibited by standard specimens of architecture have been noted down and catalogued with wonderful and praiseworthy minuteness. But may it not be doubted whether the neglect of principles for the sake of forms, savour not somewhat too strongly of servile coyping! An intelligent student-artist will, it may be fairly supposed, endeavour rather to become imbued with the spirit and genius of his master, than to reproduce every minute mark and characteristic of his works.

Here seems to be the real cause why some who in our own time have laboured zealously to restore one kind of architecture to its original purity, have failed of the full recompense of their talents, industry, and zeal. An indiscriminate adherence to precedent has produced its never failing fruits—bigotry and intolerance. Had the same labour which has been spent in recording proportions and copying outlines, been devoted to the examination of the beautiful philosophy of which those dimensions and proportions were the results, we should hear of few efforts to exalt one system of pure architecture at the expense of another, and we should probably have far advanced in reducing our knowledge of ancient architecture to a system by which alone we can hope to rival the masterpieces of that art of which we profess to be disciples.

But there may be some who would say further that we ought, not only to avoid servile adherence to precedent respecting architectural forms, but even to disown all obligation to be bound by the abstract principles of the old architects. To this it seems sufficient answer that in that case we must no longer profess to adopt the old modes of architecture; we must discover for ourselves some altogether new system. And though we have no warrant for denying *a priori*, the possibility of such a discovery, still until it be made—until we disown all similarity of our works to those of the classic and mediæval architects, we are clearly mere mimics, when we borrow from them some of the forms which they adopted, and apply them without any regard for their original purposes. This at least is certain that if we endeavour to confound together principles, which are not merely different, but directly antagonistic, the result must be discordant and inharmonious.

It surely were no difficult task to show that the genius of Greek and Gothic architecture are diametrically opposed to each other. Where we see the two brought into direct contrast (as for instance in the interior of a cathedral which the admirable taste of the last age has decorated with Corinthian columns,) the discordance is so offensive to the eye as to be immediately condemned. But why should we not carry the principles of the condemnation a little further, and condemn buildings when the details belong to the one system, and the outline to another system of architecture—buildings, for instance, in which it is enduavoured to give a lofty vertical effect by architectural members, which were originally proposed to produce a horizontal effect?

It is not to be denied that even where these considerations (indisputable as they seem,) have been neglected, there have been produced buildings, which, by the richness of their decorations, fail not of a certain claim on our admiration. But this is certain, that though the effect in such cases be gorgeous, it cannot, in the very nature of things, be pure. To copy such work is, at least, but to copy second-hand; and surely, if we be not going altogether wrong in our endeavours to purify our taste for Christian architecture, it is but a legitimate extension of our efforts to free classic architecture of the foreign ideas which have been imported into it. It may be, indeed, require a certain amount of adaptation, in the application to modern purposes; but the requirements of those who invented, and first used classic architecture, too nearly resembled our own to permit the supposition that the adaptation would involve a total subversion of their original principles.

These considerations will explain, with sufficient accuracy, the course we would endeavour to adopt with respect to the two leading divisions of our task. We make no profession, however, of being always able to attain the true philosophy of architecture and engineering. It is safe, sometimes, to simply record facts, and to wait until direct experience shews the value of them. In such cases, our labour is little more than that of compilation; and even where we undertake the more hazardous labours of direct criticism, we have frequently to confide in the consideration that our readers are, for the most part, those who are practically aware of the diversity and complexity of our task, and will make full allowance for the difficulties of it. At the same time, we are well persuaded of the importance of rendering all knowledge systematic; and we have this trust in the principles here set forth, that if they do not always lead to rapid discoveries of great truths, they will at least prevent the admission of great errors—that even if we sometimes loiter on our road, they will keep us from wandering altogether out of it.

ARCHITECTURAL DECEPTIONS.

To restore to architecture the excellence which it attained in the periods of its greatest purity among the Greeks and Mediæval Christians, it seems absolutely necessary that it should regain that hold on the popular mind which it possessed during those epochs. With the Athenians the erection of a temple, with our Christian forefathers, the building of a Cathedral was a work of no isolated or merely local import, but one which engaged the interests and tasked the energies of a whole nation. Whiel printing was not yet discovered, architecture, according to the beautiful theory of a great writer of our times, was the only method by which the mind of a people could express itself—and this at least is certain, and independent of all theory, that public architecture engaged far more of public attention heretofore than now. The slighest reflection will show that the national importance thus given to the constructive arts must have contributed much to their perfection and purity, and also, that on the other hand the very excellence of those arts, by re-action, greatly advanced the public estimation of them.

Nothing seems more fatal to the progress of architecture in modern times, nothing a greater obstacle to the resumption of its former rank than the custom which has unhappily crept into modern practice of using imitative and therefore deceptive materials. The feeling of honesty and candour which characterised the olden architects seems fairly out of date: and in its place we have almost universally a spirit of ostentation, an affectation of show, the dishonesty of pretension, the vulgarity of making things appear something different from, something better than, what they really are.

Where we cannot afford to build expensively, it would seem the best taste to use what humbler materials are at command honestly, and without any attempt at disguise; and to compensate as far as may be, for the want

* We may refer, in proof, to Airy's Theory of Gravitation, a work which exhibits in a most extraordinary manner the practicability of explaining, in ordinary language, the results of elaborate mathematical researches.

of more costly appliances, by simplicity and correctness of design. This rule ought at least to be observed in public buildings. For domestic architecture, the showy system of building is so nearly universal that it seems hopeless and useless to utter one word of protest against it at present. In this latter case there seems no better course than to wait patiently till another race of builders may arise too free from vulgarity to emulate the jackdaw in his assumption of the finery of the peacock. But with respect to public edifices the case is different, and against the building them of deceptive (and for the most part perishable) materials, a public protest ought to be decisively pronounced.

If it be desired to determine on what principles good taste universally decides against architectural imitations, the answer appears to be two-fold. In the first place deceptive materials are almost always less durable than those substances which they imitate; whereas one of the chief sources of the pleasure of viewing beautiful architecture is the consideration of its permanence. In admiring an ancient edifice, we shall find on analysing our own minds, that a great part of our gratification arises from the reflection that this very building, the object of our admiration, has been the wonder of many by-gone generations; and if, again, we are delighted by a noble work of modern architecture, our delight is in a great part made up from the consideration that we have bequeathed to posterity a worthy monument of the skill and intelligence of our own times.

But a second argument against architectural deceptions may be alleged which cannot be like the preceding one answered by the allegation that the deception may be made as endurable as the reality. An important source of the pleasure afforded by pure architecture is the recognition of the skill and energy of the architect. The curiously fretted roof and the elaborate window tracery delight, not only because of their intrinsic beauty, but because of the labour and patience exhibited on the part of the workman. If it were possible to conceive that these beautiful forms were ready made to the builder's hands by some fortuitous process, the feeling of admiration would be greatly moderated. In all master-pieces of architecture (and not of architecture only, but of all other noble arts) a distinguishing characteristic is that their full beauties are ascertained only by reiterated examinations. Every closer inspection serves only to reveal fresh instances of the skill and perseverance of the builder—but if these closer and more penetrating examinations should disclose traces of deception only, and want of candour, if we find that there has not been all that skill and perseverance bestowed which were promised at first view, the feeling of disappointment is proportionate to the former feeling of admiration, the mind retaliates by contempt of the juggle—retaliates in the same degree as it has been misled.

We have been led to make these observations by observing one of the most flagrant instances of the vulgarity of "make-believe" building which we remember to have ever met with. The fault is aggravated by appearing in Church-architecture, where, if any where, everything should be real. "The church at Platt," says the *Builder*, "is being erected from the designs of Mr. Sharp, who was the architect of a church at Lever-bridge, near Bolton-le-Moors, previously noticed, also built of *terra-cotta*. The plan consists of nave and aisles, chancel, a sacristy south of the chancel and a tower at the south-west of the nave. The style is decorated. The architect has probably had many restrictions to contend with, to which we may attribute the slightness of the internal piers, and increase of distance between the buttresses. The tower is united to the aisle by a lofty arch, which is worthy of praise. The church has more than the usual amount of decoration, and ornament is introduced with good effect in capitals and buttresses. The windows have two lights with foliated heads, and are, in the aisles, of two varieties. The design is evidently the production of a clever man, but we are compelled to express an unfavourable opinion of its execution.—Each separate piece of the terra-cotta is cast to the required form, and is much about the same size as a corresponding block of stone. Every piece is hollow, being, as it appeared, afterwards filled or backed up with concrete. *They are all nothing more than pots*, and from the trial we made, seem to have less cohesive power than brick. Nevertheless, they are made to support great weights. The piers of the church, which, as we have said, appear remarkably slender, are entirely composed of these pots. The plan is the clustre of four shafts. There are the usual defects incidental to the burning; parts of the mullions are out of the perpendicular, and the lines of the window-sill undulate in a very unsatisfactory manner. Indeed, the whole building, though good in design, and not deficient in ornament, will not bear a near approach. The face of each piece is scored with lines to imitate the tooling; and the mortar joints are large, and obtruding."

A church "built of terra-cotta"! Piers "composed of pots"! Lines scored "to imitate the tooling"! The faults of execution are not the only faults of such a building—are far outweighed the errors of principle which produced them. The notice which has just been copied is followed by some judicious general remarks—so judicious that we cannot but regret their brevity. "Unless *the skilful hand*" it is remarked, "be apparent, the result is disappointment rather than delight, and regret that the mind of the artist should have conceived it vain." Here truly there was no appearance of the *skilful hand*. Let us rejoice that it was un-skilful—otherwise perchance unskilful observers might have applauded an essay which the judicious would censure in proportion to its successfulness.

ARCHITECTURE IN MANCHESTER, LIVERPOOL, AND BIRKENHEAD.

SIR,—I resume my notices of the Building Arts in Manchester, and, having lately had opportunity of looking over some of the principal works going on in Liverpool and Birkenhead, propose adding a few remarks upon the progress there, which may be acceptable to your readers.

In my former letter I alluded to the proposed extension of the present MANCHESTER EXCHANGE, as designed to be carried into effect by Mr. A. W. Mills; since that time two great schemes have, with Mr. Mills's design, divided the attention of the public. The first was for an erection in Market-street and High-street, and a design of considerable merit was prepared by Mr. Gregan. The second scheme was to erect the Exchange on a site in Mosley-street, on part of which the Theatre Royal formerly stood. The latter seems now to have been decided upon, as on Thursday, Nov. 13th, the proprietors of the present exchange agreed to dispose of their buildings to the Mosley-street committee, on the condition that an Act of Parliament be obtained, in the next session, for the erection of the Exchange and other public buildings on the site in Mosley-street.

It is to be hoped that on this occasion an opportunity for public competition will be afforded to Architects, and doubtless the committee will have many first-rate designs sent in, from which they may select one which shall be an ornament to the town.

The head offices for the *Manchester and Leeds Railway*, at Hountsbank are advancing rapidly to completion, being raised to the level of the second floor. Much delay was experienced at first, owing to the unstable character of the ground on which the building is placed, and the architects, Messrs. Holden, have taken all proper precaution to have the foundations firm and secure, going down in some parts to a depth of 43 feet below the ground level. It is pleasing to notice instances of care and attention in foundations, as so many fine buildings are sadly deficient in this respect; as for example the Town Hall and the Athenæum in Manchester, both of which show cracks in stonework, arising from a sinking in the foundations. The erection for the head offices is built of Yorkshire stone, and the design is in the Italian Palatial style of architecture usual in the 16th century. The site is an irregular piece of ground, the principal front being 76 feet long, from which the building extends back about 96 feet. The height from ground line to cornice is about 42 feet, divided into two lofty storeys. The whole of the rooms in the basement is fireproof, and of very strong construction. Below the level of the ground floor windows is a broad tooled string course, under which is rustic worked masonry. In the centre of the principal front is a handsome Italian doorway, with the customary moulded jambs, dentelled cornice, trusses, &c. The ground floor windows, two on each side of doorway, have unusually bold broad moulded architraves; and the upper storey has Italian corniced windows; level with the bottom of the latter runs a moulded string course. A bold dentelled cornice will surmount the whole. The back parts of the erection are in rockfaced Yorkshire stone. These offices, with the arching over of the River Irk, will when completed materially improve the approach to one of the handsomest railway stations in the kingdom. The station for the Manchester and Leeds, and Manchester and Liverpool railways, which I allude to, ranks high as an engineering work, having two iron bridges of great span, and embankments of considerable height. The erection for refreshment and waiting rooms, offices, &c., are designed with a substantial simplicity and fitness, which we look for in vain in structures of greater pretension.

Warehouses.

A warehouse of novel character is near completion in Faulkner-street, for Mr. Dentith the drysalter. It has an elaborately worked stone front in the Grecian Doric style, and is the design of Mr. Thomas Fish Taylor, Architect. The width of frontage to the street is about 40 feet, and below the level of footpath are two cellar storeys, and above it four storeys.

The basement, up to the ground floor window sills, is of large blocks of Aberdeen granite, which from its hardness will resist any of those casualties which so frequently disfigure basements of our usual soft stone. The remaining height of the ground floor is built of faced Halifax stone, having segment headed windows and doorways. Above this floor are two pilasters and four three-quarter columns, fluted two-thirds down, and two stories in height, with suitable capitals. The windows are in the recesses formed by the columns and pilasters. The architrave, frieze, and cornice break round with the columns, and the frieze is enriched with a Grecian fret, deeply cut, and presenting a varied play of light and shade. Upon this cornice and over each column stand bold double pilasters of natural faced wallstone, with tooled bases and caps; on these, and on cantilivers between them, is the horizontal part of the pediment. The pediment spans the entire width, and would have had a much better effect, if more boldness of projection could have been obtained laterally: this, I suppose, is prevented from a fear of encroaching on a neighbour's territory. It is said that the original designs were for a fire-proof building, and it seems a pity that a building intended for the stowage of such combustible materials, and in the design and erection of which such pains and expense have been gone to (though I understand the whole will not exceed 2,400*l.*) should not have been built on the fire-proof principle. It seems doubtful policy to run the risk of total destruction, if a fire should occur, for the sake of saving 200*l.* or so, in original outlay;—as the warehouse is now built (with wooden trussed beams, joists and boards), if a fire took place the whole would, ten chances to one, be destroyed; if built fire-proof, the chances are that one storey only would be burnt.

A large warehouse, of four storeys besides the cellar, has been built for Mr. Carver, in Portland-street, from designs by Mr. Donnison. It is of brick, with stone basement, doorways, window sills, and cornice, and is of plain and substantial construction. The same Architect has another large warehouse in progress for Mr. Behrens, of five storeys and cellar. The first storey is externally of tooled stonework, and has coupled pilasters between the windows, and a dentelled cornice runs below the second floor windows. A stone cornice resting on corbels surmounts the whole.

Messrs. R. H. Greg and Co. are having a warehouse built in Tib-street, from designs by Mr. Whittaker, and Messrs. Taylor and Williams are the builders. The basement is externally of vermiculated stonework. The first storey is of good tooled ashlar, with a dentelled cornice. The upper part of the warehouse will be of best brick with handsome stone quoins, and all the windows will have moulded stone architraves. It is intended to place an elaborate stone cornice at the top. The whole is fireproof and of good strength, and I understand that the cost cannot be less than 8,000*l.*

Mr. Lane, the Architect, is at the present time employed in entirely remodelling the old "Queen's Theatre," in Spring Gardens, and from what I can learn of the alterations it seems likely that a most convenient and beautiful interior will be the result. The walls of the building have been underset, the stage and pit lowered five or six feet below the original level, the pit extended under the boxes, and the stage enlarged. It is intended to erect a new proscenium, and to alter the whole decorative character of the house. Mr. Bellhouse's workmen are now busily proceeding with the alterations, and it is intended that all shall be ready for an opening in March next.

Schools.

The MANCHESTER COMMERCIAL SCHOOLS are now nearly finished, and are to be opened in January next. They have been built under the auspices of the Church Education Society, from the designs of Messrs. Holden, Architects, on a plot of ground in the Stretford New Road. The building is three storeys high, and in the Tudor style of architecture. The front is of stone, and the first story has two entrance doorways, with three windows between them, the centre one a triplet, and the others double windows, with flat or four-centred arches; the second story has an oriel window with enriched panneling above and below, and two smaller windows with hood mouldings on each side of it; the upper storey has a large window in the centre, with a depressed four-centred arch, and rich tracery in the head, and two smaller windows with hood mouldings on each side. The ground floor contains the assistant-master's offices, porter's residence, &c., and also a covered play-ground, about 42 feet by 30 feet, communicating with a spacious play-yard. The second floor is set apart as four class-rooms, a large hall, and a book and model room. The whole of the upper floor will be occupied as the general school room, 55 feet by 42 feet, and as the roof is open to the rafters the room is an airy one. In these schools a good church and commercial education will be afforded to the youth of the middle classes upon reasonable terms.

The Roby Day and Sunday Schools, for children of the independent denomination, situate in Aytoun-street, were built a short time ago from designs by Mr. A. W. Mills, Architect. The building is in the Elizabethan style, and of best brick and stone. Considerable skill is displayed in the arrangement for supporting the building so as not to interfere with the burial ground over which it is erected; the front wall goes down to good brick foundations, but the back part is carried on iron pillars and beams. There are three gates into the yard through the lower part of the front wall, and also other smaller arches which are filled in with ornamental iron-work. Above are three projecting oriel windows of two storeys; the front is surmounted by ornamental gables. The internal arrangements are spacious and well ventilated.

Roman Catholic Church, Salford.

The largest ecclesiastical building in the neighbourhood of Manchester at this time in progress, is the edifice being built by the Romanists in Chapel-street, Salford, from designs by Messrs. Hadfield and Weightman, of Sheffield. The general plan is cruciform, with a central tower and lofty spire. The cardinal points have not been regarded in the placing of the building, as the chancel is towards the north. On the south side of the tower projects the nave, which is divided into four bays, and has a lofty clerestory. The principal entrance doorway is at the end of the nave. On the north side are the choir and chancel, which are now intended to be carried out about the same length as the nave. The original design showed it projecting only one bay beyond the tower, but a school-house has been taken down to allow of the extension. The transeptal chapel is on the western side of the tower, and will be lighted by a large wheel window; there will be an entrance to the chapel from the outside, and the vestry adjoins it. The transept on the east of the tower has a central entrance doorway. The roof of the choir will be groined in wood, and that of the nave framed in square panels, and painted in light colours by Bulmer. Sticklers for orthodoxy and correct imitation will discover little to cavil at in the details of the work, such as tracery of windows, arch mouldings, &c.; they are generally copied from Howden church, Yorkshire, or from contemporaneous structures; indeed the principle of imitation seems to have been carried too exactly throughout, for the most elaborate mouldings of that exquisitely delicate period of architecture the early decorated, are given in places where a simplification of them would have produced an adequate effect; if this be an error, however, it is on the right side. Newark furnishes a model for the spire, Howden for the nave, and Selby for the chancel; indeed the last will be a counterpart of its prototype, even to the canopied niches over the columns.

The Irish Presbyterians are now erecting a place of worship, session-house, schools, &c., in New Bridge-street, Strangeways, from designs which are highly creditable to the architects, Messrs. Travis and Mangnall. The style selected is the Gothic, which prevailed in England during the reign of Henry VI. There will be a tower 80 feet in height, next to the street, which will be flanked by bold diagonal buttresses; these will diminish in size towards the top, and will finish at the battlements with crocketted pinnacles above. The central entrance doorway will have bold moulded jambs, and a label finishing upon carved heads; above this doorway will be a large window with perpendicular tracery and moulded jambs and labels; similar windows will be situated at each side of the tower on the front face of the building, and in the back will be a four-light perpendicular window. There will be two side entrances near the tower end, having square-headed doorways with labels, &c. The sides of the building will be divided by massive buttresses into five bays each, and the windows between them will be enriched with tracery and labels terminating on grotesque heads and shields, and will have a transom in the middle on account of their height. The roof will be open-timbered, and in one span of 47 feet. At the back of the chapel are buildings to be used as session-house, schools, and residence for the minister, the whole of which are built in the style of the domestic buildings of the period.

Mansions.

A mansion in the Italian style for Mr. Percival, situated near Kersal Moor, from designs by Messrs. Dickson and Brakespeare, is in a forward state. There are two good specimens of gentlemen's residences nearly ready for occupation in Victoria Park; one for Mr. Critchley, designed by

Mr. Walters, in the Italian style, the walling being of rough pierrepoints with tooled stone dressings: and the other for Mr. James Bellhouse, in the Tudor style, having the fronts of tooled stone, and the back of rough pierrepoints.

Mr. Bowman is the architect for a house lately commenced in the same park for Mr. Langworthy.

A residence is also in course of erection for Mr. Wilson Crewdson, at Moss-side; it is being built from designs by Messrs. Holden, and is externally constructed of stone; the style of architecture is the Domestic Tudor.

The residences we have mentioned are in good taste, but there are many houses in the suburbs which are in the style which will be known by the title of "Gingerbread Gothic," which style appears to have professors in every locality. I am glad to observe, that in and about Manchester, the use of stone is becoming more general; the "Yorkshire pierrepoint" rough dressed on the face, and in courses of five or six inches, is the kind most in demand at this time, which, although more expensive than brickwork, is not so much so, but that the effect obtained fully compensates for additional outlay. The yellow firebrick is occasionally used for dwelling houses, and the effect is very good.

LIVERPOOL.

St. George's Hall.

In Liverpool, that magnificent pile of buildings, St. George's Hall, is assuming an imposing appearance, and already justifies the high expectations which have been entertained with respect to it, and all who view the structure must agree that the Architect, Mr. H. Lonsdale Elmes, has produced a noble design, and that the superiority of the workmanship in each department proves that he has been ably seconded by the contractors, Mr. Tomkinson and Messrs. S. and J. Holmes.

I had prepared a description of the plan and different elevations of the building, but on referring to vol. vi. p. 329 of your journal, I find excellent drawings and a well written account of the whole; I therefore proceed to notice only the present state of the work.

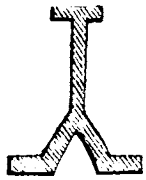
The exterior of the building is now in a very forward state, the parts most behind being the row of columns on the east front, and the covering in of the large hall.

The north end of the building (that having a semicircular projection) is completed; and when I visited the place the workmen were engaged in laying the top stones of the south portico. The great hall is 169 feet long, and 75 feet wide, and is intended to be covered by a semicircular arch, springing from the side walls. The height from the floor to the top of the arch will be 87 feet. Around the large hall in the interior will run an ornamental moulded plinth, with 24 projecting pedestals, similar in character, and 24 columns upon them: the plinth, pedestals, and columns are of highly polished Scotch granite. Some of the columns are in their places, and are as beautiful specimens of workmanship and materials as it has ever been my lot to examine; they are each 31 feet long, and average 3 feet in diameter.

The columns and the die of the pedestals are of red granite, from Peterhead near Aberdeen, and the plinth and impost of the pedestals of grey granite, from the same neighbourhood. The whole of the parts have been worked and polished at Aberdeen, and when put together in their places, the joints are perfectly true and good. The mechanical arrangements for the removal and working of the large blocks of stone required in this building are admirable, especially the powerful and lofty derricks with steam engine and boiler complete, working along the lines of railway laid parallel to the main walls of building; and also the various railways with travelling cranes over the stone yards.

Docks.

The Albert Dock and warehouses now being built by the Liverpool Corporation, under the able superintendance of Mr. Jesse Hartley, the Dock engineer, are nearly finished; the dock, with all the entrance gates, &c., is complete, and several of the immense piles of warehouses are in a condition to receive goods. These erections are exceedingly strong, and built throughout on the fireproof principle. The iron beams are somewhat different in form of section to those generally used, inasmuch as they have inverted V grooves running along the underside of the beam, so as to divide the web near the bottom into two parts, and forming a good abutment for the brick arches to be built against thus:—



The beams are also slightly curved longitudinally. The columns and beams are of massive proportions; indeed the whole of the work is strong and of good design.

The well-holes for the purpose of hoisting the goods up are large, and surrounded with strong iron curbs, and enclosed by wrought iron doors. All the window frames are of cast iron, and the entrance doors of wrought iron plates strongly put together. The roofs are framed in iron, with a covering in some cases of sheet iron, and in others of zinc. Some of the floors are covered with tiles, others with planed flags, others with asphalte, &c.; indeed there seems to have been a disposition to give each kind of roofing and flooring a fair and impartial trial. This is as it should be, as these experiments can best be made by a public body; it is to be hoped that the results of a due trial of the different kinds of material, as regards cost and duration, may be published for the benefit of those engaged in building similar works, in the Journal.

The approaches from the town to St. George's Hall, and the railway station, have recently been considerably improved by the widening of Lime-street, Charlotte-street, and Ranelagh street. Rows of shops are being built; and a Register Office is nearly completed in Lime-street, from designs by Mr. Clayton, Architect. The building is fronted with tooled stonework, and consists of three lofty storeys. The first floor has circular-headed windows, splayed from the outside, with plain moulds round them. The upper windows are square headed with moulded jambs and caps. A plain cornice runs alone above the first floor windows, and at the top of the front elevation is a stone cornice with scroll corbels. The safe is spacious and of good construction; the floor, side walls, and arched top, are of fire-brick, and the arches are built upon strong iron beams, and skewbacks connected by tie rods. A set of double iron doors, with Chubb's locks, are strongly fixed in the safe doorway.

BIRKENHEAD.

At Birkenhead, on the opposite side of the Mersey to Liverpool, we have the strange spectacle of a noble city springing, as if by magic, into existence; numerous spacious streets and squares have been layed out, sewered, paved, and lighted with gas, and rows of splendid shops and comfortable habitations are being erected with unexampled rapidity; whilst the surrounding neighbourhood is becoming diversified by picturesque mansions and villas, which are intended for the residence of the wealthy.

The new Docks at Birkenhead are speedily progressing, and a visitor cannot but admire the manner in which the natural advantages of the locality have been made available. The site of the docks was formerly Wallasey Pool, a large area which was entirely sand bank at low water, but covered by the tide at high water. The Woodside Pier has been considerably widened and improved, and will form one side of a tidal basin of 16 acres in area. Between this basin and Seacombe will be two spaces of quay 60 acres each, between which will be a large low water basin of 37 acres, forming the main entrance to the Great Floating Dock, which when complete will have an area of 150 acres, and be 19 feet in depth. There will also be a small dock near the entrance. The land adjoining the basins and docks, and the reclaimed land, will be used for quays, yards, &c., and will be built upon with warehouses, depots, offices, and other necessary erections. Mr. Tomkinson has undertaken the contract for the whole of the dockwalls, &c.; and the energy with which the work is being executed is highly creditable. Several steam engines have been put down which are working mortar mills, and hoisting the materials from the bottom of excavations to the top of the quays; two limekilns are in full operation; and a range of workshops and smithies are occupied by artizans busy preparing the ironwork requisite for the railways, cranes, &c., about the works. The cost of the dock walls and gates is expected to be about 400,000*l*.

Birkenhead Park.

The Commissioners of Birkenhead have set apart a space of 190 acres as a park; 60 acres to be appropriated to detached villas and grounds, and 130 acres devoted for the use of the public for ever. Mr. Paxton has made the most of a very flat and unlikely piece of ground, and laid out the whole in an admirable manner, and the trees and shrubs appear in a healthy condition. Two lakes with rustic bridge and boat house are well situated, and add to the interest of the scene. There will be six fine lodges or gate-houses, three of which are now completed; Messrs. Walkers, builders, have contracted to complete two grand entrance lodges of stone, for the sum of 3,642*l*. It is said that the total cost of the enclosures, lodges, and laying out of the park, will amount to 20,000*l*.

New Market.

The New Market is now open for the use of the public, and is a great attraction, as it combines every modern improvement. The building is 430 feet long, and 181 feet broad, and is divided into three avenues by two rows of iron columns, which support a light iron roof in three spans. A handsome fountain is situated in the centre of the building, and a row of elegant gas pillars run along each of the three avenues.

Light is admitted from two rows of semicircular windows at the sides, as well as from skylights in the roof. The whole is cellared below, and the floor is arched on iron beams supported by columns. Messrs. Fox, Henderson and Co., of Birmingham, were the contractors.

Four new churches are being provided by the munificence of private individuals. I had not opportunity of learnnig particulars about them, but from what I saw they appear to promise well.

In concluding this sketch of what is doing in architecture and building in the localities I have had opportunities of visiting, it may be well to state that, generally speaking, the works in progress are decided improvements, as regards taste in architecture, skill in construction, and quality of materials used, upon previous works of a similar character in those localities.

There appears less disposition to substitute the sham for the real, and it seems as though people were at length becoming more generally acquainted with the fact, that it is in reality little more expensive to erect buildings which shall be ornamented and not offend good taste, than it is to provide those which have no pretension to design.

December 12th, 1845. A. B.

THE COLOSSEUM IN THE REGENT'S PARK.

There is a Colosseum at Rome, and another at London, but their likeness extends no further than their names, for hardly can any two things similarly denominated less resemble each other; the first being one of the most stupendous monuments of antiquity,—a truly colossal fabric, which, though deeply scarred by time, or rather by the hand of man, still bears the look of being eternal; while the other is merely a thing to day—a toy in comparison with the latter—an architectural butterfly as contrasted with an architectural *megatherium.* The Flavian Amphitheatre or Roman *Coliseo*—for such is the Italian orthography of the name—is a work to be classed only with the pyramids and some of the gigantic temples of Egypt; such an enormous mass, that it would seem to have required not merely a few years but a century to quarry the stone and put the materials together. It is to ancient Rome what St. Peter's is to the modern city, the "sovran" pile among countless others, the leviathan structure that engages attention, whatever else be passed unheeded; the object of universal admiration, be the admiration genuine, or, as no doubt it frequently is, merely affected and acted for fashion's sake. The Roman Colosseum has been a theme for poetry, both in verse and prose: sublime in itself, it is also arrayed in the halo of antiquity, and an imposing one it is, for it is apt to play tricks with and delude the imagination. Whereas our modern Colosseum is the very antithesis to all this: to the antiquarian it is a mere nullity: if he looks at it, it is only to turn up his nose at it with a contemptuous sneer; with him its very name crushes it into insignificance, by calling up more forcibly the image of the other to his mind. Still, there is something—nay, very much—to reconcile us to the disparity between the two buildings—to the disparity of their purposes, if nothing else. The arena of the ancient one was drenched with human gore. "There man was slaughtered by his fellow-man," to gratify the passion of a brutalized population, for spectacles of carange and bloodshed. Humanity will rather exult than sigh over the proud ruins of the Colosseum, though it must at the same time blush with indignation for the race who could coolly look upon the cold-blooded and wholesale murder of wretches, "butchered to make a Roman holiday," and call it *amusement!*

Most happy is it for us that the exhibitions at our modern Colosseum are of a far different character from the savage pomps and proudly atrocious spectacles of the ancient and right imperial one. This consideration may more than console us for the inferiority of our own edifice in comparison with the one after which it is named—or rather *misnamed,* because, leaving the vast difference as to size, between the two, out of the question, they bear as little of architectural resemblance and analogy to each other as they do of similarity of purpose; whereas the modern structure does really bear a strong likeness to another ancient Roman edifice that is of no less celebrity than the Colosseum itself. But the title of "Pantheon" had been preoccupied by the building in Oxford-street, which, even now that it is completely altered from its original shape, still retains a name that though in some points applicable when first bestowed, has now become a complete misnomer. Therefore, as ancient Rome possessed no more, one Pantheon was considered quite enough for modern London, vast as it is; accordingly the building in the Regent's Park was dubbed the Colosseum, for even the veriest Cockneys would have been scandalized at the absurdity, had it been named after the great pyramid. Of the exterior of the main building we may be allowed to say a word, because it is of considerable merit as a piece of architecture,—better worth than many that have obtained an infinitely greater share of notice from critics, and which, notwithstanding that they are now quite eclipsed by later productions of the art, still retain the rank first assigned them, owing to the character given of them being scrupulously transmitted from one book to another. The portico of the Colosseum is by very far the noblest specimen of one in the Grecian Doric style that we possess in London, one upon a nobler scale than any other, before the magnificent portico of the new Royal Exchange was erected, the columns full as lofty, (40 feet,) and of course of much greater diameter, those of the Exchange being Corinthian, consequently of slenderer proportions. The situation, indeed, takes off somewhat from the effect of size, for did the building stand in a street or other confined space, we should be more impressed by its magnitude of. It possesses, however, one very decided advantage over almost every other of our attempts at pure classicality of style, inasmuch as nothing is mixed up with the portico itself to disturb the antique physiognomy aimed at by that feature; there are no modern windows peeping out between the columns, or showing themselves elsewhere;—none of that intermixture of *columniation* and *fenestration* which is so contrary to correct Grecian architectural idiom.

Except that it has been renovated, the exterior of the building remains in *statu quo,* but the interior has been, if not absolutely remodelled in plan, metamorphosed into something altogether different in character,—transformed into one of the most captivating and fascinating pieces of internal architectural scenery that can well be imagined. The exquisitely tasteful rotunda or circular colonnaded saloon, into which it is now converted, stands almost unparalleled for both beauty of design, and felicitous originality of idea. If there be anywhere aught comparable to or resembling it, our acquaintance with matters of the kind does not extend to it. Although rooms far more sumptuous may be found, enriched with treasures of art, and set off to all possible advantage by the costliest furniture, we know not of one that is so charming for intrinsic beauty of design. Neither any of our royal palaces, nor of our most palatial club rooms, the Reform and Conservative not excepted, can show an apartment that is at once so novel and so impressive, so fraught with loveliness and witchery, as in this saloon or gallery of the Colosseum. Loveliness is the epithet that best describes it, since striking as the coup d'œil on first entering it may be, whether in the day time, or when lit up of an evening, the effect is not so much that of showy splendour, and dazzling brilliancy, as of mild and serene elegance, and of that tasteful simplicity which satisfies the eye, every part being complete and in perfect keeping, nothing superfluous and nothing deficient. In order to convey to our readers something like a positive idea of this truly charming interior, we may begin by describing it as a circular hall, completely surrounded by a peristyle of twenty Grecian Ionic columns, which divide the entire circumference into the same number of inter-columns or compartments; within, and corresponding with which, are as many recesses, the two compartments excepted, one on the west and the other on the east side, which serve as entrances. The columns are of scagliola, or to be more exact, of Keene's cement, in imitation of polished white marble; and the mouldings of their bases and capitals being gilt, produces a peculiar delicacy of enrichment, in which the monotony of uniform white, and the spottiness occasioned by scattered masses of gilding, are equally avoided. The entablature corresponds with the columns, with this difference, however, that the frieze being enriched with basrelief, (copied from the Elgin marbles,) the figures are raised upon a ground of a blue grey tint. The attic over the entabulature is ornamented with twenty oblong panels, containing allegorical subjects painted in fresco; and the ceiling or roof is divided into the same number of compartments by as many ribs, between which the light is admitted, the compartments being entirely glazed, yet not after the manner of a skylight, but so as to produce the appearance of a transparent roof, since it consists of *tesseræ* of cut-glass set in reticulated framing; consequently the light is somewhat refracted, and the raw look of a room almost uncovered and open to the sky, is avoided.

Thus far, description has been easy to ourselves, and, we trust, sufficiently intelligible to our readers, but without some drawing of it, it becomes difficult to explain that peculiarity which renders this rotunda so unique in plan, and so widely different in character from every other interior of the same class. Instead of the whole space that is surrounded by the colonnade being entirely open, so as to be fully exposed to view from every part, and be completely covered by a dome, the centre of the rotunda is occupied by a mass of cylindrical form, whose diameter may be about a third of that of the larger circle. Thus the rotunda assumes quite a different character from what is usually understood by that term, it being converted into a spacious '*ring* gallery' enclosing and running round another portion of the structure. Now, there is such a general prejudice in favour of having as much open and uninterrupted space as possible, that most persons may be apt to consider it a pity that the structure was not planned as a simple rotunda or single circular hall. Those who affect connoisseurship may even go further and say that we have here only the noble idea of the Pantheon spolled by the excrescence in the middle of it, obstructing a perfect view of the colonnade in its entire expanse and circumference. Happily, however, or else unhappily for ourselves, we do not hold with such narrow and one-sided criticism which, instead of estimating things according to what they are, depreciate them very summarily for not being what they are not designed to be. The same flower cannot be both a lily and a rose, nor can the same fruit give us the flavour of both the peach and the pine-apple. But for a circumstance which we shall presently explain, we might have had a copy of the interior of the Pantheon—nay, one that might in some respects have been rendered an improvement upon the original; yet, though that would have been positively and exceedingly good in itself, we should not thereby have acquired something altogether new in character, and which, if they are able or care to profit by it, opens quite a fresh train of ideas to architects for hitherto untried and unadopted combinations of plan. Had the striking peculiarity of plan in this structure been chosen solely for its own sake and that of the effect attending it, we should even then have been disposed to welcome so graceful a *caprice;* instead of which, it was a matter, not of choice, but actual necessity—a most fortunate necessity—compelling the architect to deviate from all precedents, whether he would or no, it being indispensable to obtain a staircase in the centre of the building, leading up to the platform gallery, from which the panorama is viewed. That staircase is accordingly concealed within the upright cylindrical mass, or tower-like shaft, that forms what may be called the *core* of the entire structure; and this staircase encloses within itself, and winds round another shaft, which is also hollow, and which is turned most admirably to account. Within it is a small octagon room, or cabinet, capable of containing seven or eight persons, and fitted up in a fanciful yet tasteful manner, having, among other decorations, a transparent ceiling of coloured glass, through which it is lit up by means of a gas-burner fixed over it. You enter this very fairy-looking closet, seat yourself on one of the velvet-cushioned benches, and before you have finished examining its embellishments, the door opens, and you find yourself at the top of the building—that is, on the platform of the panorama—without having been sensible of any motion during your ascent. Here then, we have not only a quite novel idea and most ingenious contrivance, but one that may occasionally prove essentially serviceable. Most assuredly Catherine II. would have liberally rewarded the inventor of such an enchanted flying cabinet; for when she began to grow infirm, and found it too fatiguing to go up and down a staircase, her architect was ordered to construct one that should be less toilsome of ascent, but he could hit upon no better expedient than that of substituting a series of inclined planes, or slopes, for steps, which, besides being not very satisfactory in itself, was attended with the inconvenience of rendering the distance to be walked over very much greater; whereas an ascending chamber, like the one at the Colosseum, would have spared Her Imperial Majesty the trouble of walking, or even standing. There are also others besides empresses who would be glad to be spared the trouble of going up a great number of stairs. To ascend, for instance, to the top of the Monument, toiling up a frightfully narrow, dark, and winding staircase, is not only a laborious task, but a somewhat formidable exploit: an ascending closet, or even mere platform, within the shaft of the column, instead of stairs, would have obviated all difficulty and danger—though, we ought to observe, it would have required a different mode of construction for the shaft itself, as there would have been neither newel nor steps within it, which now serve to hold it together. But there are far more probable and frequent occasions where the same mechanism might be employed: a single visit to the top of the Monument, or other structure of that kind, is sufficient for the curiosity of most persons; but, if it is to answer its purpose, a lofty prospect tower, or *belvedere*, whether in the grounds of a mansion or attached to the mansion itself, ought to be as easy of access as possible, or it will very rarely be made use of; whereas it would be most pleasant and convenient to be able to step at any time into a handsome little closet adjoining your sitting-room, and a minute or two afterwards step out again into another room in the upper story of a lofty belvedere tower, where, secure from intrusion, you might, like the tower-loving Beckford, enjoy both the wide expanse of surrounding landscape and literary study, merely glancing your eye from the book in your hand, or the well-stored portfolio on the table before you, to the prospect stretched out below and around. But halt! or our readers will fancy that we ourselves have ascended into an altitude, and taken a flight very far away from our proper subject; so we will descend as expeditiously as we can, without so much as stopping to speak of the "Panorama of London," which part of the Colosseum remains in *statu quo*—that is, in the day-time, for in the evening it produces quite a different effect, it being then transformed into a veritable bright moonlight night. However it be managed—and of course there must be a good deal of artifice besides the painting itself—this view is the triumph and perfection of scenic skill, for the full moon actually shines out from the picture, shedding its radiant light upon the platform and the spectators themselves; its beams flicker upon the surface of the Thames, while the mighty labyrinth of streets presents a flaming network of gas-lights gradually dying away into the far distant horizon. Happy magic! that can create for us brilliant moonlight on any or every night in the year, in the despite of the almanac. Bidding adieu to the upper region of the Colosseum and its moonshine, we again enter the Rotunda, and find it quite as charming as at first; nor must we hurry through it, for though we have already reconnoitered it, there is more to be said concerning it,—very much more, in fact, than can even be touched upon in an article like the present. One thing which we have not yet told our readers is, that which is now denominated the *Glyptotheca* (or Repository of Sculpture), in consequence of its being made to serve as an exhibition room, for casts of statues and groups by many of our principal modern English sculptors, including one or two by Thorwaldsen, and other foreign artists; all of them disposed in the most tasteful manner between the columns and within the recess, so that the mere arrangement of them becomes in itself a picture; the architecture and sculpture mutually set off each other to advantage, and both together, thus harmoniously combined, render this Glyptotheca the most admirable sculpture gallery in the world. It would be absolute folly to pretend to compare it with many others either for its magnitude, or for the value and excellence of the works of art which it contains; what we mean is, that taken in its ensemble and as an architectural picture, it has no rival, if only because there is nothing at all similar to it. The sculpture galleries at the British Museum are very little more than very large yet blank-looking rooms, that would be quite empty were it not for the sculpture itself; and many other places of the kind also, look very little better than so many statuaries' warehouses, or show-rooms, when their works are exhibited for sale. As to the sculpture room at the Royal Academy, that is so utterly unfit for its purpose, so wretchedly confined, and contemptibly mean, as to be little if at all better than a mere lumber-room, into which things sent to be *exhibited*, are stowed away during the exhibition. Yet that dismal "black hole," as it has been called, belongs to an academical body rejoicing in the ear-tickling epithet "Royal," where the delicious Glyptotheca,—and "delicious" is the epithet it truly deserves—together with all the rest of the Colosseum, is merely a private speculation, of course with a view to ultimate profit, which it richly deserves, but entered upon in a most liberal spirit, and carried through with admirable ability. It is moreover no less striking an instance of sound economy than of liberality, the best of all economy being to do well what is worth doing at all; although it is a species of it, which very few seem to understand; for how frequently do we observe some little paltriness suffered to peep out amidst splendour, some mark of penny-saving niggardliness to betray itself amidst extravagance, some jarring deformity to obtrude itself amidst beauty.

Runcorn.—Stupendous Bridge.—We have been favoured with a view of the plans of the Grand Junction Extension Railway from Aston-grange to Huyton, and also with those for the bridge in connexion therewith, to cross the river Mersey at Runcorn. Our readers may form idea of its magnitude when we state that there are to be five wet arches of 280 feet span, 100 feet above high water mark at spring tides, and 168 dry arches of 30 feet span, and 51 feet high, making a total of 2,480 yards of arching, which will be, when completed, the greatest work of the kind in Europe. This great architectural design will be a boon to the counties of Chester, Lancaster, and Stafford, giving the required facility to the Potteries and to the fertile mines of Cheshire. We predict that the rising port of Runcorn is destined to become a great emporium of commerce; and Lord Francis Egerton, with a desire to meet the coming exigency, is about to erect docks of great extent on the shore of the Mersey; and will also apply, at the next session of Parliament, for a trunk railway; thus affording the port a ready transit for goods, in addition to the two canals in his lordship's possession. We are credibly informed that it is the intention of Lord Francis Egerton to erect a new Custom-house, the present edifice, now in use for the Customs, being found most inconvenient for the growing trade of this thriving port. We congratulate the officers who are immediately concerned, and the trade generally, upon this wise and judicious measure, and are much pleased to find that his Lordship intends to act with so much liberality.

ARCHITECTURAL SYNOPSIS OF SOME OF THE PRINCIPAL BUILDINGS IN EDINBURGH.

Buildings.	Date.	Architect.	Remarks.
Academy, New Edinburgh ..	..	W. Burn	Said by Britton to be "illustrated by a beautiful portico."
Advocates' Library ..	..	W. H. Playfair	New Room, 140 x 42 x 28, recesses with Corinthian colonnades along sides, central compartment with low dome and skylight.
Assembly Rooms	1787		Plain Roman Doric on basement—tetrastyle portico (added 1818). Ball-room 92 x 42 x 40.
Assembly Hall	1844	J. Gillespie Graham	Gothic, with spire.
Bank of Scotland	..	R. Crichton	Corinthian on rusticated basement. The south front very much in Adam's style—petty and pretty.
„ Royal	..	Sir W. Chambers	Originally the mansion of Sir Lawrence Dundas. Tetrastyle Corinthian pilasters, on basement, and crowned by a pediment.
„ Commercial	1845	D. Rhind	On site of Physician's Hall. Portico Corinthian, hexastyle in antes.
Bridge, North	1765-9	W. Mylne	Connecting High-street with Princes-street. Three arches 72 feet span; entire length 310 feet.
Chapel, Catholic	1813	Gillespie	Gothic. Internally 110 x 57.
„ St. George's	1794	R. Adam	An octagon structure in Pseudo-Gothic style.
„ St. John's	1816-18	W. Burn	Gothic of feeble character.
„ St. Paul's	1816-18	A. Elliot	Gothic, perpendicular style, internally 105 x 63.
„ Dr. Jamieson's	1819-20	Gillespie	
Church, St. Andrew's	..		Portico, Corinthian, tetrastyle, monoprostyle. Body of church an ellipsis.
„ St. George's	1811-14	R. Reid	Ionic loggia; dome 60 feet diameter externally 140 high from ground to summit; style poor.
„ St. Giles's	..		Nearly consumed by fire, 1844. A heavy and patched-up Gothic mass.
„ St. Stephen's	about 1826	W. H. Playfair	Plain Doric, on a basement story; square tower of two stories at one angle.
County Hall	1816-19	A. Elliot	East front, tetrastyle Grec. Ionic portico.
Exchange	1754-61		Irregular in style, partly Corinthian.
Heriot's Schools	1845	Alex. Black	
High School	1825	T. Hamilton	The happiest and most picturesque application of Grecian style in Edinburgh. Centre portico hexastyle, lateral colonnades of seven intercolumns, and end pavilions with four antæ-pilasters in front.
Hospital, Donaldson's	1842, &c.	W. H. Playfair	Elizabethan style. Building 269 x 275 feet. Internal quadrangle 176 x 164.
Holyrood Palace	..	Sir W. Bruce	The quadrangle and chief part of the actual buildings by Sir W. Bruce.
Hospital, Heriot's	1628-50	Inigo Jones?	Style later Elizabethan, but rather poor, yet the building interesting as an architectural monument.
„ Merchant Maidens' ..	1816	W. Burn	Grec. Ionic, tetrastyle portico; in other respects of quite ordinary design.
„ Watson's	..	W. Burn	Doric, hexastyle, monoprostyle portico, ditto, ditto.
„ Gillespie's	1801	W. Burn	A mixture of castellated, Tudor, and 'sash-window' styles.
„ Lunatic Asylum ..	1810	R. Reid	Not completed.
Monument, Melville	1821-2	W. Burn	A fluted Doric column, 136 feet high, including pedestal (18 feet).
„ National	1822	Cockerell?	Intended to have been externally a copy of the Parthenon, but was discontinued after a few of the columns had been erected.
„ Nelson	..		A lofty circular tower of five stories—style intended for castellated.
„ Playfair	..	W. H. Playfair	This cenotaph a square mass formed by four Grec. Doric columns on each side, on a lofty solid stylobate.
„ Scott	1840-5	G. M. Kemp	A Gothic *Cross*, with pinnacles.
„ The Martyrs ..	1844	T. Hamilton	Egyptian Obelisk.
Observatory	1818	W. H. Playfair	A low Grec. Doric structure, with dome and hexastyle portico on each of four fronts.
Parliament House	..	R. Adam?	The building towards Parliament-square, a rather handsome elevation in the best Adam style, but disfigured by the second floor windows having no dressings.
Physicians' Hall, Old	1775-7	J. Craig	Tetrastyle Corinthian portico. Now taken down.
„ New ..	1845	Thomas Hamilton	Tetrastyle porch with statues over the end columns, and a *distyle* over the two centre columns.
Post Office	..		Plain Grec. Ionic, on a basement floor.
Register Office	1774	R. Adam	Considered one of his best works.
Royal Institution	1825	W. H. Playfair	Grecian Doric, portico double octastyle, recessed colonnades alone sides.
Regent's Bridge	1815-19	A. Elliot	Carried over Carlton-street in continuation of Waterloo-place, on an arch or tunnel 40 feet wide, 55 high, and 80 in depth. The parapet adorned on each side with a small colonnade, and an open arch and Corinthian columns in the centre.
University or College	1789, &c.	R. Adam	The largest pile of building in the city—about 400 x 250 feet. Handsome, but not sufficiently dignified; the original design, as then intended, published in Adam's works.
St. Bernard's Well, Leith Water ..	1790		A handsome small open circular temple or monopteros, of Doric order, on stylobate and basement; but now in a very ruinous condition.
Debtors' Prison	1845	T. Brown	Carlton Hill.

GREAT BRITAIN STEAM SHIP.

(With an Engraving Plate I.)

It is with great satisfaction that we commence the series of plates illustrating this volume with a subject of so general and valuable interest to engineers, as the engines of the "Great Britain." Plate I. is a copper-plate engraving representing the position and general arrangements of the engines. The vessel is supposed to be cut a-midships; so that one half the machinery is shown; two of the four cylinders, half the drum whicq drives the endless cogged chain, &c. A full description of the Great Britain was given in the last October and November numbers of this Journal, which it is not necessary here to report, as the engraving is not sufficiently explanatory of itself. It has been carefully reduced from the original drawings of the Great Britain, which were courteously placed at our disposal of the purpose: the scale of the plate is a quarter of an inch to the foot.

EXPERIMENTS ON STEAM.

A paper by M. Regnault was read at the Paris Academy of Sciences, on Dec. 15, relative to his experiments on steam. The Minister of Public Works assisted M. Regnault with the means of making these experiments on an extensive and practical scale. The questions to be determined by M. Regnault were—1. The law which unites the temperatures and elastic powers of aqueous vapour at saturation. 2. The quantity of heat absorbed by a kilogramme of water at 0 degree, to be converted into steam for saturation at different degrees of pressure. 3. The quantity of heat absorbed by the same quantity of water, in order to raise the temperature to the point in which it assumes the state of vapour under different pressures. 4. The specific heat of aqueous vapour at different stages of density, and at different degrees of temperature. 5. The co-efficients of dilatation of aqueous vapour in different stages of density. In his present paper M. Regnault gives the law of the elastic powers of steam up to 23 degrees centigrade, which temperature corresponds to 28 atmospheres and a half. He next fixes the total heat of steam taken at different pressures, from 1-5th to 15 atmospheres; and finally, he treats of the calorific capacity of water from 0 to 190 degrees. Many distinguished men have devoted their attention to the elastic powers of steam. We may mention Achard, Greu, Dalton, Christian, Arzberger, Watt, Robinson, Betancourt, Schmidt, Southern, Ure, Gay-Lussac, August, Kaemtz, Dulong, and Arago, the two latter of whom commenced their experiments in 1823, at the request of the Minister of the Interior, and published an account of them in 1829. They carried their operations up to 25 atmospheres. About the same period a commission of scientific Americans performed a series of experiments on this subject, but went up to only 10 atmospheres. The results, however, of these different experiments were not alike, consequently M. Regnault had to take entirely new ground, greatly aided, however, by the progress which science has made since the period alluded to. In his results he agrees most with MM. Dulong and Arago, particularly as regards high rates of pressure. Watt had supposed that the total quantity of heat necessary for the transformation of a kilogramme of water into the state of steam was certain under a constant pressure. The number admitted was 650. This law, although not exemplified by any precise experiment, had been, until very lately, regarded as positive, and so adopted in theory and practice. M. Regnault, however, has ascertained that this number increases constantly from 622 under the pressure of one-fifth of an atmosphere up to 670 under 15 atmospheres. At the ordinary pressure the average of 38 experiments gives 636·37. As to the calorific capacity of water, it is 1,000 between 0 and 30 degrees, 1,005 between 30 and 120, 1,013 between 120 and 190.

THE CATHEDRAL OF ST. DENIS.—The monument erected to the memory of Louis XVIII. in the vaults of the Cathedral of St. Denis is about being completed, and, when finished, that of Charles X., his successor, will be proceeded with. When this is done, all the French Kings and Princes up to 1830 will be there represented either by a tomb, a monument, or a statue.

CHRIST CHURCH, PLYMOUTH.

We have received some information respecting the architecture of this church, which has recently been completed, from the designs of Mr. Wightwick. The dimensions are about 70 feet by 90 feet. The style, Perpendicular. The western front presents three entrances and three gable roofs, of which the central or highest gable reaches the height of 50 feet. Between it and each of the wing gables rises an octagonal turret, and at the outer sides of the wing gables are pinnacles.

It will be concluded from this description of the western front, that the interior of the church is divided into three compartments—of these the central one, or nave, is divided from the lateral aisle by piers. There are five arches on either side of the nave, and over them clerestory windows, which give the principal light; for owing to the contiguity of neighbouring buildings, there are no windows whatever in the side aisles, and consequently there is no means of lighting the church except by these clerestories and the windows at the east and west ends.

Our informant says it was absolutely necessary to introduce galleries. However, it appears that the galleries are set so far back, as not to abut on the piers, and as they do not cross the aisle windows (there being none to be crossed,) this "absolute necessity" is not so much to be regretted as it otherwise would have been.

The architect has shown great judgment in the selection of some of his details, from ancient examples. The western entrances are copied from those of Tattersall Church, the crockets and finials of the octagonal turrets from those which many of our readers may remember at Magdalene College, Oxford.

The nature of our information does not warrant a very decided criticism on the merits of the new church—the general character of the architectural details is probably unexceptionable. Unless, however, we be greatly mistaken, the building has one great fault—a *show front;* the elevation towards the street exhibiting considerable pretensions, while the other sides of the church are merely plain masonry. If misinformed on this point, we shall be glad to be set right. If, however, the fact be as here assumed, it certainly will materially diminish the architectural value of the building. One of the most admirable characteristics of the old Christian architects was their total freedom from pretence. They never adorned one side of a church and left the other three sides plain—taking care to turn the *dressy* side where it would be most seen. There is no ancient cathedral, minster, abbey, church, or chapel in Christendom with a show side. The old architects never attempted to cheat beholders into a belief that their works were elaborate, when in truth they did not deserve the character. Of course these remarks must not be considered to imply a censure on the architecture of the Plymouth Church. The architect cannot of course be blamed for the defect alluded to, if he had no power of remedying it. Still it is greatly to be regretted that he should have had to exert his talents under circumstances which would of necessity produce an unsatisfactory result. At the east end of the Church, in the place where the chancel is usually built, is a "communion recess," ten feet deep.

Since the above was in type, we have received a description of the church, taken from the Plymouth Journal. As however this description is very similar to that given above, we avail ourselves of the following part only of the extract sent to us. "The interior presents an effect of lightness and elegance which is admitted by all who have seen it, and fully justifies the architect in his idea, that the details of Gothic architecture may be employed in the fullest consistency with that expression of *openness* which should characterize a Protestant church. In fact the public of these towns have now an opportunity of making a fair comparison between the peculiar characteristic of the *Camdenite* structure, and those of the Reformed Church. St. Michael's, at Stoke, and Christ Church, at Plymouth, are now before them. In the former, we have the picturesque—in the latter, the elegant. The first shows a handsome, though unfinished exterior; the latter its single front of far more ornate character, the means of the architect being concentrated on one point, and that being brought to perfect completion. St. Michael's is of the most simple plainness within, and affects no more than a general expression of shadowed gloom. Christ Church exhibits, within, the decorative amount promised without, and unites solemnity with grace. Though 'cheerful as the day,' it is not less, as Cowper would say, the house of 'true piety.' What the cost of St. Michael's may be, we have yet to learn; but we know, that Christ Church has been completed, including 85*l.* for extras, for only 6*l.* 8*s.* 6*d.* above the architect's estimate—the total cost of the building being 3,475*l.* The accommodation is for 1120 sitters, of whom 35 may, hereafter, have to make way for an organ. The clear internal dimensions of the church are, from east to west, 87 feet, and from north to south 68 feet."

ON THE CHANGE OF OSCILLATORY INTO ROTATORY MOTION.

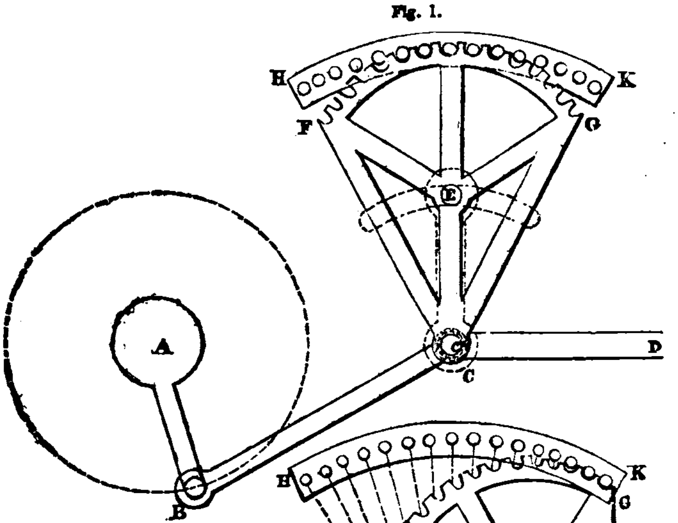
By F. Bashforth, B.A., Fellow of St. John's College, Cambridge.

Notwithstanding all the disputes respecting the crank, it appears that no better substitute has been or probably can be found. In fact, the beautiful adaptation of the velocity of the end of the connecting rod to the requirements of the piston is such as cannot be surpassed. Still there appears to be a great objection to the present method of employing it in locomotives and some of the steamers, as the Great Britain. The piston rod and the connecting rod are inclined at a considerable angle during the most important part of the stroke, and this gives rise to very considerable friction.

In the beam engine, and where there is room for its application, the parallel motion of Watt has been found to answer completely every purpose, but in locomotives, &c. there is not the necessary space. For this purpose it is proposed to make use of the well-know property, that if a circle of radius r roll in the interior of a circle $2\ r$, any point in the circumference of the former will constantly describe the same diameter of the latter. This geometrical principle has been already applied in mechanics, but never, it is believed, in the manner about to be explained.

In figs. 1 and 2, H K represents an arc of a circle, having equal cylin-

Fig. 1.



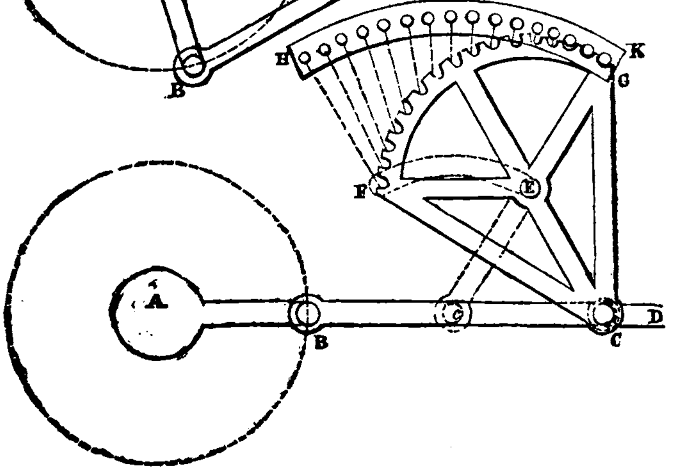


Fig. 2.

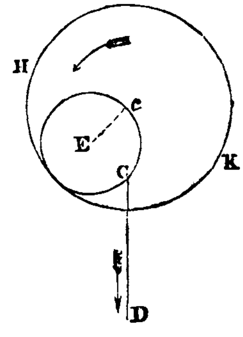
drical studs fixed at equal distances in the pitch circle of radius $2\ r$, c being its centre. These are fixed firmly to the frame. The bar c E, represented by the dotted line, is capable of moving about the fixed centre c, and at E carries the centre of the segment F G of radius r; c E $= r$ C D is the piston rod, and during its oscillations C F is compelled to roll on H K, and C will describe a perfectly straight line. The pivot E had better be rigidly connected with the arm c F. The figures represent a projection on a plane perpendicular to the axis, which is turned by the crank. The diameter of K H must not be less than the length of the stroke of the piston. The figures represent the necessary sines of the several parts to ensure a stroke C B, the whole of the guarding machinery being on one side of the piston rod.

Figs. 3 and 4 represent two differnet states of the same contrivance for



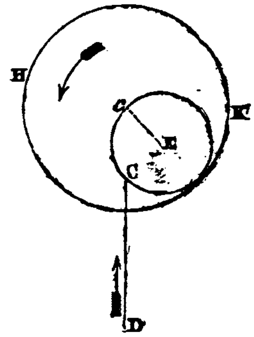


Fig. 3. Fig. 4.

communicating motion directly to the crank, without the employment of any connecting rod, and so that the axis to be turned may be placed at little more than half the length of the stroke from the end of the piston. The letters refer to the same parts as before, the pitch circles alone being represented.

In this arrangement the cranks must be at the end of the axis to be turned. This, however, would not be of great importance in its application to the screw propeller, or to locomotives, where the connecting rod acts outside the wheels. It is evident, from an inspection of the figure, that the velocity of C is greatest when passing c, and that it is gradually brought to rest at each end of the stroke, although c E may be revolving all the time.

In order, however, to render these suggestions of any practical utility, it will be necessary to point out the method of rendering the motion extremely easy and durable. The studs should be made sufficiently strong to withstand the forces to be applied, and covered by short triblet-drawn brass tubes, and left at liberty to revolve. These could easily be changed in a short time, if they should become bruised or worn, and would save from injury the constant parts of the machinery.

It is well known, that by the geometric chuck almost perfect epicycloids and hypocycloids can be traced with ease and rapidity. Now, hese are the curves required wherever pin wheels are used. Suppose that we have a large chuck, and that we replace the tracing point by a circular drill or cutter kept constantly revolving with its centre in the place of the point, as the chuck, on which the wheel to be cut is mounted, is caused to move slowly, the exact form of the teeth will be given. The teeth ought to be cast sufficiently large to bear shaping by the revolving tool. On account of the certainty with which almost perfect forms can be given to the teeth of such wheels by ordinary workmen, it appears that this method of changing angular velocity would be useful where strength and freedom of motion are required, whether for turret clocks, or for increasing the angular velocity of the screw propeller.

The methods of forming the teeth of spur wheels in common use appea to be very defective. There are so many chances of error in the setting out and cutting of patterns, and afterwards in the alteration caused by unequal construction of metals, that it appears desirable that some improvement should be made; and I am in hopes of being able to point out a method by which teeth of any pitch may be formed without any change of cutter, and approximating very nearly to the forms recommended by Professor Willis.

THE RAILWAY SUSPENSION BRIDGE.

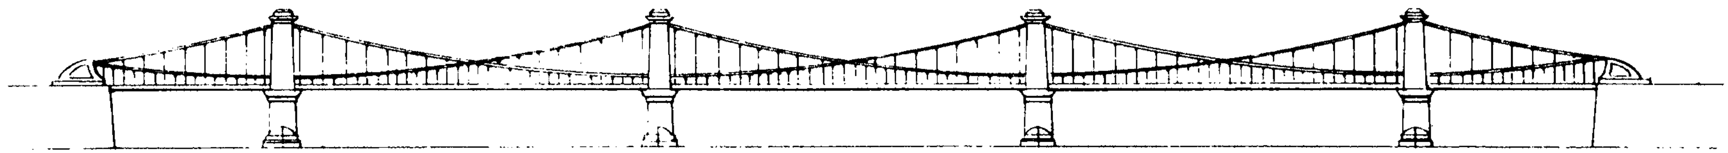
Patented by Mr. H. H. Russell.

(*With an Engraving, Plate* II.)

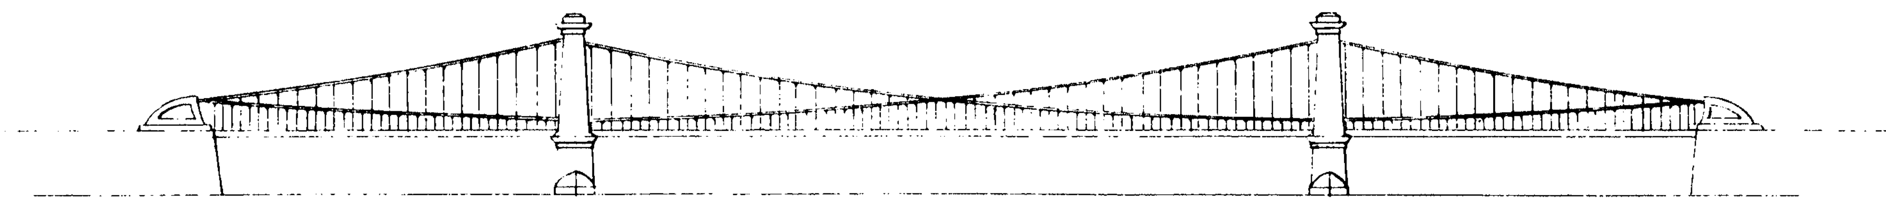
The accompanying illustrations (Plate II.) exhibit the construction of a recently patented suspension bridge, which the inventors propose to apply to the purposes of railway traffic. We have been favoured by Mr. Lapidge, the county surveyor for Surrey, at whose expense the patent was secured,* with a description of this invention, written with a mo-

* A model of the bridge, upon a large scale, may be seen at Mr. Lapidge's offices, Derby-street, Westminster.

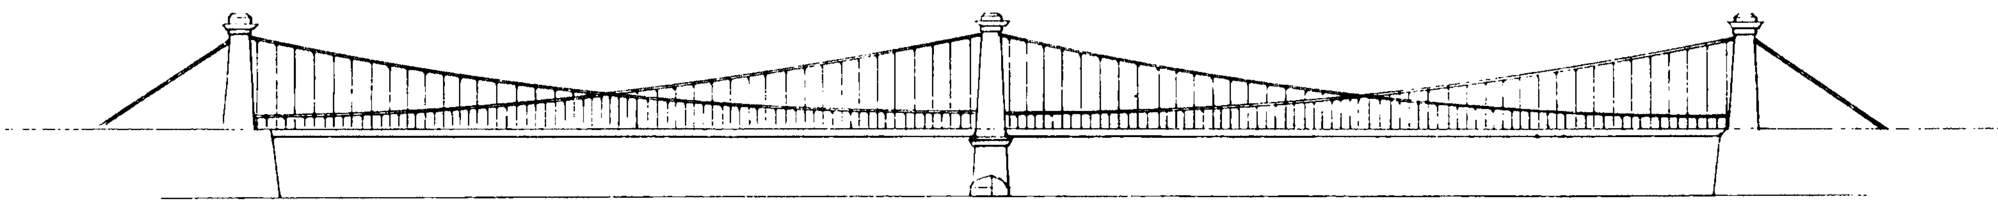
PATENT RAILWAY SUSPENSION BRIDGES.



Bridge applicable to a Site where a Line of continuous Arches to any extent are required.



Bridge applicable to a Site where a Centre and Two Half-arches are required.



Bridge applicable to a Single Span of 400 Feet or less width.

deration all the more praiseworthy because it forms a nearly unique contrast to the extravagant encomiums which inventors usually bestow on their own productions. As, however, on consideration, we think we can discern advantages in the present invention which are not quite apparent at first sight, and which are not commented on in the description which we have received, we have ventured to give our own version. The inventor will have no cause to complain of the determination.

It is not, however, to be understood that on a subject so complicated as the theory of suspension bridges, any judgment, however carefully considered, can have the same value as one pronounced in simpler cases. The general problem of the equilibrium of suspended chains is so difficult when applied to practice, that it is impossible to predict with certainty the exact practical effect of any untried arrangement. However, as in the present instance, the inventors do not apply themselves to the complicated questions respecting the relation of the various tensions to the strength of material, but confine their attention to the means of preventing *oscillations* and *undulations* of the platform, the subject can be satisfactorily examined without the use of mathematics.

The leading idea of the invention is so simple, that a very few words will suffice to explain it. Each chain of the ordinary suspension bridge is replaced by two lighter chains *crossing each other*. Each of these crossing chains is suspended by its *highest* and *lowest* points, and the two may also be fastened at their points of intersection. The suspending rods are fastened to each chain alternately, and the edge of the platform will be therefore supported, throughout its length by a series of alternately long and short rods.

Every practical engineer knows the importance of strengthening a structure by supports or ties arranged cross-wise. The roofs of railway stations may be referred to as familiar instances of the value of cross ties. Wooden bridges, in which the beams are arranged diagonally, and cast iron girders, with cross ribs, are examples of the same principle. In fact it may be laid down as a general principle that all structures where the points of support are at considerable distances from each other, derive stability and rigidity from a system of oblique rods or beams.

Let us now see how this principle applies to the case before us. The disturbances to which a suspension bridge is liable, from external forces, are of two kinds—first, oscillation, or swinging of the chain from side to side—secondly, undulation, or the vertical rising and falling of the several parts of the platform. Now, with respect to this first kind of disturbances it is obvious that a chain suspended from the tops of two piers must be more *pendulous* than one fastened by its highest and lowest point. That a catenary suspended by its two highest points is readily set in motion, and can be maintained in motion by a slight force, may be readily seen from the familiar instance of a child's swing. But it may also be seen from the same instance, that if the lowest point of the curve be *fastened*, the liability to oscillation is almost entirely removed. In the invention before us, this method of preventing oscillation is adopted, and the advantage is further increased by the union of the two cross chains at their points of intersection.

The second kind of disturbances of suspension bridges—the undulatory—is by far the most important. The height of the undulations of the Menai bridge in a storm has been known to be some 8 or 10 feet, while the transverse oscillations were scarcely observable. By far the most important part, therefore, of the invention of intersecting suspension chains is the means they afford of preventing the rising and falling of the platform. This effect is, however, not immediately obvious, and we shall perhaps have some little difficulty in rendering the explanation of it intelligible.

What we wish to show is this—that the effect of two chains, both united to the platform, is such that, where the deflection of the one chain would tend to raise the platform, the other chain would tend to depress it—so that the two chains would, during the passing of a load, counteract the tendency of each to elevate or depress the several parts of the roadway.

To make the point clear we will refer to the figure of the single-span bridge in the accompanying plate. We will suppose that a heavy carriage has got some distance across the bridge, but has not yet reached the centre of it. Now let us see what is the effect of this load on each chain *separately*—first, for instance, on the chain which at this place is the highest. The load rests on the platform, and tends to sink it, and this tendency is communicated by one of the long rods to the upper chain. If, however, the action of the rod pull down the chain at this point, we know by the nature of suspended chains, that the whole of the curve will be acted upon, rising at some points and sinking at others. Now let us see what the effect of the passing load is on that chain which at the place in question is lowest. Here the effect of the load is transmitted by one of the short rods, which tends to depress this chain also; and here again, if the chain be actually depressed, the whole curve will be acted upon, rising at some points and sinking at others. But if the matter be attentively considered, it will be found that *the parts of the one chain which tend to rise are directly above those parts of the other chain which tend to sink*, so that these tendencies are opposite to each other, and are counteracted by the attachment of both chains to the platform.

Or, to express the same thing another way, a passing load tends to alter the whole curvature of both chains—to draw the two chains, in some places, closer together, and, in others, wider apart, than they are in their positions of equilibrium. In the ordinary single-chain suspension bridges there is nothing but the weight of the chain and platform to resist this tendency to alter the forms of the curves; but in this double-chain bridge the alteration is resisted by the tensions or thrusts of the connecting rods.

If we have succeeded in making this point clear, the reader will see that these counteractions occur, not at one or two points of the bridge, but at every point of it. Everywhere therefore there will be a tendency to bring the two chains closer together, or move them wider apart, and these effects are everywhere prevented by the connexion of the vertical rods, each of the rods exerting either a tension or thrust to resist the effect of the passing load. The two curves cannot either recede from or approach each other on account of the rods, so that the case is altogether different from that of the ordinary suspension bridge; for there a passing load acts only on the suspending rods immediately adjacent to it—but here every vertical rod of the whole bridge is acted upon by the load, and resists its tendency to depress the platform.

The effect therefore seems to be to convert the whole structure into a system almost perfectly rigid, to give it, without any additional weight of iron, nearly the stiffness and stability of a girder. This is by far the most important part of the invention, and deserves the careful consideration of the engineer.

It is a point worth noting, that the vertical rods would not always be in a state of tension as in other suspension bridges, but occasionally would have to resist compression also, (where the load tended to bring parts of the two curves closer together), and therefore these rods would have to be made with more than the usual rigidity.

Of course on so complicated a subject as that of suspension bridges, no opinion on practical points is perfectly trustworthy till verified by experience. We cannot determine exactly to what extent rigidity might be attained in a suspension bridge on this new principle, still we think enough has been said to show that the rigidity would certainly be far greater than what can be obtained in the common suspension bridges, without additional stiffening by strong diagonal ties. These greatly increase the weight of the structure, and are generally inapplicable from the difficulty of finding convenient points for attaching them.

REVIEWS.

Companion to the Almanac, or Year Book of Information for the year of our Lord 1846. London: Charles Knight, 12mo., pp. 260.

This is the nineteenth of a series of annual volumes published under the superintendence of the Society for the Diffusion of Useful Knowledge. The information in this volume is collected under two heads—first, "mathematics, natural history and philosophy, chronology, geography, statistics," &c.—secondly, "the legislation, statistics, public improvements, and chronicle of 1845." The first chapter is on the "earliest printed almanacks," and treats very fully of the history and successive improvements of the calendar. This paper is written by Prof. De Morgan; it contains, however, no display of his mathematical genius, but exhibits a vast amount of antiquarian erudition. We have chosen one or two short extracts, as well for the curious nature of the information they afford, as to give a general idea of the style of the paper. Speaking of the difficulties which the Church experienced in determining the time of Easter, and reviewing the various remedies proposed for these difficulties, it is observed—

"Regiomontanus is the next after Bacon who declared that the *usus ecclesiæ* was not in accordance with the *decreta patrum;* he does not attempt the usual historical falsehood of fixing the existing method upon Eusebius and the other Nicene bishops, but refers it (and truly, as we showed in our last number) to the Abbot Dionysius, "whose pascal calender," says he, "we are using to this day." He mentions the diffusion of the Scriptures among the people in their native tongues as giving rise to many doubts and questions upon the subject; and alludes to this diffusion as having taken place in Italy, and specifically as having caused a reference to Cardinal Bessarion when he was legate at Venice. He further says that the Jews very frequently raised objections to the existing Christian mode of determining a feast which was asserted to be connected with the Passover; and so far had the dissatisfaction gone, that some priests of Bremen* (*sacerdotes premenses*) had undertaken to correct the error themselves, and had kept Easter a month before all the rest of the Church—for doing which the adjective *premenses* had become a standing joke against them with a double meaning.

Between clocks and watches, lighted roads, and public announcements, we are now so well provided with information, that an almanac is not a matter of the first necessity to most persons. It was otherwise in the fifteenth century; and if we consider how much comfort must have depended upon being able to arrange business with reference to the numerous holidays and the moonlight, we shall see that the mere list of saints' days and moons must have been a matter of consequence."

The topic of astrology is naturally touched upon as pertinent to the subject in hand.

"There are many manuscript almanacs of the fifteenth century yet remaining. They may be divided into what we now call *astrological* (a word which was then frequently used in its original sense), and those which were simply astronomical. The majority of the astronomers in the middle ages believed in the prognosticating power of the stars: even Roger Bacon inclines to the supposition that they have a physical influence on the body, and through it on the acts of the mind. The Church of Rome always, collectively, set itself against this absurdity. Not that its popes and cardinals were by any means universally free from belief in it; but those who believed considered it as magic, while those who disbelieved thought it of course an organized fraud. So that, upon the whole, divination by the stars met with little public encouragement, and its professors were obliged to write about it under modified phrases. We have never found, in ancient astrologers, such impudent pretensions as those which have been published in London in our own day. If the members of the Stationers' Company, who still continue to publish an astrological almanac, could see this trash, and could know that there are shops in London which sell nothing else, and that there are persons who make a trade of imposing on the ignorant, and who doubtless quote their authority, we suppose they would not allow any consideration of profit to induce them to lend their names to the continuance of so vile an imposition. We should recommend them never again to do what they have done in *Moore's Almanac* for the present year, namely, insinuate that unbelief in astrology is infidelity, and denial of the providence of God. This is an oversight, arising from an unskilful attempt at imitation of the old almanacs; it must show the Stationers' Company that if they will play with edge tools, and call it sport, they ought to be very careful how they use them."

The note referred to in the above extract is as follows:—

"We quote our ground for this charge from Moore's Almanack for 1845. The italics, when mixed with Roman, are our own."

'Astrological Predictions. *Judicium Astrologicum, pro anno* 1845. *Vox Cœlorum, Vox Dei: The Voice of the Heavens is the Voice of God. He speaketh in all the Changes of the Seasons and of the Times.*—Courteous Reader,—In this my annual production, I have a long time sounded the *above important truth* in your ears, and I trust *not in vain*. It is, *however*, to be lamented that there is a *great deal of infidelity* upon the face of the earth, and even no small portion thereof cleaves to the skirts of Britannia. .... That wonder-working Hand, which placed each mighty orb.... is clearly manifest in our earth by the changes of seasons..... Let those who are disposed to *deny the existence of Divine Providence* reflect on these words of holy writ, Not a sparrow falleth.....'—Such an innuendo would have been too bad for the sixteenth century."

The following extract is taken from a foot note, p. 17.

"Those who observe that Boyle has let Melancthon off for his astrology with two words and a reference, would hardly imagine the lamentable extent to which this weakness was his master. On his death-bed, he half predicted that he should die on the day on which a conjunction of Mars and Saturn would take place: and on one occasion, being seen bathed in tears, and showing every sign of the greatest grief, it was found on inquiry that on looking at the stars in his evening's walk, he saw that a dreadful war was going to burst upon Germany. The first story is from his most accredited biographer, Melch. Adam; the second from a less respectable source, the "Jocorum atque Seriorum Centuriæ" of Otho Melander, whose grandfather, Dion. Melander, was the person who asked Melancthon what was the matter with him. This same Otho relates a severe rebuke which Melancthon received from Luther, for saying that persons born when Libra was in the ascendant must be miserable through life: and a ridiculous attempt to cast the nativity of an infant child of his (Otho's) grandfather, whom he supposed to be of the male sex, and to whom he promised learning, honours, and religious contests. Being told that the child was a girl, he was out of countenance for a time, and at last said—then she will rule her husband. But on second thoughts he cast a new scheme, in which he condemned her to death at seven years old, and staked the validity of his art upon the prediction. The girl lived, however, till the age of fourteen. Otho was of the reformed church, and was therefore free from one bias against Melancthon, at least."

* At least Bremen is called Premis and Premen in contemporary cosmographies: but it may be that these priests were of Parma, and that Parmenses was altered into Premenses for the joke's sake.

The paper of Prof. de Morgan is followed by a very useful article on foreign exchanges, and some elaborate tables of the fluctuations of the funds. We should have liked to have made some extracts from the tables of the "statistics of crime," as the subject is intimately connected with one for which we have frequently endeavoured to enlist the attention of our readers—the sanatory conditions of large towns. We must, however, for lack of space, pass on to a subject more immediately connected with the objects of this work, "the railways of Great Britain." Under this head there is a brief abstract of all the railway acts passed during last session—forming a synopsis somewhat similar to that which appears in our present number, excepting that no notice is taken of the amalgamations and other private arrangements of companies. The following extract is likely to be read with interest, as giving a good compendium of parliamentary proceedings respecting railways during the past year.

"On the 31st of December the Railway Department of the Board of Trade issued the first of a series of reports upon the schemes thus examined by them, in which reports, after enumerating all the projected lines in a certain district, they expressed their intention to report to parliament in favour of certain schemes and against some others, while they recommended the postponement to a future period of such as they considered might be modified to advantage, or might be rendered unnecessary by the introduction of better or more comprehensive schemes. The more detailed reports in which they explained the reasons which had influenced their selection, were not, in most cases, published until some weeks after the announcement of their decision. In selecting from a mass of rival, or partially rival, projects, the Board usually gave their recommendation in favour of the new lines projected in friendly connection with, rather than those in opposition to or competition with, already existing lines; and in cases where the engineering features of two or more rival schemes were essentially different, they entered, in their detailed reports, at considerable length into such questions as the comparative merits of the locomotive and atmospheric systems of propulsion, of different systems of gradients, of width of gauge, and other peculiarities of construction. In consequence of an idea that such reports would decide the fate of railway bills, some projects which had been prepared for parliament were withdrawn in deference to the recommendations of the Board of Trade; but in many instances the promoters determined to proceed with their bills in the face of adverse reports, a course which appears to have been by no means disapproved by parliament, since many such schemes were successful in obtaining their acts, while some of those most warmly supported by the Board of Trade were defeated in Committee upon their merits, and others, in consequence of informalities (resulting, in some cases, from the impossibility of preparing the requisite parliamentary plans and sections by the appointed day, or of submitting them to the searching examination necessary for the detection and correction of clerical errors, when the demand for surveyors, levellers, draftsmen, and engravers was so urgent as in the autumn of 1844), were thrown out for non-compliance with Standing Orders. It being very evident that, whether the Railway Officers of the Board of Trade had or had not exceeded the powers committed to them, their recommendations were distasteful to the Select Committee of the House of Commons, upon whose right of decision they appeared to trench, the Railway Department has been completely remodelled by a minute of the Lords of the Committee of Privy Council for Trade, dated the 10th of July, 1845, by which the distinct Board constituted by the minute of the 6th of August, 1844, was discontinued, and it was determined that in future all railroad business should be transacted by the Lords of the Committee of Privy Council for Trade in the same manner as the ordinary business of that Committee.

In the House of Commons, the enormous amount of railway business formed the most remarkable feature of the session, and such of the Standing Orders as relate to the composition of the Committees on private bills were suspended, so far as railway bills were concerned, it being impossible, under such extraordinary circumstances, to adhere strictly to the usual practices of the House. Railway bills were, at the commencement of the session, divided by a "Classification Committee" into *groups*, each of which was referred to one Select Committee, who were allowed to sit during any adjournment of the House, in order to get through the immense mass of business before them. Notwithstanding every exertion, many competing schemes failed, from want of time, to obtain a hearing; and some bills which were virtually passed, were necessarily left over to next session, a special arrangement having been made to allow the privilege of re-introducing in 1846, and carrying on from the point where the proceedings left off in 1845, such bills as had been ordered by the House of Commons to be ingrossed. Before the close of the session some alterations were made in the Standing Orders, by which the additional maps and statements required by the minute of the Board of Trade above quoted, are required to be deposited, and the amount of deposit required before presenting a petition for a railway bill is again increased to *ten*, instead of, as in the last session, *five* per cent. of the amount subscribed. This increased deposit, however, is not required in the case of bills which have been before parliament in 1845, and may be re-introduced in 1846, or of undertakings provisionally registered before it was issued, or such as had their subscription contract executed, or partly executed, on the 29th of July, 1845. Among the important parliamentary proceedings of the session we may refer to the passing of the Railway Clauses' Consolidation Act, by which all future railway acts will be much simplified; and the appointment, in consequence of a motion in the House of Commons by Mr. Cobden, of a Royal Commission "for inquiring whether, in future Private Acts of Parliament for the construction of railways, provision ought to be made for securing a uniform gauge, and whether it would be expedient and practicable to take measures to bring the railways already constructed, or in progress of construction, in Great Britain, into uniformity of gauge: and to inquire whether any other mode of obviating or mitigating the serious impediments to the internal traffic of the country, which are represented as likely to arise from the want of a uniform gauge, could not be adopted."

We regret we cannot find space for more than a brief enumeration of the greater part of the remaining subjects of information. There are some very valuable tables comparing rates of life insurance in different companies, abstracts of public acts of parliament, and parliamentary documents, a chronicle of the sessions, and a numerical account of petitions and private bills. The information throughout these chapters is arranged in a very careful and satisfactory manner.

The thirteenth chapter treats of "Public Improvements," and is divided into three sections headed respectively, "General Improvements," "Churches," and "Miscellaneous Buildings." Of this part of the work we regret to say that we cannot speak in the same terms of commendation as of the rest. Whether it be that the conductors have here towards the end of the volume been compelled to put their remarks together in a more hasty manner than in the preceding parts, we cannot tell; but the diction is careless and very frequently ungrammatical, and many sentences require to be read several times before the meaning of them can be ascertained. Of these faults however we should not complain, (as we do not here profess to write a literary criticism) were the language sufficiently perspicuous to explain the views of the authors. This however is by no means invariably the case, and even when we succeed in finding out what ideas on architectural subjects are intended, we are seldom recompensed for the labour of discovery.

The first piece of criticism is on the architecture of the new buildings behind the Royal Exchange. Unfortunately enough these buildings are praised for the qualification which they least of all possess. Speaking of the arrangement of the windows, it is observed that it "is such as not to cut up the mass itself into littleness, as is too generally the case owing to *the windows being put too closely together*, which inevitably occasions an ordinary dwelling-house look to prevail." Now without offering any opinion of our own on the merits of the building in question we may state, as a simple fact, that the ground floor of the building exhibits one continual series of arched window-openings, separated only by piers. In many of the conservatories which are attached to large country seats, and are built to assimilate in architecture to the contiguous buildings, the aggregate surface of the windows is not so great compared with that of the masonry, as it is in the ground floor of the buildings behind the Royal Exchange. The observation that "this arcade is exceedingly well proportioned as to the quantity of window opening as compared with the entire surface," was written, it may be suspected, *before* the writer saw the building.*

The next subject of commentary is Trafalgar Square. Of this it is said, "The two fountains seem to have altogether disappointed the public; for not only have they been ridiculed by those who make mere ridicule pass for criticism, but have been spoken of seriously by those who profess to deal in sober criticism as things of 'intense ugliness,' which *is rather too severe, since the insignificance of their appearance is at least an equal defect*." This passage, of course, contains a reference to the criticism of the Trafalgar-Square fountains, which appeared some time since in the *Civil Engineer and Architects' Journal*: the objection now raised to that criticism is odd enough. First, insignificance of appearance is spoken of as something distinct and separable from ugliness; secondly, the former of these qualities, though it is said to be an "equal defect" with the latter, is assigned—not as an additional reason for its condemnation—but on an altogether new system of logic, as a proof that our criticism was "rather too severe"!—"which is rather too severe, *since* the insignificancy of their appearance is at least an *equal defect*"!

Another "defect" is discovered in the architecture of Trafalgar Square, which certainly never suggested itself to ourselves. The writer, whose knowledge of the English language is as profound as his knowledge of architecture, says that "a singularly disagreeable effect" is produced, because "the tops of the wall are not made to rise and fall like hedges." We confess that this plan of making Trafalgar-Square "agreeable" never occurred to us. An excuse for all the defects noticed, is, however, found in the consideration that the site was a very bad one! "Barry certainly here undertook a very ungrateful task, it being hardly possible to make anything satisfactory out of such an ill-arranged spot." We always imagined that the principal cause of the public disappointment respecting Trafalgar Square, was, that "one of the noblest sites in Europe" was sacrificed in an abortive attempt at architectural display.

In commending the new buildings in Lincoln's Inn, it is observed that the ceilings, "though only of deal *unpainted*, have the appearance of being of a superior kind of wood, great depth of hue and lustre being imparted to it by some novel process or preparation." The word "unpainted" is marked in italics, to intimate, we presume, that the imitation is excused from censure, because it is not produced by paint—that the weight of the censure depends not on the simple fact of deception, but the method of effecting it. This principle is that of the Spartans who used to punish their children for larcenies—when they committed them clumsily.

Had the writers on "public improvements" been accustomed to be present at the hall-dinners at Lincoln's Inn, they might frequently have heard the merits of the ceilings in question dismissed somewhat unceremoniously by the appellation—"Brummagem." The criticism, to be sure, is not that of professed architects, but it is at least that of gentlemen and men of educated taste.

In noticing buildings deserving of admiration, there is a particularly unfortunate tendency to choose for commendation the very particulars which a judicious friend might have passed over in silence. The above is a striking instance, but there are many others. In the Colosseum, the first subject of commendation is the circumstance, "that the columns, &c., are of white marble—or, at least, have all the appearance of being so," being formed of a composition "that imitates that material *most deceptively*." The new church at Leeds is said to exhibit a "most praiseworthy regard to *permanent* excellence," the last quality we should assign to a Gothic Church with plaister ceilings.

The final chapters of the work are a "Bankruptcy Analysis," and a "Necrological Table of Literary Men and Artists." The volume, though not absolutely free from grave faults, may, on the whole, be pronounced a valuable and certainly cheap repository of the information usually contained in a "Year-book."

Ancient and Modern Architecture; consisting of Views, Plans, Elevations, Sections, and Details of the most Remarkable Edifices in the World. Edited by M. Jules Gailhabaud. Series the second. Parts 35, 42. London: Firmin Didot, 1845, quarto.

We have already noticed some of the previous numbers of this series of engravings; those before us embrace almost every kind of architecture, as may be seen from the following list of the principal subjects:—Church of St. Zachary, at Venice; Theotocos Church, at Constantinople; St. Etienne du Mont, Paris; Flavian Amphitheatre, Rome; the beautiful temples of Vesta at Tivoli; Celtic Monuments, &c. The engravings are executed in a very satisfactory manner, a due regard to pictorial effect being observed, without a sacrifice of the accuracy of the architectural details. The letter-press, however, occupies by far too small a portion of the work, which, owing to this defect, has too much the character of a picture-book for a work on ancient and modern architecture. The archæological notices are, however, carefully selected, and are verified, for the most part, by formidable arrays of authorities. We have selected the following extract, to give some idea of this part of the work. It is a description of the Church of the Theotocos (mother of God) at Constantinople, a very important specimen of a style not very well known in this country—the Byzantine:—

"The plan lies east and west, the surface of the soil sloping from the apsis to the façade, so as to require a double flight of steps to reach the principal entrance; two porches, with columns opening towards the west, admit the the light to a spacious vestibule, which is extended round the corner, along

* By these observations we do not intend the slightest censure of the actual arrangement of the windows, which is perfectly unobjectionable, considering the purpose and site of the buildings; we state the simple facts of the case to shew the ridiculous and ignorant absurdity of the criticism. From a rough admeasurement which we have made, we are quite certain that the space for glass occupies upwards of two-thirds of the ground frontage—which is, in fact, no more than a continued series of glazed arcades!

the lateral faces of the church—an arrangement precisely similar to that adopted in the church of St. Mark at Venice. In the interior, this vestibule, or narthex, is decorated with a number of marble columns, which, from the general form of their shafts, and the sculpture of their capitals, seem to have been obtained from some ancient edifice..... A second narthex, or vestibule, surrounded on three sides by the one we have just described, communicates immediately with the aisles of the church, from which it is separated by a thick wall, with three large doorways in it. This second vestibule receives its light from the outer one by two arcades, and communicates with it by a large door on the axis of the edifice. According to the general usage among the Greek Christians, the three aisles of the church are traced in a space exactly square, with four thick columns arranged symmetrically in the centre, to support the roofs and the principal dome—a disposition resembling the Corinthian *atrium* of the ancients. The nave, much wider than the side aisles, has two massive pillars at the end, which divide it from the sanctuary, the first part of which is square, but it terminates towards the east in a semicircular apsis, with three windows separated by small columns attached in piers. On each side of the sanctuary is a door leading into the sacristies, which are at the end of the side aisles.....The façade of the Theotocos is very regular; the floor of the narthex is raised to the level of the church by a basement. The principal entrance is approached by two flights of steps, under which there is a circular brick arch. The arched doorway projects a little, and above it there is another arch divided into two parts, and open, to give light to the vestibule. The sides of the façade are each divided into two zones; the bottom ones are occupied by three arcades, separated by short marble columns, whose capitals and bases, of the same material (see fig. 3, pl. 3), have all the peculiar characteristics of the Byzantine style. The arches are turned with stone and bricks alternately. Tablets of white marble, ornamented with crosses and crowns, are placed between the columns, and support narrow jambs, that reach as high as the capitals, and appear to have supported lattice casements, or perhaps glazed windows, to protect the narthex. Towards the corners of the facade, beyond the open porches, there is, on each side, a semicircular niche of very elongated proportions. The wall is composed of courses of stone and bricks of equal thickness. Between the arches over the columns, the builder has introduced lozenge-shaped bricks, separated by horizontal lines; near the two niches which occupy the extremities of the facade, the bricks are turned in arches concentric with those of the niches.....Above the whole rises the central cupola of the church. This cupola stands on a square basement, and consists of twelve small columns, supporting arches under which are the same number of windows, to light the dome. The spherical portion of the cupola is covered with sheet lead, and in the centre there is a very graceful little ornament. East and west of the cupola we see the roofs of the church, of the interior narthex, and the sanctuary. This last is lighted from above by a window in the vaulted roof.....The apsis stands on a polygonal stylobate of five equal sides. In the upper part there is the same number of arcades, two of which are closed, and three open; these last, which give light to the sanctuary, and are probably intended, as in the church of St. Sophia, to be an emblem of the Trinity, are supported by columns inserted in square piers, and are repeated inside in exactly the same form and size. Their bases, composed of a fillet and a torus, stand upon a stone that forms a common plinth, and is of a pyramidal shape. Their capitals have a kind of ornament composed of numerous bevilled mouldings, in the Byzantine style; a thin ledge, which projects considerably outside, supports the ribs formed by the junction of the polygonal faces of the apsis. In the square pillars against which the columns are backed, there are a number of holes, from which it is evident that these windows have been closed by iron gratings. Above these arcades there is a row of arched niches, which have been exactly copied in the cathedral of St. Mark, at Venice. The back of the vaulted part is ornamented with brick zigzags. The roof of the apsis is a demi-cupola, covered with lead, and hipped, to correspond with the five sides of the vertical portion. On each side of the apsis are the constructions that form the eastern end of the side aisles and vestries; in the centre of each there is a polygonal apsis, not projecting, but merely cut in the thickness of the walls."

It would have been better to have devoted a larger portion of the work to pure, and less to bastard, architecture. What possible architectural value, for instance, can there *now* be in the church of St. Etienne, at Paris, a lamentable instance of the sacrifice of a fine mediæval edifice to the pseudo-classic mania? It were hard to find another Christian church in which the original features have been so completely effaced by hideous imitations of Roman details. The barbarous mutilations of the church of St. Etienne exceed even those of the west front of Westminster Abbey.

Railway Almanac, Directory, Year-Book of Statistics and Digest of Railway Law for 1846. London: Groombridge, 8vo., pp. 182.

We are somewhat late in our notice of this work; still, as almanacs are seldom purchased till the beginning of the year, our recommendation will appear about the right time. In addition to the ordinary information, the *Calendar* contains the dates when the existing railways were opened, the periods when the dividends of each company are payable, &c. The *Railway Law Digest* (written by Mr. Shaw, of Furnival's Inn) is the most perspicuous explanation of a very difficult subject which we have met with. We have read it through carefully, and can pronounce it well worthy of the labour of perusal. The *Directory* contains the names of the directors and officers of all the completed and projected railways; it gives also the lists of the members of the Stock-Exchange of London, and the chief commercial towns. The work is very well printed, and in the arrangement of it great care has evidently been taken to secure facility of reference.

Jabez Hare's Illustrated Engineers' Almanac for 1846. Simpkin and Marshall.

This is a large sheet Almanac. In addition to the calendar, it contains wood engravings of several mechanical inventions, such as the railway excavator, the steam hammer, and screw propellers, of which also brief letter-press descriptions are given. There are also tables of areas of circles, of specific gravities, and the pitch of toothed wheels, &c. Mr. Hare evidently far exceeds Lord Chesterfield in his admiration of proverbs: the Almanac is garnished by a double belt of them.

First Steps to Anatomy. By J. L. Drummond, M.D., Professor of Anatomy and Physiology in the Royal Belfast Institution. London: Van Voorst, 1845. 12mo. pp. 210. 12 lithograph plates.

It would be somewhat travelling out of the record to give a critical notice of this book, even if we laid claim to the editorial omniscience which alone would warrant us in undertaking the task. The work is a digest of lectures to the "first-year students" in the Royal Belfast Institution, and is written in a very pleasing and perspicuous style.

NEW MODELS OF THE PARTHENON

In the British Museum.

The trustees of the British Museum have recently made a most valuable addition to the collection of antiquities of two large models of the Parthenon, made by Mr. Lucas, the sculptor. We are unavoidably compelled to postpone till next month a critical description of these admirable works of art; the following notice of them, however, which is extracted from the Athenæum, will be read with interest.

Mr. Lucas, the sculptor—of whom we have heretofore had occasion to make honourable mention,—has been for some time engaged on a work, which, while it is at once very interesting in itself and honourable to the artist who planned and performed it, comes usefully as a sculpture-lesson in this time of awakened attention and improving prospects for the Art. His object has been to achieve two models of that most perfect of temples, the Parthenon—one of which shall represent it as it appeared in its dilapidated state in the seventeenth century, and its other being, in the sculptor's words, "an attempt to restore it to the fulness of its original beauty and splendour." The scheme is one, especially in its latter portion, which demanded for its successful execution a rare combination of sobriety and enthusiasm. Any merely conjectural re-construction could have satisfied none of the serious demands of the subject; while it would have been an unpardonable assumption, that affected to clothe the fancy of the artist with the sanctions of the highest authority known to art. Luckily, the material and other documents yet exist in sufficient distinctness and abundance to furnish certain evidence, for the conscientious student, as to the general plan and many of the details of this great temple,—and, for the sound and accomplished artist, reasonable inferences as to the rest. Mr. Lucas has carefully consulted the authorities on the subject—both those of fact and speculation—remains and drawings of remains, with the opinions of scholars as to the interpretation of these where their language is obscure: and where, all these failing him, it has been necessary to connect the known by the unknown, he has taken the principles upon which Phidias wrought for his guide, and sought only in what is expressed for what is meant. In this species of questioning he has shown great judgment—generally winning the assent of the critic to the testimony which he makes ths monument bear of itself. A passionate worshipper at that shrine of Art which he has chosen, he is, nevertheless, careful that his worhip shall approve itself as a reasonable service; his undisguised enthusiasm for his task is not imported into it from without,—but born legitimately of the embodied principles before him, and appealing to their qualities of fitness and beauty for its justification. Better discipline, teaching more sure and sublime than this, the sculptor could not propose to himself; and, amid that visible want of earnest thought—that general defect of spirituality—which may have some excuse in the long tendencies of public patronage amongst us, but by which the school is held back from the high destinies awaiting it, we see with more than ordinary pleasure this patient and zealous search into the fountains of the true in-

Art and the immortal in thought. In the progress of his labour, Mr. Lucas has made sure acquaintance with principles which are likely to have an elevating effect on all his future works; and, better still, what he has found, he has commemorated—embodying, for the use of others, the instruction which he sought for himself. We have here, by his means, the text of the Parthenon restored, with fewer conjectural readings (and those, certainly, for the most part, true in their character) than might have been hoped; and, in this view of the matter, we rejoice that the British Museum has purchased the model of the completed building—to stand in the Elgin Gallery, as a key to the matchless remains which are so many of the original parts, and an important element of this restoration.

The faded and, to the uninstructed eye, somewhat enigmatical character of these remains will be more fully understood by the public, and more readily by the artist, in this easy reference to their context; the meaning of the restored whole more readily suggests the meanings of the several parts. The amateur may here catch the full expressions, and the artist the true canon, of Greek sculpture. In this point of view, the reading-made-easy of the Parthenon, with its sculptures, is an invaluable lesson set up in our schools of Arts. While the mere sentiments of the Arts finds here its full satisfaction in perfect beauty of forms, the intelligent student perceives how little the secret of that satisfaction is dependent upon the forms themselves. The principles of art are all summed up in this great and perfect work; yet the work, while involving all the truths which are necessary to perfection, is not the truth itself, but only one perfect and harmonious form of its expression. The careful reader of this magnificent poem, with the full epic before him—who sees how its endless varieties of detail all tend to the production of one great unity of thought, cannot overlook the leading secret which lies at the bottom of all excellence in Art,—and so takes a lesson which has been greatly needed in the modern schools. In every page of this matchless book is enforced the great and eternal principle of *fitness*. No single word has the chisel written on this immortal volume which has not a meaning—and those meanings are *one*, and such as could be directly understood and fully tasted by the national heart to which they are addressed. He who takes these mere forms, and reconstructs them in the heart of London, is but the anatomist of sculpture—and scarcely that; the resurrectionist who produces from its tomb the skeleton of Art—a worthless thing, now the living soul is gone out of it. The secret of their meaning in Greece is that of their no-meaning here; and the sculptor learns, from such works themselves, that he can, for the most part, only adopt the principles of the Greek by rejecting his combinations. The language of Art, when rightly learnt, will be found to be universal—and, therefore, universally intelligible; but he who has wholly different things to express must seek wholly different expressions. The Gods of Greece, who were all at home upon their own Athenian hill, are strangers, every one, in the streets of London and Paris. The true teaching of Greek sculpture forbids to copy it. The letter of Greek Art is a dead thing, amid the changes of the world; but its spirit is immortal amid the ruins—and speaks and breathes from every mutilated page of this great book.

The materials which Mr. Lucas has had to assist him in his work of restoration are the drawings made by Carrey, in 1675, for the Marquis de Noistel, before the Parthenon suffered its last great dilapidations at the hands of the Venetians—the work of Stuart and Revett on Athens, who saw the ruin in 1751, when the Ilissus and the Torso of the group of Cecrops and Agraulaus maintained their place in the western pediment—the comparatively perfect condition of the eastern pediment itself, as drawn by all these artists; from which Mr. Lucas has deduced very ingenious consequences of his own for a restoration of the eastern pediment, in opposition to those of Quatremère de Quincy and Edouard Gerhard, and differing from those of Lusieri and Mr. Cockerell—the scanty hints of Pausanias—the works of Spon and Wheler, the Chevalier Brondsted and Professor Welcker—the advice and arguments of Colonel Leake, Professor Cockerell, Mr. Hawkins, and Mr. Pittakis, the present curator of the Parthenon—and the most invaluable document of all, the actual remains in the Elgin Room of the British Museum. The principal question which presented itself for solution was that of the eastern pediment—of which Pausanias merely says that it related to the creation of Minerva; while the western had reference to the contest of that goddess with Neptune for the territory of Attica. In the latter case, however, the drawings of Carrey, made from the sculptures themselves when the pediment was nearly perfect, are better evidence of the intentions of Phidias than the casual remark of Pausanias,—and demonstrate that his expression will not strictly describe their subject. It is evident that the victory of Minerva in this contest, rather than the actual contest itself, is expressed in the pediment in question: and Mr. Lucas demands merely a similar latitude in the correction of the loose language of Pausanias, as the basis of his restoration of the eastern pediment. A liberal construction of the word γενεσις, he contends, will render it unnecessary to suppose that the very *act* of the creation was intended to be described as the subject,—and will let in any of the incidents attendant upon that great mythological event, the advent of Minerva. But it is to be observed, that it is not in the mere idle spirit of speculative amendment that this correction is proposed, but under the compulsion of the principles on which Phidias wrought, as written in every other part of this great work. "Keeping," says the sculptor, in some printed remarks on the Parthenon, wherein he has very ably stated his own views, "stedfastly in our minds the means by which Phidias has produced so sublime a result in the western pediment, we will endeavour to approach the eastern one in the same spirit. The manner and method in which the myth was represented in the western pediment open to us the understanding of the easter pedimental composition; and if we apply this mode of viewing the subject to this eastern pediment (of which we have noticed the entire destruction of the central portion in the early times), we may feel quite sure that the myth must have been treated in a manner equally satisfactory. . . Hence we have little doubt that the restoration of the eastern pediment, proposed by Brondsted and executed by Quatremère de Quincy, where Vulcan is represented as having cleft open the head of Jupiter, and one of the two goddesses who preside over births is drawing out a little figure of Minerva, while the other is supporting Jupiter as though he were fainting under the agonies of child-birth, can never be an adequate expression of Phidias's own design. It may be said that Homer's description is sufficient warrant for Q. de Quincy's restoration; yet still we feel that the strict letter of the poet is inapplicable to pedimental composition. Homer describes the glorious form of Minerva as rising from the brain of Jupiter, and all Nature struck with awe at the splendour of her form and golden plumage; but in the adaptation of that moment to sculpture, the glorious form of Wisdom sinks into an insignificant puppet. And hence we have no reason to suppose that the existence of such a subject on a patera (itself taken from a picture) was any motive with Phidias for the selection of that which, as well from scantiness of space as from unfitness of material, could not be treated with propriety. Nor did the incongruity of the French conception of the subject escape the eye of Flaxman; who, in his lectures, observes, that the composition was no doubt filled, not by a representation of the *actual* birth of Minerva, but rather, as would be far more fitting in a temple peculiarly dedicated to her honour, by the introduction of the goddess to the august assemblage of the gods on Olympus—a subject in the highest degree imposing, and admitting of a sculptural treatment of the greatest majesty. And this view of the subject is also taken by Mr. Cockerell; who has demonstrated that the fragment on the floor of the Elgin Room was the base of the statue of Minerva in the eastern pediment—a judgment in which M. Welcker entirely coincides with him."

This view of the matter Mr. Lucas has himself adopted; and out of such fragments as remain, with what we know positively from Carrey of their place,—supplying the blanks from inferences and reasonings whose artistic soundness are deserving of great commendation—he has reconstructed the whole into a splendid composition; which, if not the true one, is certainly in a Greek spirit,—and where the parts filled up offer no discord with what remains of the ancient text.

One valuable lesson Mr. Lucas has drawn from the consideration of these pediments—which we must not omit. The sculptures that adorn them—or rather of which they are *composed*—so far from being arbitrarily confined within the pedimental lines, as barriers which the genius of the sculptor must not venture to infringe—a practice that gives to the figures on pediments in general the character of mere after-thoughts for the embellishment of the building, are here, by latitude in the size and projection of the figures, not only made to seem an original and expressive part of the great intention, but the effect of a bold and beautiful variety to the eye is thus obtained by the same simple act of mastery which gives this addition to the unity of the thought. "I have the highest authority," says Mr. Lucas, "for stating that not one modern pediment has been constructed in accordance with the rules which this pediment of Phidias prescribes to us; and as to the sufficiency of this example as a rule, we have the united testimony of all authorities on the subject, that this pedimental construction contained the result of seven hundred years' experience,—and that used by the discretion of Phidias."

We cannot follow Mr. Lucas at length, through all the parts of his restoration. The frieze is recomposed in its entirety, on the outer wall of the cellar—the existing parts being made to suggest the lost. The columns are restored to the interior in a double row, Mr. Lucas having finally decided, as a choice amongst difficulties (for this is the point on which the evidence is most contradictory and the decision the least satisfactory), on Corinthian placed above Ionic. The Goddess is replaced in the glorious shrine which was built up for the sole purpose of containing her idea, in her garment of ivory and gold, and with her rich sculptural accessories, as described by Pausanias and seen on ancient coins and gems. The missing metopes are restored, the subjects supplied being in every case sought from coins and vases, and for this purpose on a principle of connexion suggested by a judicious consideration of those which exist, in fact or in drawing. Even the shields, of whose former presence on the exterior of the temple the traces remain, are here replaced,—though nothing can be known of the devices which they contained—that no feature may be wanting to convey the general effect of the whole. The adoption of these devices is, therefore, confessedly, quite conjectural—but not quite arbitrary, notwithstanding. They have been selected from vases, coins, and the work *Monumens Inédits*, published by the Institute of Rome, which contains a large number of the shields of Minerva. Nothing has been left out that could be authenticated,—or restored upon presumptive testimony furnished by the temple itself. Only in the case of the Polychromatic adjuncts, of which evidence is supposed to exist, has Mr. Lucas (with that same sobriety of judgment which has ruled his enthusiasm throughout this work,—and which is but the deep passion for his theme, chastened by the reverence with which he approaches it,) refrained—because, as he says, it cannot be demonstrated that they were as early as the period of Phidias—and because, "as it appeared to me to impair the chasteness of the temple, I am not called on to run any risk of making a gaud of this restoration of the Parthenon, or to depart from that severe simplicity which is the characteristic of all the art of Phidias."

In one other point of view, we rejoice at the adoption of this model by the Museum;—we think it calculated to help the sculptor to his place in England, and inspire him with the determination to take it. Nowhere does the genius of sculpture seem so *great* as in the Parthenon. There is no other work in which its marvels have been turned to such epic account; and though we hesitate to go all the way with Mr. Lucas, who supposes the temple itself to have been designed as a mere pedestal for the foot of the Genius—a frame for the sculptor to work on—yet certain it is that if, in this unrivalled union of the Arts, there be one spirit that presides over the others with authority, it is sculpture. But the true lesson taught by this temple is the *oneness* and entirety of Art—the joint and harmonious contribution of its several forms to the production of a great whole—the embodiment of a perfect thought—in proportions varying with the demands of the particular subject. That splitting into separate members of the great family of Art, which has left something unsatisfactory in its best achievements in England, is authoritatively rebuked in presence of this majestic result produced by their combination. Most of all, in this presence, is that ignorant error detected which has assigned to sculpture, amongst ourselves, a lower place than the highest in Art. By academicians who have given it the coal-hole, it is well it should be seen here with the glory on its brow; and the sculptor who is content to work as the mere decorator to the architect—called in to ornament, as with mere artistic surplusage, *his* finished and self-reliant design—may learn how, as a master, sculpture wrought in Greece. The architect and the sculptor, where they are not *one*, must *plan* together. Sculpture must be a portion of the *soul* of great architectural works, not their garment, ere the one or the other can achieve, with us, the marvels which have testified so long in vain of the old Greek spirituality. Till sculpture shall be architectoric, its great destinies cannot be accomplished amongst us. The sculptor who comes fresh from the study of the Parthenon will feel that he is a minister in the very highest place of Art; and the public, instructed by the same great revelation, will, if the former be true to himself, help to get him his own again in the new era of Art which is dawning over England.

The other model is as yet unfinished—and unpurchased. We trust the Museum will add it to the other; and shall have some words to say of it when complete. The models are, severally, twelve feet in length by nearly six in width.

REGISTER OF NEW PATENTS.

If additional information be required respecting any patent, it may be obtained at the office of this Journal.

John Cleveland Palmer, of East Haddam, for "*Improvements in machinery for making augurs*," &c.—Granted March 17; Enrolled September 17, 1845.

The object of the mechanism is for manufacturing the "single twist" augur, usually made of a rod of metal, twisted round a cylinder into a helical curve. The augur which the inventor's machinery is intended to manufacture is to be formed of a long rod of metal (either of a triangular or other proper shape, in its cross section). The iron should be rolled in square bars or rods, of the size required, and be cut into pieces of sufficient length, to make the tool or instrument intended. A small piece of steel of proper size for the cutting lip, (and the conical screw, if it is to be added,) is next welded upon one end of each one of the said pieces, and the end is next turned or bent down, at right angles to the remainder, upon an anvil, so as to fit into the cavityof the lower section of the dies, for forming the lip, or the lip and screw cone. About three-fourths of the length of the rod from the steel knob, is next heated to the necessary temperature, to be rolled down by the next portion of the machinery. The next portion of the process of manufacturing the augur consists in forming the cutting lip, or the cutting lip and conical screw blank upon its end. For this purpose, dies are employed to form the lip without the conic blank. The head of steel being heated, is placed between the dies, and the upper of them caused to descend, with the force necessary to swedge or compress the metal into the shape required. The knob thus formed, is next bent down to the angle required, to be applied to the machine, by which the rod is twisted in the helical curve. The next operation is, to give the requisite degree of uniformity to the size and spread of the twist, which is accomplished by hammering in the machine, consisting of a trip hammer, arranged and operated over and upon a die anvil or bed-piece, grooved out, so as to receive the twisted helix when laid thereon. By turning the augur around, first in one direction and next in the opposite, successively, so as to cause it to pass back and forth between the hammer and bed-piece or anvil, the twist is spread out in a uniform manner. The lower part of the hammer should be curved to correspond with the circumference of the exterior of the twist of the augur. The twisted portion of the augur is again heated, and rolled between heavy iron plates, for the purpose of straightening the twist, during which operation, care should be taken that the cutting lip of the augur does not come in contact with the plates. The augur is next to be finished by filing, and upon grinding and polishing wheels, or by other proper means, in such manner as may be desirable; and when a screw is to be connected with the cutting lip, it may be cut upon the blank by any contrivance adapted to the purpose.

William Robinson Mulley and George Mason, jun., of Ipswich, contractors, for "*Improvements in collecting and raising stone or substances from below water.*"—Granted April 2; Enrolled October 2, 1845.

This invention is chiefly intended for raising cement stone from below water off West Rock, near Harwich, or other places similarly circumstanced, which at present is performed by sailing vessels, the dredging bags being raised by manual labour. The object of this invention is to apply the power of steam in a suitable vessel to drag dredging bags, and to raise them and cement stone, or other matters collected thereby, into the vessel.

Thomas Moss, Esq., of Gainsford-street, Barnsbury-road, for "*Improvements in printing and preparing bankers' notes, cheques, and other papers, for the better prevention of fraud.*" Granted, April 22; enrolled October 22 1845.

This invention consists in impressing patterns on the surface of paper used as bankers' notes, and other documents, on which designs or letters have been or are intended to be printed, that the paper so treated will be smooth on one side, whilst the other side will have a pattern indented thereon, so as to produce the appearance of a reticulated surface. The apparatus consists of a pair of steel rollers, one plain and the other engraved with the reverse of the pattern to be formed on the paper; and pressed heavily down upon the plain roller. The paper then becomes indented with the pattern or design; and if the engraved roller be inked, as in surface printing, the indented pattern will at the same time be coloured.

Joseph Hill, of Ipswich, Suffolk, wireworker, for "*Improvements in manufacturing wire fabrics for blinds and other uses.*" Granted May 6; enrolled November 6, 1845.

The first improvement consists in giving a corrugated form to woven wire fabrics, to obtain greater stiffness, and render them more useful for making blinds, and other purposes. The corrugated form is given by passing the wire between two grooved iron rollers; the side of the corrugations will generally vary from ½ to ⅝ inch. The second improvement consists in submitting woven wire fabrics to a process of embossing, so as to produce ornamental patterns thereon. A die is formed of brass or other metal, with the pattern upon it in relief; over this is placed a sheet of "vulcanized India-rubber," ¼ inch thick; and then, by means of a powerful screw-press, the wire fabric is pressed down upon the die, and the required embossing is produced. The employment of the India-rubber renders a counter die or matrix unnecessary; and the same sheet of India-rubber may, as it is plain, be used with different dies.

Frederick Ransome, of Ipswich, engineer, for "*Improvements in combining small coal and other matters, and in preserving wood.*" Granted May 10; enrolled November 10, 1845.

The invention consists in combining small coal with a solution of silica or siliceous cement, made by dissolving 100lb. of crystallized carbonate of soda in as much water as will make a solution of 1,150 sp. gr. at a temperature of 60°, and the soda is rendered caustic by the addition of lime; or, instead of carbonate of soda, 50lb. of carbonate of potash are dissolved in the requisite quantity of water, and rendered caustic by means of lime. This caustic alkaline solution is introduced, along with about 100lb. of finely-broken flints or other siliceous substances, into an iron boiler or digester, and the mixture is kept for ten or twelve hours at a temperature of about 300° Fahr.. being at the same time frequently stirred. When sufficiently incorporated, the mixture is passed through a sieve, to remove any undissolved stone therefrom, and it is then evaporated until its specific gravity is increased to 1,500, at a temperature of 60°. The cement or solution is now fit for use; or, if too thin, it may be brought to the required consistence by evaporation, or by the addition of sand, or of calcined flints in a finely-powdered state; if too thick, it can be reduced with water. The mode of combining small coal into blocks is, by mixing any suitable quantity of coal-dust or small coal with from $\frac{1}{20}$th to $\frac{1}{10}$th of its weight of the siliceous cement, which is put into moulds, and subjected to pressure; after which it is allowed to dry in the air, and then placed in an oven or hot room. For pressing timber, the wood is saturated or impregnated with a solution of silica, in such a manner as to cement the fibrous part of the wood with the silica, so as to form a solid and durable mass. The wood is placed in an air-tight vessel, from which as much air is abstracted as is practicable, by an air-pump or other convenient means; a sufficient quantity of siliceous cement to cover the wood is then admitted, and, in order to cause the cement to penetrate further into the pores of the wood than would be effected naturally, artificial pressure is applied, by means of a pump; when removed, the wood is immersed in some acidulated or saline solution, which will render the silica insoluble.

RAILWAYS OF BELGIUM.

By John Anderson, Esq., F.R.S.S.A.

(Abridged from a Paper read before the Royal Scottish Society of Arts.)

The accumulated length of the Belgian railroads amounts to 348 miles. They consist partly of a double and partly of a single way of 4 ft. 8½ in. betwixt the rails of the track, and a distance of 6 ft. 6½ in betwixt the railroads.—The following table gives the length and cost of the different lines, the stations thereon, and the total cost of the whole establishment:

Lines.	Length of Lines.	Cost of Lines.	Cost of Stations per Line.	Total Cost.	Cost per Mile.	Remarks, with reference to the Estimates.
		£	£	£	£	
Brussels to Antwerp (including branch from the station of Borgerhout to the Scheldt)	29·028	303,378·12	228,061·48	531,439·60	18,308	Double way.
Malines to Ostend	76·025	633,350·24	84,847·76	718,198·00	9,447	Double way to Ghent.
Malines to Ans (including branch to the Canal at Louvain)	55·100	743,458·92	42,658·08	786,117·00	14,267	Double way.
Ans to the Prussian frontiers (including branch to the interior of Liege)	29·500	1,240,303·47	132,400·00	1,372,703·47	46,532	Double way to Verviers.
Landen to St. Trond	6·350	48,336·72	6,823·08	55,159·80	8,686	Single way.
Ghent to Courtray	27·130	170,923·88	17,900·00	188,823·88	6,960	Single way.
Courtray to the French frontiers	9·359	131,000·00	8,920·00	139,920·00	14,950	Double way.
Mouscron to Tournay	11·890	111,560·00	10,520·00	122,080·00	10,267	Single way.
Brussels to Quiévrain	50·127	648,875·94	99,011·96	747,887·90	14,920	Part double way.
Braine-le-Comte to Namur	50·699	563,239·39	75,800·00	639,039·39	12,604	Single way; but embankments for a double way.
Junction of Stations at Brussels	2·914	29,546·04	..	29,546·04	10,139	
	348·122	4,623,972·72	706,942·36	5,330,915·08	15,313	
			Material of Transport ..	823,921·12		
			Total General Expense..	6,154,836·20		

Up to the end of 1842, 271·587 miles had been constructed; and in the autumn of last year the first way, and probably more, of the remaining lines had been completed. On taking an average of the cost of the British railways, it will be found that those in England cost fully double, and those of Scotland and Ireland fully a third, more than those of Belgium. Even the French railways, on the following average, are constructed at nearly double the expense of the Belgian lines:—

		Per Mile.
The line from	Lyon to St. Etienne cost, in round numbers	£19,000
..	Paris to Versailles - -	26,000
..	Paris to St. Germain - -	30,000

In the Belgian lines, both parallel and *fish-bellied* rails are used. There is nothing particular in their mode of laying them down. The ballasting consists of sand and gravel, and, from various circumstances, formed a considerable item in the expenditure:—

			s.	d.	
Between	Waremme and Ans,	it cost	8	5¼	per cubic yard.
..	Louvain and Tirlemont	..	6	9¼	..
..	Tirlemont and Waremme	..	5	6¼	..
..	Denyze and Courtray	..	5	1	..

Weight and cost of rails.

The rails were furnished in 1834-35-36-37, and at different times in the following years, in lengths of 15 feet, 16·4 feet, and 14·8 feet. Those of 15 feet were furnished of different weights, weighing 40·1 lb., 39·7 lb., 35·3 lb., 43·7 lb., 54 5 lb. to the lineal yard; those of 17·4 feet weighing 50·4 lb., and those of 14·8 feet weighing 50·4 and 48·8 lb. to the lineal yard. The whole rails are of the manufacture of the country, with the exception of about 200 tons, which were brought from England in 1834, to serve as models. Their price during the first four or five years varied very much; no doubt from the competition to which the extensive demand give rise. The ton of rails, which could be furnished at Malines, for instance, in 1834, for 14*l.* 12*s.* 6*d.*, rose to 15*l.* 4*s.* 6*d.* and 18*l.* 1*s.* 6*d.*, and descended again to 17*l.* 1*s.*, 13*l.* 16*s.*, and came even so low, in 1840, as 10*l.* 6*d.*, but rose again the same year to 11*l.* 3*s.* 6*d.* Those, however, produced in 1840 were much inferior to the rails first manufactured in the country. Until 1838, chairs, keys, and spikes, were furnished with the rails; but since that time the contractors have bargained to supply them separately. The ton of chairs, in 1834, was supplied at 10*l.* 7*s.*, but rose the year following to 10*l.* 15*s.*, and, in 1836, to 12*l.* 16*s.*, 13*l.* 4*s.*, and 14*l.* 4*s.*; and. in general. fluctuated with the price of rails. Keys and spikes, in 1834, cost 22*l*, 7*s.* per ton, and rose the following year to 24*l.* 3*s.* 6*d.*, 21*l.* 11*s.* 6*d.* In 1826-7, they varied from 28*l.* 9*s.* to 30*l.* 1*s.*; and, in 1838, came down, after many fluctuations, to 24*l.* 7*s.* 6*d.*, and 23*l.* 19. 7*d.* In short, the cost, in general, likewise varied in proportion with the rails and chairs.

Principal Works.

From inexperience or oversight, the section from Brussels to Malines was made upon so low a level that it was often overflown by the Senne, which greatly damaged, and sometimes even perfectly obstructed, the railway. The rails, moreover, were too weak, and the sleepers made from white and pine wood. From these circumstances, it became necessary to raise the railway at least upwards of a foot and a half, and protect the banks, and form viaducts through which the waters could flow. The old rails were nearly all thrown aside, and others of greater strength laid down, and the sleepers subjected to M. Boucherie's process for the preservation of wood. Between Brussels and Quiévrain, the ground on several sections consists of peat, and bogs; on this account it has been necessary to build a greater part of the bridges on piles, and raise the railway in some places 13 feet; the tunnel of Braine-le-Comte is 16·4 feet of span, and 25·7 chains in length.

From a short distance from Malines the railway begins to ascend to Ans. The works upon the line, though numerous, are light. The greatest undertaking is the tunnel of Cumptich, which has been lately constructed for the double way. It is entirely built of brick, and is 20·6 feet in height, and 45·73 chains in length. The heavy works, however, of the Belgian railroads only begin at Ans, where the railway descends into the valley of the Meuse.

The Liege Incline.

Ans stands upon the west bank of the valley of the Meuse, about 581 feet above the level of the sea; and Liege is situated in the bottom of the valley, about 358 feet below Ans. The distance betwixt Ans and the Meuse at Liege is 4 miles 9 chains, thus making on the length of the line the general gradient about 1 in 60. To descend this valley was a matter of no little difficulty, and it was only after many years' study, in which time numerous projects were examined, that the administration saw the necessity of descending it by inclined planes. The plan adopted by them consists of two inclined planes of equal lengths, with a platform or level space of ground, on which the engines are placed, situated at the bottom of the first and the summit of the second incline. The platform is about 16¾ chains in extent, and the inclines 1 mile 1¾ chains each of length, of a rise of 1 in 36, both of which are constructed with a double way, the one being employed for ascending, and the other for descending. Referring to the section, the railway proceeding from Ans describes a curve of 1 mile 37 chains of radius, and descends the first incline. Having crossed the platform, it descends the second incline, and arrives at the principal station of Liege. The trains descend the inclined planes by gravitation, their velocity being regulated by drags attached to the carriages and wagons. Two fixed engines, of 160 horse power each, are placed on the platform for raising the trains, which is accomplished by means of an *endless rope.* Both engines being situated close together, are supplied with steam from the same boilers. The system of signals, we are told, they employ, is somewhat novel:—A tube of fully one inch diameter is laid along the railway. Each of its extremities communicates with the interior of a bell, the mouth of which is immersed in water. Into the top of the bell a whistle is fixed, which, as in the case of the locomotive whistle, acts by the vibration of the metal. When it is required to communicate the time of departure of any of the trains from either station, the signal-man has only to shut off communication with the whistle, and immerse the bell further amongst the water. The air in the one bell will thus be forced, by pressure, through the tube into the other bell at the further end of the tube, and will escape by passing through, and at the same time acting upon, the whistle.

Nothing strikes the traveller so much with astonishment, when he descends the valley of the Meuse, and enters that of Verviers, as the contrast the face of the country presents to that which he a few minutes ago left. The scenery, indeed, as soon as he leaves Ans, is entirely changed. Instead of the flat and monotonous country through which he has just passed, he is ushered into a finely varied district of hills and valleys. The number and extent of the different works of art he observes, tell him also of the nature of the country through which he is passing, and the difficulties which the engineer encountered in the execution of this part of the national system of railroads.

It may be remarked, that, in the execution of the different works of art throughout the different lines, the workmanship is inferior to that of similar undertakings in this country; and that also in their construction, due attention has always been paid to the fortifications of the towns by which the railway passes.

Curves and Gradients.

The curves and gradients, as necessarily follows, from the extent of the different lines, vary very much, and present many of the results which arise from their existence on railways in general. The radii of the principal curves are as follows:—3·73 chains; 9·44 chains, (both on the branch of Louvain to the canal); 9·94 chains; 12·43 chains; 17·4 chains; 18·14 chains; 19·88 chains; 24·25 chains; 29·83 chains; 34·8 chains; 37·28 chains; 39·77 chains; 43·74 chains; 44·74 chains; 49·71 chains; 54·68 chains; 59·65 chains; 62·14 chains; 67·1 chains; 69·59 chains; 72·58 chains; 74·56 chains; 79·54 chains; and 1 mile 4·5 chains.

The most important gradients are:—

That towards Waremme, at the station of Landen, of 1 in 241, of 2 miles 39 chains in length.—That towards Tirlemont, at the station of Louvain, of 1 in 250, of 3 miles 58 chains in length.—That between Tubise and Braine-le-Comte, of 1 in 200, of 5 miles 47 chains in length.—That on the branch from Louvain to the canal, of 1 in 71, of 32 chains in length.—That betwixt Jurbise and Braine-le-Comte, of 1 in 250, of 4 miles 3 chains in length.—That betwixt Mons and Jurbise, of 1 in 250, or 6 miles 42 chains in length.

Stations.

The stations throughout the different lines are numerous, and, in general, neat and commodious buildings. Antwerp, Brussels, Malines, and Ghent, are reckoned of the first order, and contains the warehouses and arsenal for provision and material. Ample accommodation is set apart in them for passengers; one large room being always devoted to first and second, and another to third class, passengers. The next stations in importance to these are, Bruges, Termonde, Louvrin, and Tirlemont; and then the minor stations upon the different subdivisions of the line. Malines was, from the very first, chosen as the central station through which the greatest number of passengers was expected to flow; and it was also fixed upon as the workshop for the repairs of the heavy machinery, and of the railways in general throughout the country, the workshops at any of the other stations being only of a secondary importance. But, notwithstanding its many advantages, Brussels has become the principle station, and draws one-fourth of the receipts of the whole of the different lines. In consequence of this unexpected result it became necessary to build a more extensive station at the north of Brussels. The stations, with the exception of Ostend, Bruges, and Ghent, are placed without the towns, for the purpose of evading the local taxes, which can only be accomplished by placing them beyond the boundaries of the excise. Tickets for the trains are issued from the windows of the different offices; and, to avoid confusion during a crowd, stalls are erected, through which the passengers pass one by one, receive their checks, and return by a passage parallel to the one by which they entered. If the traveller has luggage exceeding 44 lb. weight, he has to proceed to the luggage depôt, where it is weighed, and he is charged a trifling sum per lb. Upon paying this sum he receives a ticket with a number marked upon it, corresponding to one which is put upon his luggage. From this time he sees no more of his property until he arrives at his destination, where it is brought from the luggage-wagon, and the number marked upon it called out by one of the officers in attendance, who returns it to its owner on presenting the ticket which he had received.

Locomotive Engines.

The locomotive engines, at the 1st of January 1843, were 129 in number, 42 of which were made in England, and the remainder in Belgium. Of these, 95 are in good working order, and 34 undergoing repairs. In addition to these, however, 10 were in course of being constructed, which will make, in all, 139. The following table gives the makers' names, and the number each has made, with the diameter of the cylinders and driving wheels:—

Makers' Names.	Diameter of Cylinder.	Diameter of Driving Wheels.	Number of each Size.	Number by each Maker.
England.				
Stephenson	11 inches	5 feet	8	30
	12 ..	5 ..	6

Fuel.

The coke required for the consumption of the locomotives is manufactured at Monplaisir, Malines, Antwerp, Ghent, Ostend, Ans, and Hal; and costs at these places respectively, 1*l.* 4s. 2½d., 1*l.* 3s. 11½d., 1*l.* 7s. 7¾d., 1*l.* 3s. 8½d., 1*l.* 5s. 2½d., 17s. 0¾d., and 1*l.* 1s. 5d. per ton. The quantity consumed in 1841, in running over 927,080 miles, was 29,303 tons, or 70·80 lb. per mile. This is including, however, the quantity required for the *reserve* and *lighting*, which amounted to 4399 tons, and which, if deducted, will make the consumption 60·17 lb. per mile. In 1842, the distance run over was 987,432 miles, and the total quantity of coke consumed was 28,317 tons, or 64·24 lb. per mile. The quantity required for the *reserve* and *lighting* was 5635 tons, and which, if deducted, will make the consumption 51·46 lb. per mile.

Carriages.

The carriages consist of three classes, as they do in this country, but are much more commodious, and, in some cases, vastly superior in comfort. For example, second class carriages possess not only windows, but the seats are cushioned, and almost as comfortable as those of the first class, though, perhaps, a little less elegant. Even third class carriages have covered seats, and very often roofs supported upon perpendicular iron rods fixed at the corners of the carriages. The seats are placed transversely, and without any proper mode of entrance, which is a great inconvenience to passengers; and the doors are, in every case, unlocked, but are held close by a catch, which can be opened and shut from either side of the carriage.

The rate of travelling, generally, is about 20 miles per hour; but on some lines, on account of the gradients, it varies from 19 to 25 miles per hour.

Power of the Engines on Inclines.

The greatest gradient, with the exception of that betwixt Ans and Liege, is 1 in 71 on the branch from Louvain to the canal. A locomotive, of a 12½ inch cylinder, and driving wheels of 5½ feet diameter, can ascend this slope with a train of three loaded and three empty wagons, of a total weight of about 44¼ tons; but a locomotive of a 14 inch cylinder, with coupled driving wheels of 4½ feet, can ascend it with six loaded and three empty wagons, of a total weight of about 69 tons, the rate of travelling in both of these cases being three miles per hour. From a curve in several parts of this line, however, of 3 73 chains of radius, it is thought to be more convenient to work it with horses. A strong horse upon this incline can draw a wagon of about six tons weight, at the rate of 2¼ miles per hour.

On the inclination betwixt Tubise and Braine-le-Comte of 1 in 200, two trains, of 16 and 17 carriages each, with a total weight of 88½ to 98½ tons, and a locomotive of a 12½ inch cylinder, and driving wheels of 5½ feet diameter, were unable to proceed in unfavourable weather. At another time, equally unfavourable, an engine of the same size took up two trains of 13 and 11 carriages each, with a total weight of about 88½ and 78¾ tons, with great difficulty. On the inclination betwixt Jurbise and Soignies of 1 in 250, two trains, of 12 and 13 carriages each, with from 78¾ to 88½ tons, and an engine of the same dimensions could not ascend. A third, however, with 13 carriages of 88½ tons, succeeded in mounting the slope.

From these observations it was concluded, that the greatest weight with which an engine of a 12½ inch cylinder, and driving wheels of 5½ feet diameter, can ascend either of these inclinations, is from 88½ to 98½ tons in ordinary weather, but otherwise with only from 73¾ to 78¾ tons. With the same of cylinder, however, either of these inclines can be ascended with 69 tons, at a velocity from about 12¾ to 15½ miles per hour; or, with an engine of a cylinder of 14 inches diameter, about 108½ tons can be taken up, at the rate of about 12¾ miles per hour.

On the inclination betwixt Lonvain and Vertryck of 1 in 250, the following trains ascended with difficulty in unfavourable weather :—

Locomotive.	Inch cylinder.		Feet.	Carriages.	Tons total weight.
1	14	with coupled driving-wheels of	4½	20	137½
1	14	..	..	23	147½
1	12	not coupled ..	5	16	98¼
1	14	coupled ..	4½	18	137½
1	14	.. ..	..	24	147½
1	14	.. ..	..	39	270½
2	14	.. ..	..	18	118
1	14	.. ..	..	22	137½
1	14	.. ..	..	22	137½
1	14	.. ..	..		

From these experiments it was concluded, that a locomotive of a 14 inch cylinder, and coupled driving wheels of 4½ feet diameter, could ascend this incline with difficulty in ordinary weather, with from 137½ to 147½ tons, but during times of snow with only 69 tons; and a locomotive of a 12 inch cylinder, with driving-wheels of 5 feet diameter, not coupled, could ascend, in ordinary weather, with from 78¾ to 98¼ tons, and in times of snow with from 44½ to 49 tons. They ascend this slope regularly, however, with trains of 73¾ and 108½ tons, including the weight of the locomotives of 12 and 14 inch cylinders, about the rate of 15½, and from 12¾ to 15½ miles per hour.

The whole railway buisness is under the management of a director, who is under the control of the Minister of Public Works. It is divided into four branches—namely, the general management of the whole system; the management of the lines; the locomotive department; the traffic of the railway; and the management of the stations. The first of these, generally speaking, includes the other three, one of which consists in the management of the lines, and the finishing and constructing of new works of art; another in the traction of the trains, the manufacture of coke, and the management of the arsensal at Malines, including the workshops for repairing the locomotives and carriages; and the third, in the management of the stations and the passenger and merchandise traffic. Over each of these four departments a functionary, entitled Engineer-in-Chief, or Inspector of Administration, is placed, who furnishes an account of the proceedings of his department to the Minister, and makes such proposals to him as he thinks necessary or advantageous. The propositions he submits are sent for examination to the Council or permanent Commission of Ways and Bridges. Besides the surveillance exercised by the director, and the agents under his orders, the Minister causes all the works to examined by the Inspector-General, and by the Divisionary Inspector of Ways and Bridges; and with the documents received from the different departments, renders an elaborate report of the whole business annually to the Chamber of Deputies.

ICEBERGS OF THE ANTARCTIC SEAS.

"Icebergs were seen in all stages of formation, from five to two hundred feet above the surface, and each exposed its stratification in horizontal layers, from six inches to four feet in thickness. When the icebergs are fully formed, they have a tabular and stratified appearance, and are perfectly wall-sided, varying from one hundred and eighty to two hundred and ten feet in height. These were frequently found by us in their original situation, attached to the land, and having the horizontal stratification distinctly visible.

"In some places we sailed for more than fifty miles together along a straight and perpendicular wall, from one hundred and fifty to two hundred feet in height, with the land behind it. The icebergs found along the coast afloat were from a quarter of a mile to five miles in length; their separation from the land may be effected by severe frost rending them asunder, after which the violent and frequent storms may be considered a sufficient cause to overcome the attraction which holds them to the parent mass. In their next stage they exhibit the process of decay, being found fifty or sixty miles from the land, and for the most part with their surfaces inclined at a considerable angle to the horizon. This is caused by a change in the position of the centre of gravity, arising from the abrading action of the waves.

"By our observations on the temperature of the sea, it is evident that these ice islands can be little changed by the melting process before they reach the latitude of 60°. The temperature of the sea (as observed by the vessels going to and returning from the south) showed but little change above this latitude, and no doubt it was at its maximum, as it was then the height of the summer season. During their drift to the northward, on reaching lower latitudes, and as their distance from the land increases, they are found in all stages of decay, some forming obelisks, others towers and gothic arches, and all more or less perforated; some exhibit lofty columns, with a natural bridge resting on them, of a lightness and beauty inconceivable in any other material."—*Narrative of the United States Exploring Expedition.*

The Rattler screw-propelled steam-sloop, Commander Smith, is having an altered screw fitted; the screw having proved a great drawback to her speed when under sail, a hatchway is being cut from the upper deck down into the dead-wood, by which means the screw may be lifted up so as not to impede her progress when under canvass, and may be altogether removed or replaced, if damaged, without going into dock. An extra number of millwrights were put upon her yesterday to get her out of hand as quickly as possible.

EAST INDIA COMPANY'S NAVY.

The comparative strength of the East India Company's Navy at several periods, from 1829 to the present day, will be seen from the Table here subjoined.

Planet	335	60	2	Iron Vessels.
Satellite	335	60	2	Iron Vessels.
Nitocris	153	40	2	Iron Vessels.

† It is understood that this vessel has been condemned, and the 'Queen,' from Bengal, put on as a packet in her room.

EVAPORATIVE POWER OF TURF, COMPARED WITH THAT OF COAL.*

The following results, as to the comparative effective power of turf and coal, are derived from the working of the Lansdowne, one of the steamers of the Inland Navigation Company which ply upon the Shannon with goods and passengers. They have been kindly placed in my hands for my present object, by Mr. C. W. Williams. Before the use of turf was introduced there was burned in a week, which comprises forty-nine hours of work, twenty-four tons of coal, which, costing on an average at Killaloe 15s. per ton, amount to 18l., or 7s. 5d. per hour. To do the same work at present, burning nothing but turf, there are consumed per week 315 boxes of turf, which, at 7d. per box, costs 9l. 12s. 7d., or 3s. 11d. per hour of work—but a shade more than half the cost with coal. The engines of the Lansdowne are condensing, of thirty-eight inches and a half diameter, and three feet and a half stroke. The usual velocity is twenty-five strokes per minute.

The box of turf contains twenty cubic feet; not very closely packed. It weighs about 3½ cwt.; so that the ton weight of turf costs about 3s. 6d. The weight of 315 boxes is hence fifty-five tons and a quarter, and the practical value of the turf is to that of the coal as 24 to 55¼, or as 43 to 100. It is interesting to consider the influence which the substitution of turf for coal in the Shannon steamers has on the population residing near its banks. In the year 1839 there was no turf burned, and the coals consumed on board the company's boats amounted to 3,108 tons. In 1843 there were burned but 724 tons of coal, although the amount of trade was much increased. The quantity of turf consumed was upwards of 7,000 tons, which, at 3s. 6d. per ton, gives an expenditure of more than 1,200l. distributed in wages of labour, by which almost the entire cost of the turf is made up. The equivalent quantity of coals would have cost above 1,800l., so that at the same time the Company saved 600l. a-year.

Those remarkable facts are well exhibited in a letter written by Mr. Williams to the Board of Admiralty, which is subjoined, as it illustrates some additional circumstances. Mr. Williams's estimate of the saving is greater than mine, for, in the preceding analysis of the results, I have taken coal at a lower price than is assumed in his letter. The reason is, that it has fallen since those results were obtained, and I have calculated from what the price is, whereas he calculated from what it was at the time quoted:—

"6, Princes Street, Cavendish Square, July 21st, 1843.

"Sir,—I have had the honour to receive your letter of the 12th instant, addressed to the Secretary of the City of Dublin Steam Packet Company, inquiring, for the information of the Lords Commissioners of the Admiralty, the proportionate duration of turf to coal in the Company's boats which ply up the Shannon from Limerick, to which I beg to give the following reply, derived from experience of the boats on that river.

"The Lansdowne, a steamer with two engines 38½ inch cylinders, at 3 ft. 6 in. stroke, consumed upon an average 120 tons of coal per month, running daily (except Sunday) a distance of forty-six miles, at 18s. per ton, covering expenses	£108	0	0
"The same duty is done with 1419 boxes of turf of twenty cubic feet, about 250 ton weight, at 7d. per box	41	7	9
Difference in the cost of the fuel per month	£66	12	3

"2. The difference in weight is, therefore, as two of turf to one of coal, and on the Shannon the difference in price is less than one-half that of coal.

"3. Its proportionate duration may be estimated by the quantity required, compared with coal to perform the same duty, that being double its weight; its duration in the furnace is half that of coal.

"4. From recent experiments with turf in the experimental boiler in the Company's yard at Liverpool, it is found that turf can only be profitably used when it is of the quality that is obtained in good seasons. If bad or damp, its evaporative power is reduced one-third and more. To improve the evaporative power of this fuel, however, results have shown that an addition of 40 per cent. of a preparation of turf by an improved method, which I have been engaged upon for some years, will render it cheaper than coal used with bad turf, or than coal burned alone; and that the same per centage of this prepared fuel added to good turf, greatly increases its evaporative power, with a very trifling addition to the cost.

"From these facts it is evident that turf may be used advantageously in localities where it abounds, and where there is an absence of coal. Care, however, must be taken that the furnace bars are lowered, not only to admit a greater bulk of fuel, but also to prevent too great a volume of air passing in the ash-pit, and then through the bars. I may add also, that in burning turf it is highly essential that air be admitted in the air chamber behind the bridge, in consequence of the rapidity with which the gases from this kind of fuel fly off. If it be excluded there upon the common furnace principle the weight and bulk of fuel will be increased, the evaporative power reduced, and the cost proportionably greater.

"It will give me much pleasure to furnish you with any further information in my power.

"I have the bonour to be, Sir, your obedient humble servant,

"To Sidney Herbert Esq., Admiralty." C. W. WILLIAMS.

I have already noticed, that from my own inquiries the best turf may be had in the turf districts for 3s. 6d. per ton, and as it is a fuel that will never be drawn far for any industrial use, we may take 4s. per ton as the practical value of turf well dried within the range of the central counties. At the price, and allowing it 44 per cent. of the calorific effect of coal, the horse power should cost 6d. per day, that is, one-fourth cheaper than coal. Mr. Williams, using the same sort of fuel as is employed at the corn mill, and paying 6d. per box, but drying it well, found that, with a large working wagon boiler there were 3·87 lb. of water evaporated per pound of turf, and that it cost 3s. 7d. to evaporate 100 cubic feet of water. Now this is at the rate of 5¼d. per horse power per working day. When the turf was burned in the furnace without Mr. Williams's peculiar mode of effecting perfect combustion, the cost per horse was 6¼d., coinciding with the result which I have derived from other sources.

From all these examples, it may be decisively concluded, that in Ireland the horse power of steam costs per day in fuel:—

Using coals, whether British or native	7¾d.
Using turf, properly dried	6d.
Using turf in Mr. Williams's mode	5¼d.

* From the "Industrial Resources of Ireland."

COLOURED DECORATIONS.

At a meeting of the Decorative Art Society, on November 26th, a paper "On Chromatic Decorations," was read by Mr. E. Cooper. He commenced with a chronological review of various modes of applying or using colour in Egypt, and on the continent of Europe, from remote times to the end of the 17th century. In referring to the stupendous and richly-decorated remains of temples and porticoes in Egypt, he commented on the dull and opaque colours, contrasted with mat and burnished gold (laid on in leaves) which are found therein, and also upon mummy cases; he described the coloured intaglios on the walls, and the painted ceilings of deep azure, studded with stars in the temple of Medeenet Haboo, at Thebes; he exhibited drawings of Egyptian ornament of excellent design, and remarked that no progressive improvement in decorative art is discernible in these works.

The temples of Greece were then noticed, where colour was applied to capitals, frieze, entablature, and the backgrounds of the tympanum; also on the ogee mouldings, where honeysuckle, egg, and other enrichments were painted or stencilled; and it was observed that, although no remains have been discovered, it was reasonable to infer, from the eminent state of plastic art, that contemporary pictorial art had arrived at considerable perfection, and the names of some Greek artists were given, on the authority of Pliny and Quintilian. After some remarks on the vases of Greece, and the mural decorations of the sepulchres of Etruria, he directed especial attention to the magnificent baths, or thermæ, of Titus, at Rome (erected A. D. 70), and (referring to the illustrations by M. Ponce), he observed that the fresco paintings found there display, in the grouping, drawing, and management of drapery, a refined feeling and knowledge of art; and in his remarks on the colour used, he observed that the decorations were executed, most probably, by Greek artists.

The decorations of Pompeii and Herculaneum, being of the same period, were then described; but, as might be supposed, from their being provincial towns, they would be found inferior in execution and splendour to those of the capital. The arrangement on the walls, of masses of black, red, and white, exhibited a principle which was commented on at some length; and it was also remarked, that these examples do not afford an absolute criterion by which to estimate the perfection of the arts of that or the preceding age. Passing over several centuries, he next noticed the early efforts of Christian art, remaining to us in the mosaics of the churches and palaces of Italy; and after some remarks on the productions of Cimabue, Giotto, and Leonardo da Vinci, he entered upon a consideration of the decorative works of Michael Angelo and Raphael.

In this period of Italian art, the anachronisms and disregard of relative proportion, in the parts composing arabesque or grotesque decorations, were especially noticed, as well as the enrichments, similarity in design and colouring, existing between the works of Raphael and his school, and those in the baths of Titus, before alluded to, and which were discovered at this time: a striking instance was exhibited, in the decorations at Mantua, by Giulio Romano, and Andrea Montagna. (See Gruner, plate 24, and plate 5 of the Baths.)

The magnificent decorations by the Venetians were next described, in which massive mouldings richly carved and gilt, divided the surface of ceilings and walls; the coffers or panels being filled with paintings by Titian, Tintoretto, &c., produced a gorgeous effect. The decorations of the ceiling of the sacristy attached to the Duomo, or cathedral at Venice were said to be worthy of recommendation, on account of durability and splendour, for open colonnades in this country (such as at the Royal Exchange); the back grounds were of vitrified gold, and exhibit all the beauty of ancient mosiac, combined with the harmonious colouring and beautiful ornament of the sixteenth century. This century witnessed the rise and decline of fine art in Italy, and in the following one, although we meet with some good artificers, they were mere copyists and mannerists, and not great artists.

In discussion, the terms arabesque, grotesque, moresque, &c., were argued; the modes of lighting, and the principles of *gravitation* of colours on walls of apartments were commented on, and a regret expressed that decorations in the houses of nobility are not sufficiently known or accessible to the inspection of decorators and artists.

BELFRY TURRETS.

No large tower can be considered complete without a staircase-turret of stone, containing an ascent by a newel stair to the bell-chamber.

This very important feature of a church tower has been singularly neglected in modern designs, in which the effect has been often much impaired, and an essential part of the construction omitted, under the idea that it is either a useless appendage, or an awkward and unsightly excrescence. Both these notions are extremely erroneous, and in urging upon architects the more general adoption of belfry turrets, we will endeavour to show that both utility and the principles of effect suggested their use to the ancient builders.

Belfry turrets are usually placed in the south-west, more rarely in the norte-west, angle of towers; they occur also in the south-east and north-east. They are polygonal, and project half externally and half internally, and have a small doorway opening into the inside. They are carried up either to the height of one or two stages, or to the belfry windows, and then weathered off with a bold and picturesque slope, or they rise above the parapet, and form a kind of castellated pinnacle turret, sometimes carrying a weathercock or other pointed termination. Very frequently they are lost in the buttresses, which are, as it were, thrust prominently outwards by a bulging swell of the masonry in one angle, readily distinguished from the rest by its visible protuberance, and by small slits to admit light and air air into the staircase within. Sometimes, as at All Saints, Paston, near Peterborough, the head of the turret merges into a broach of the spire, which gives an extremely bold and irregular effect.

There can be no doubt that irregularity gives effect to a tower, or indeed to any Gothic building. Not irregularity for irregularity's sake—that becomes affectation. But such irregularity as arises from the absence of hypocrisy, or show, or making one side the same as the other, or the like. There is no need to fear a broken or shapeless mass as the result; uniformity is far less pleasing than variety; and the eye can never be offended in Gothic buildings by a door, a window, or a buttress, being fairly pushed aside by the intervention of any necessary constructive feature.

Nothing was more fully felt by the ancient architects than this; while nothing is more cautiously and timidly adopted by modern imitators. We have seen with much pleasure, in very elaborate and splendid towers, one belfry window placed quite on one side, instead of in the middle, even though the belfry staircase which caused this remarkable irregularity was scarcely visible on the outside. Examples of this are St. John, Ryhall, and All Saints, Oakham, in Rutland. Sometimes, as at St. Wulfran, Grantham, the splendid decorated tower of which has scarcely a rival in the kingdom, one of four pinnacles is considerably larger and higher than the other three, because it forms a capping to a staircase turret. Yet who shall be bold to say this is a fault? We would say, by all means break up monotony and sameness of sides by some such expedient; and a belfry turret seems most admirably adapted to produce almost any kind of bold picturesque effect. From a distance, the lights and shadows, the peaks and the broken lines, are vastly imposing and arresting to the eye. On a near view, the bold abutment of an angle seems at once to flank and to prop the stages of a lofty tower; and on every point whence the effect is visible, the mind is gratified by the idea of ingenuity or pleased by the suggestion of necessity made subservient to decorative effect.

Some belfry turrets are corbelled off a little above the ground externally. This, though not a material difference of construction, is to be deprecated, because the tower is apt to appear overbalanced by an excrescence which emerges from the wall itself, and does not rest upon its own basis on the ground. We have seen (as in St. Peter, Barton, near Cambridge) the south-west angle singularly prolonged into a wedge-like form from the internal formation of a belfry tower; and again, we have noticed the most beautiful forms and enlargements of buttresses to give scope for the staircase.

It is true that many ancient towers were ascended by ladders, and in a few we have seen wooden stairs inclosed in wattled or boarded turrets constructed in the interior. The ascent to the floor on which the bell-ringers assemble, if above the ground, should be the belfry turret; though we may here repeat what we have often urged before, that the entrance to it should never be from without, independently of any other communication with the interior of the church.

Modern architects are generally compelled to construct a staircase in their towers; but then they strive to hide rather than boldly to display it externally; and herein consists their error. We are inclined to prefer those belfry turrets of which three or four sides project externally, sometimes even in the middle of the north or south side, and are weathered off at the upper or belfry stage, to those which are only partially developed from the outside. The attention, however, of architects needs only to be directed to the subject, and their observation will abundantly supply fit models and devices for imitation.—*Ecclesiologist.*

LIGHTNING RODS.—In a recent communication in the New Haven Courier, respecting some recent instances of houses being struck by lightning, Professor Silliman states that the lightning rods cannot be relied upon unless they reach the earth, where it is permanently wet, even in times of the severest drought; and that the best security is afforded by carrying the rod or some good metallic conductor, duly connected with it, to the water in the well, or to some other water that never fails. Professor Silliman's house, it seems, was struck; but his lightning rods were not more than two or three inches in the ground, and were therefore virtually of no avail in protecting the house. He states that his confidence in the efficiency of rods is in no degree diminished.—'New York Observer.'

SYNOPSIS OF RAILWAYS INCORPORATED IN 1845, WITH THEIR ALLIANCES.

[For the following important paper we are indebted to the indefatigable and well directed exertions of an old correspondent, who under the signature O. T., has contributed several invaluable papers to this Journal.

In the formation of the following synopsis, the Supplement of the "Times," Nov. 17, 1845, the Railway Almanac and Directory for 1846, the Companion to the British Almanac for 1846, the Railway Shareholders' Manual, by Henry Tuck, 6th edition, and two Parliamentary Returns, dated July 17th and August 4th, have been consulted. None, however, of these authorities give the alliances of the new lines which are here added. The parliamentary return of August 4th, 1845, which is important, as it gives the number of shares subscribed for, as well as the number of shares empowered to be created, which shows the statistics of each line in public opinion, and the means of the directors in controlling the market by gradually selling shares where the number authorized exceeds the number subscribed for.]

1. *Irish Great Western.*

20,000 shares of 50*l.* each; capital 1,000,000*l.*

From Dublin to Mullingar, connecting the Valley of the Shannon with the Irish capital. To commence in connection with the Dublin and Cashel line, near Luccan, passing near the towns of Leixslip, Celbridge, Maynooth, Kilcock, Clonard, Kinnegar, and Kilnear, to Mullingar, and thence by Meale to Athloue.

Length of line 77 miles, 2 furlongs, 4 chains. Reported against by the Board of Trade. Capital subscribed, 903,000*l.* and 18,060 shares. Estimated cost, 986,651*l.* Power to borrow on loan 333,000*l.* Embodied in group Z, and recommended by the committee.

Working expenses estimated at 40 per cent. Royal Assent July 21. Sir John M'Neil engineer.

2. *Londonderry and Coleraine.*

10,000 shares, of 50*l.* each; capital 500,000*l.*

To commence at Londonderry, passing the border of Lough Foyle, and terminating at Coleraine, with a branch to Newtown. Length of main line and branch, 38 miles, 6 furlongs, 3 chains. Amount subscribed, 380,000*l.* Power to borrow 166,666*l.* Reported against by the Board of Trade. Considered by committee of group S, and recommended. Working expenses 14,000*l.* per annum. Royal Assent August 4. Charles Lanyon, engineer.

3. *Belfast and Ballymena.*

7,700 shares of 50*l.* each; capital 385,000*l.*

From the former to the latter place, with a branch to Carrickfergus. Deposit 2*l.* 10*s.* per share. Amount of deposits 19,250*l.* Total length of the line 37 miles, 7 furlongs. Power to borrow 128,333*l.* Recommended by the Board of Trade, and recommended by the committee of group S. Single line. Estimate of working expenses 11,000*l.* Royal Assent, June 21. Charles Lanyon, engineer.

4. *Dublin and Belfast Junction (and Navan Branch).*

19,000 shares of 50*l.* each; capital 950,000*l.*

Deposit 2*l.* 10*s.* per share. Amount of deposit 47,500*l.* Total length of the line, from Drogheda to Portadown, 73 miles, 4 furlongs, 8 chains. Estimate 950,733*l.* Power to borrow 316,665*l.* Recommended by Board of Trade; also by committee of group R. Branch to Kells. Working expenses 40 per cent. Royal Assent July 21. Engineer Sir John M'Neil. Meeting August 20. Miles Reck, Secretary. Office, 2, Talbot-street, Dublin. Call September 10, 2*l.* 10*s.* Proposed Great County Down company are to inspect a trial section of the line to Hillsborough.

5. *Dundalk and Enniskillen.*

15,000 shares of 50*l.* each; capital 750,000*l.*

Deposit 2*l.* 10*s.* Amount of deposit 37,500*l.* Total length of the line, including branch to Monaghan, 40 miles, 6 furlongs. Estimated expenses 450,000*l.* Power to borrow 250,000*l.* Recommended by the Board, also by committee of group R. Working expenses 30 per cent. Royal Assent July 21. Engineer Sir John M'Neil. Register of scrip Oct. 18, 1845. Hatfield Nicholson, secretary. Office 72, Talbot-street, Dublin. Company operates and in conjunction with Dublin and Drogheda as Belfast Junction and Irish North Midland.

6. *Cork and Bandon.*

4,800 shares of 50*l.* each; capital 240,000*l.*

To connect the towns of Bantry, Bandon, Kinsale, Berehaven, and Castletown with a rich agricultural and mineral district and the city and harbour of Cork. Length of Line 20 miles. Power to borrow 80,000*l.* Subscribed 200,000*l.* in 4,000 shares. Recommended by the Board of Trade, and by committee of group XX. Working expenses 40 per cent. Royal Assent July 21. Engineers Messrs. Sealey. Secretary J. M'Donnell.

7. *Great Southern and Western.*

24,000 shares of 50*l.* each; capital 1,200,000*l.*

Extension to Limerick and Cork. The extension to Cork will commence between Holycross and Cashel, in conjunction with the Great Southern and Western line, and pass near the towns of Tipperary, Kilmallock, Charleville, and Mallow. The extension to Limerick leaves the main line near Tipperary, passing the towns of Pallas Green, and Cahirconlish. Length of line 98 miles. Subscribed 1,184,100*l.* Power to borrow 400,000*l.* Recommended by the Board of Trade, and committee on group AA. Working expenses 40 per cent. Royal Assent July 21. Engineer Sir J. M'Neil. Subscribed to Irish Great Western (Dublin and Galway) 800,000*l.* to Wexford, Carlow, and Dublin Junction 100,000*l.* to Killarney Junction 20,000*l.* Also new line proposed, Clonmel, Cashel, Templemore, Nenagh, Borris in Ossary, to Roscrea, Parsonstown, Ennis, Killaloe, and Waterford and Kilkenny, for which an Act is obtained. Mr. Taylor, secretary.

8. *Waterford and Limerick.*

15,000 shares of 50*l.* each; capital 750,000*l.*

To commence at the city of Waterford, proceeding through the towns of Carrick-on-Suir, Clonmel, Cahir, and Tipperary to Limerick, affording accommodation to a population of more than a million, and giving to a rich agricultural district an excellent port for the shipment of produce to England. Length of line 77 miles, 7 feet. Subscribed 590,300*l.* in 118,068 shares. Power to borrow 250,000*l.* Recommended by the Board of Trade, and committee of group AA. Working expenses 40 per cent. Royal Assent July 21.

9. *Newry and Enniskillen.*

18,005 shares of 50*l.* each; capital 900,000*l.*

To commence, in junction with the Dublin and Belfast Junction, at Newry, passing through the towns of Monaghan, Clones, and Enniskillen, terminating, in junction with the Ulster railway, at Armagh. Length of line 75 miles, 5 furlongs. Capital subscribed 14,210*l.* in 284 shares. Estimate 833,847*l.* Power to borrow 300,000*l.* Recommended by the Board of Trade, and by committee of group R. Working expenses 33½ per cent. Royal Assent July 21. Engineer Sir JohnRennie. Mr. Saunders secretary.

10. *Waterford and Kilkenny.*

12,500 shares of 20*l.* each; capital 250,000*l.*

On this line the wooden rail is to be used as a substitute for iron. The wood is to be prepared by Payne's process, and the engines and carriages are to be fitted with Prosser's guide wheels. Length of line 37 miles, 3 furlongs. Subscribed capital 200 000*l.* in 10,000 shares. Power to borrow 83,000*l.* Recommended by the Board of Trade, also by the committee of group BB. Working expenses 40 per cent. Royal Assent July 21. J. Valentine, Engineer. Office, 34, Broad-street-buildings, London. Thos. Prosser, secretary.

11. *Londonderry and Enniskillen.*

10,000 shares of 50*l.* each; capital 500,000*l.*

Commencing at Londonderry, and passing through Carrigans, St. Johnston, Strabane, Clifford, Newtownstewart, Dromore, Trellick, to Enniskillen, in junction with the line to Dundalk, thus forming a direct communication between the north-west of Ireland and Dublin, and the east coast. Length of line 56 miles, 1 furlong, 4 chains. Estimate 462,123*l.* Subscribed 380,000*l.* in 7,600 shares. Power to borrow 166,666*l.* Working expenses 40 per cent. Royal Assent July 21. Sir John M'Neil. Engineer. Register of scrip 21 Oct. Fred. H. Hemming, secretary, Moorgate-street chambers, London.

12. *Dublin and Drogheda.*

Capital 150,000*l.*

Howth extension. Length 3 miles, 5 furlongs, 4½ chains. Estimated expense 40,000*l.* Power to borrow 50,000*l.* Working expense 30 per cent. Royal Assent July 21. Engineer Sir J. M'Neil.

13. *Ulster Extension.*

Estimate 133,035*l.*

From Portadown to Armagh. It was originally intended to run the Ulster line from Belfast to Armagh, and capital was taken for that purpose, so that it will not be requisite to issue any new shares. 104. *West London.*

Capital 60,000*l.*

Length of line, 1 mile, 5 furlongs, 1 chain; from West London, at Kensington, to a point near Battersea Bridge; estimated expense, 60,000*l.*, authorised loan, 20,000*l.*; working expenses, 40 per cent.; date of act, July 31; engineer, R. Stephenson.

105. *Yarmouth and Norwich.*

Capital 40,000*l.*

Length of line, 2 furlongs, 5 chains; estimated expense, 40,000*l.*; date of act, June 30; engineer, J. P. Bidder; see also Lowestoft railway; office, Guildhall-buildings, London; secretary, Richard Till.

106. *Hayle and Redruth.*

From Redruth, through Cain Brea, Camborne, to Hayle, in Cornwall; negotiating for sale to West Cornwall; secretary, Mr. Fleming, Old Broad-street, London.

The Magnetic Telegraph.—The establishment of magnetic telegraphs, radiating from New York to the east, west, and south, to the extent of three or four hundred miles, so as to connect all the large cities of the Atlantic border with this metropolis, is now in a rapid state of progress. The line between this and Buffalo is under weigh, and so also is the one to Boston, so likewise that between this city and Washington, including all the intermediate points. There is also a line commenced between this city and Coney Island. All these lines are conducted by associations of individuals who derive their powers from the inventor, Professor Morse, now in Europe. It is supposed that the whole of them will be finished in the course of three or four months; and that the principal line between this city and Washington will be completed in time to transmit the next message of the President to this city, and to enable the publishers to issue it simultaneously with the Washington papers. When completed these united lines of telegraphic communication will embrace a territory of nearly 500 miles from south to north, and from east to west—including within its ramifications the metropolis, Washington, Buffalo, Boston, with all the intermediate cities, as parts of the grand scheme of communication. Such a system of telegraphic communication of all descriptions of news will make the great Atlantic cities suburbs of this metropolis, and all animated by the same spirit and the same impulses, numbering, probably, a population of nearly two millions of the most active, talented, intellectual, impulsive, and most energetic business men on the face of the earth. It will not be forgotten that this vast and comprehensive scheme of telegraphic communication will be completed in the course of a few months, and be in the hands of individuals for their own advantage and purposes, without any responsibility to government or society in any particular whatever. One of the lines of telegraph, and the shortest and most unproductive, that between this city and Coney Island, has already made propositions to the newspapers, offering to give them intelligence of ship news and other marine matters at the rate of 50 dollars per week—a sum nearly double that which is now paid under the old method. This is a sample of what may be expected from the other companies and associations, provided they should be allowed to establish their vast and comprehensive schemes without being liable and responsible to any of the legislative powers of the country. In fact, we believe that the magnetic telegraph is going to produce a greater change in some of the social institutions of the country than any one now imagines.—'New York Herald.'

PROCEEDINGS OF SCIENTIFIC SOCIETIES.

ROYAL INSTITUTE OF BRITISH ARCHITECTS.

1st December, 1845.—J. B. Papworth, V.P. in the Chair.

A paper was read by John Whichcord, jun., Associate, on

Kentish Rag Stone as a Building Material.

This stone, now so much used in the metropolis, is principally quarried in a district extending about 30 miles east and west, through the centre of Kent, and having a breadth of from 4 to 10 miles. This district, which comprises the towns of Sevenoaks, Maidstone, Lenham, &c. has its surface within the limits of the green or Shanklin sand. The character of the sand varies considerably in the district alluded to, and the qualities of the building materials which it yields are therefore very different.

Geological Character.

The Kentish Rag Stone is usually found in beds of from 6 inches to 2 feet in thickness, and these different layers are invariably separated by a species of sand, known by the name of Hassock, which, in some cases, is sufficiently indurated to present a tolerably good working stone, used frequently in the neighbourhood as an inside lining to external Rag Stone walls. Mr. Whichcord principally confined his remarks to the quarry at Boughton, in the neighbourhood of Maidstone, from which the best qualities of Rag are now obtained, and a drawing was exhibited to the meeting, which represented a section of the strata in this part of the district. The quarry at Boughton has been worked for some centuries, and from it was very probably procured the stone employed in the metropolis during the period when the pointed style of architecture prevailed. Stones of a spherical shape, such as were used in the 14th and 16th centuries for artillery, are still found among the accumulated rubbish.

At Boughton, as in most of the Rag Stone districts, the surface layer of vegetable mould is succeeded by a bed of loam, which is sometimes 15 feet in depth, and varies in its character as it descends, changing from a stiff brick earth to a kind of gravelly loam, called in the district *Red Pins*. It is succeeded by three veins of ferruginous sand of a red colour, alternating with the same number of layers of fine Hassock, which in this case retains its sandy character, and forms, with the Rag Stone lime, a very excellent mortar.

Beneath the third bed of Hassock is found the first of about 20 layers of limestone, which bears the name of *Land Rag*, and is found much broken. It continually occurs, that this bed thins off into detached modules, and sometimes ceases altogether. Its thickness is therefore very variable, but blocks of from 5 to 6 feet in length, and 8 to 10 inches deep, can occasionally be procured from it. The stone is here tolerably free to work.

As previously stated, this bed of stone is (as are all others of the strata) followed by one of Hassock. The second bed of stone is called the *Header-Layer*, used for headers. The next is the *Green Rag*, which frequently divides and re-unites, the intervening space being filled with the Hassock sand: it is green in colour, and free to work, though not very sound. The layer of Hassock, which succeeds the Green Rag, is workable, and is much used in the neighbourhood for the purpose before mentioned; it requires very little labour in dressing, and in the quality of resistance to moisture is superior to brick. The next bed of stone is called the *Yellow Rag*, and is used principally for pitching; it is succeeded by the *Pelsea*, from which the largest blocks can be procured, some of 12 inches in thickness; it is very hard and strong.

The next two layers of Rag are called the *Coleman* and the *Little Coleman*, and are of a hard flinty nature; they are sometimes used as headers. We have then the *Great Rag*, which is a bed of considerable depth, sometimes as much as 3 feet; but as it very often cleaves into two thicknesses, and is full of crosses, no stones of a large size can be procured from it; it is much used for lime, of which it affords the best quality. The bed of Hassock immediately under the Great Rag is of a very superior quality, being of a fine, close, and free working grain, resembling the Reigate Stone, and stands exposure to the weather exceedingly well. It is followed by the *Newington Cleaves*, which, like the Great Rag, often splits into two layers; it is very hard and flinty. Two beds of Hassock, separated by a thin flinty layer of Rag Stone, intervene between the cleaves and the *Whiteland Bridge*, which is equal in quality to any in the quarry; blocks of 12 feet in length, and of almost any breadth, can be procured from it; its workable thickness is about 14 inches.

The next in order is the *Mainbridge*, similar to the preceding bed, though no stones of such large scantling can be obtained from it. It is separated by a layer of inferior Hassock from a bed called *Garl*, used generally for headstones.. The *Horsebridge* succeeds it: this is a good stone; blocks can be procured from the bed 15 feet long, and 16 inches thick. The next layer, called *Headstone Layers*, is about 7 inches thick. This is followed by two or three header layers, inferior in quality, and alternating with their respective beds of Hassock, below which are what are termed the *upper* and *under bottom layers*. These yield stones of good quality and colour, and of considerable size. Next comes the White Rag, a soft stone, resembling chalk, and crumbling on exposure to the atmosphere; it reposes on a bed of hassocky clay, below which the quarrymen have not penetrated, it being very doubtful whether any lime-stone would be found beneath it; indeed, in some quarries, it has not been thought worth while to work even as low as this. Mr. Whichcord then mentions that the most favourable manner of working these quarries is to expose the whole section of the cliff, and carry on the work in such a way as to lay open the upper surfaces of each of the best layers of stone in some convenient part of the quarry. By this means the largest scantling can be procured at once, and the frequent difficulty attending the working of quarries in a different manner (that of obtaining large stones when wanted in haste).

Practical Properties.

With respect to the mechanical properties of the stone, it stands next to granite in the list of British stones in respect of resistance to pressure—but the vents to which even the best quality of this stone are liable, render is unsafe when applied in such a manner, that the strain acts transversely to the length of the block. Mr. Whichcord then described the various modes of working and dressing the Kentish Rag Stone, mentioning that, as Ashler, it is usually worked with a pick, instead of being tooled, as the "Hassocky" spots which continually occur in it give it, when smooth, the appearance of bad Portland.

With reference to the mortars made with lime burnt from this stone, it was mentioned, that it attains, after a time, a degree of hardness *equal* to, and, in some cases, even *greater* than the Rag Stone itself. The durability of Rag Stone wall-work can therefore best be depended on when used with this mortar.

Mr. Whichcord referred to the mode of burning lime in the neighbourhood of the quarries, and the quantities used in making concrete, viz.—six of broken stone, two of sand, and one of lime. He also gave a list of the prices, both at the quarry and at London, of the various qualities of stone, and of the prices of labour at Boughton.

Chemical Analysis.

The following analysis of the Kentish Rag Stone was made for Mr. Whichcord's paper by Mr. Phillips, of the Museum of Economic Geology:—

Carbonate of lime, with a little magnesia,	92·6
Earthy matter,	6·5
Oxide of iron,	0·5
Carbonaceous matters,	0·4
	100·0

Hassocks.

Carbonate of lime,	26·2
Earthy matters,	72·2
Oxide of iron,	1·8
	100·0

ROYAL EXCHANGE.

December 15th, 1845.—Mr. KENDALL, V.P. in the chair.

Mr. Tite read a paper.

"*On the Original Foundation and Erection of the Royal Exchange, by Sir Thomas Gresham, with some Notices of the late Building destroyed by Fire, and an Account of the Roman Antiquities discovered in excavating for the Present Edifice.*"

The first branch of his subject Mr. Tite illustrated by numerous extracts from the records of which the corporation of London possesses a rich collection, commencing with the original charter granted to the city by William the Conquerer, a document which he incidentally describes as being comprised in a few lines in the Anglo-Saxon language. Coming, then, to the authorities more immediately connected with the subject, Mr. Tite detailed the transactions relating to the building of the Royal Exchange, through the munificence of the princely merchant, by whom the whole expense of the structure was undertaken, on condition that the site should be provided by the city, from his first proposal to that effect in 1564. The purchase of the site cost the citizens 3,532*l.* 17*s.* 2*d.*, including freeholds, leaseholds, and tenants' interests; and it is to be noted that the former class of property realized about twenty-three years' purchase—a value not very different from the average of later times. The building was completed and opened for use in 1567. During the progress of the work, a question appears to have arisen between Sir Thomas and the city respecting the *property* in the building, which terminated in his assuring, after his own life, half the profit of the shops and other tenements to the Corporation, and half to the Mercers' Company; and it is from this division that the affairs of the Exchange have always been in the hands of the mixed body called the Gresham Committee. The appearance of the original building is preserved to us in Hollar's engraving, which shows it to have been in a much better style of architecture than the Bourse of Antwerp, of which it has been pretended it was a copy. That of Amsterdam bears a much greater resemblance to it, but in this case the London building is the original, and not the copy; that of Amsterdam dated only from 1612. Shortly after the death of Sir thomas Gresham, some part of the building failed, upon which occasion the members of the Corporation endeavoured to cast the repairs upon the widow of their benefactor. From a report made by the Gresham Committee, after the destruction of the building in the great fire, it appears that the arcades of the court were vaulted with stone, and that it had been necessary to stay the supporting pillars by transverse iron ties. This report is dated on the 17th September, 1666, so that the committe had lost no time in taking measures to repair the calamity they had suffered. Estimates for the new building were speedily provided by Messrs. Mills and Jerman, who appear to have proceeded in the plan of making out quantities, and giving them to the tradesmen to be priced. After some coquetting on the part of the latter, who professed to deprecate any interference with the office of city surveyor, held by Mills, Jerman was at last appointed the architect, and the first stone of the new edifice was laid by King Charles II., on the 23rd of October, 1667. In erecting the new edifice, the site was considerably enlarged, and it was the wish of the citizens to disengage the building from the houses, late Sweeting's Alley, which pressed upon it to the eastward, encouraged by an offer of the proprietor, Sweeting, to dispose of his property on the most liberal terms, and which ended, as such offers usually do, in demands too exorbitant to be complied with. The tower of Jerman's building, which, from motives of economy, was constructed of timber insead of stone, yielded to the effects of time in 1818, and was replaced by a stone cupola, designed by Mr. George Smith, architect of the Mercer's Company. With reference to the building lately completed under his superintendence, Mr. Tite confined himself to the antiquities. Four glass cases, containing a numerous selection, were laid on the table, consisting of pottery, coins, writing tablets and styles, a great variety of objects in metal, and a quantity of shoes and sandals in excellent preservation. The whole of these curious objects were found in one spot, at a depth below the general level of the solid ground, and bedded in black mud—evidence that it had been a pond, and the receptacle of rubbish for the neighbourhood during the period of Roman London. Mr. Tite concluded with a powerful appeal to the members of the profession in general, on the subject of the preservation of Antiquities, and of supporting the measures recommended by Mr. Hawkins, in his letter read at a former meeting.

SOCIETY FOR THE ENCOURAGEMENT OF ARTS.

The First Meeting of the Society for the encouragement of Arts, Manufactures, and Commerce, took place on the 17th, in the great room of the Society, in the Adelphi, which was completely filled.

B. BOND CABBELL, Esq., F.R.S., one of the Vice Presidents, took the Chair, and an address from the Council was then read by the Secretary. The Council congratulated the society on the auspicious commencement of their *ninety-second session.* During the recess the society had undergone a complete reorganization, and the new system of management proposed by the Council had been almost unanimously confirmed by two general meetings, so that the society being thus rewarded, its youth would, it was anticipated, display all the vigour and energy of a new institution, combined with the stability and influence of an old one.

It was the intention of the council to add largely this year to the value and number of the premiums. In the fine arts, the mechanical arts, the manufactures, agriculture, and commerce of the country—rapid improvements were in progress, which it had been the peculiar province of this society for nearly a century to encourage and direct, and in which nearly 100,000*l.* had already been expended by it with great public advantage. In the present session many valuable subjects were about to be offered for competition by premiums, and so large a number of important papers were coming forward for notice, that the Council believed the auspicies under which this session commenced were unusually bright, and they therefore had to congratulate the members upon the improved prospects of the society.

Broad and Narrow Gauge

The first communication read to the society was a paper on certain improvements, in constructing the Locomotive Engines, and permanent Way of Railways, with reference to the question of wide and narrow gauge, by J. G. Bodmer, Esq., formerly of Manchester, now of London. In this paper the author examines the question of the relative merits of wide and narrow gauge; he ascertains that the question is not one either of relative safety or danger, but that it resolves itself ultimately into this question, which gauge will admit of the most perfect means for obtaining high velocities with greater regularity and economy. At present he admits the broad gauge has the advantage in more powerful and speedy engines. But he then proceeded to show that by placing the *cylinders outside*, and by *increasing* the firebox and the flue surface in the manner he proposes, and by adopting the principle of compensation as in his double piston locomotives, high velocities may be obtained with security, safety and advantage. In short, that as powerful an engine in every way may be placed on the narrow gauge as on the wide one, and one equally well adapted to high velocities. He then went on to show how the chief limit in increase of power, and the corresponding increase of weight in locomotive engines, consists not so much in the construction of the engines, as in obtaining a permanent way suitable for the support of such enormous loads. By these loads travelling at high velocities concussions are produced which derange the permanent way, and are at present the chief sources of danger and cost, and the chief limit to the speed. He approves of the triangular sleeper, originally invented by Reynolds, and he proposes to use a modification of that on a larger scale, as a longitudinal bearing. He also proposes that the breadth of the rail should be so increased as to diminish the continual attrition so destructive to wheels, and procure greater durability. In the conclusion of the paper he suggests that an experimental railway ought to be constructed either at the expense of the government, or of the joint railways, for ascertaining the best means for giving the increased velocity which the public are beginning to demand in the best manner. The paper gave rise to a long and interesting discussion, which elicited the opinions of engineers and scientific men present on the merits of Mr. Bodmer's plan. The principle on which his engines are constructed were approved by all who spoke on the subject, and the thanks of the meeting were unanimously accorded to the author. The next paper read was a sequel to the former by the same author, on improved crank axles and axle boxes, by which greater security and economy are obtained in railway trains running at high velocities. There were other papers on the list of the evening, one of them containing a valuable discovery by Mr. Nott, on the nature of the Photographic rays, and a method by which a great improvement is effected in Daguerreotype pictures. But the length and interest of the discussion rendered it necessary to postpone that and the other communications to a future meeting. The meeting was crowded and deeply interesting, and augurs well for the prosperity of the society under the new regime.

ROYAL SCOTTISH SOCIETY OF ARTS.

Monday, Nov. 24, 1845—John Beatson Bell, Esq., in the Chair.

The following communications were made :—

"*Description and Drawing of a new Rifle Breech.*" By Mr. Thomas Mould, gunmaker, Stirling. Communicated by Mr. Burns of Garvald. Mr. Mould's method is to attach two spiral "ribs" to the breech only, for about two inches where it screws into the barrel, and not to the barrel itself, as in the common method; the ribs being made to describe a curve equal to a whole turn in twelve inches. The breech, after being finished, is case-hardened. The barrel can be made much longer on Mr. Mould's plan without danger of stripping the ball. After firing with this rifle, the tract of the ball can be clearly seen running in a spiral direction along the inside of the barrel, if the breech be unscrewed, and the barrel be held like a telescope. The piece is also said to be much easier loaded. Referred to a Committee.

"*Description and Drawing of a Railway Alarum*", by which the guard may communicate with the Engineer. By Mr. Andrew Carrick. This proposal is for a communication to be effected from the locomotive all along the train by means of rods passing beneath each carriage, which are united by chains after the carriages are attached to each other. On the guard pulling the lever attached to this, a bell is struck on the locomotive so as to give warning to the engineer when any thing is wrong, or when it is wished to stop the train.

"*Description and Drawing of a Railway Indicator,*" for showing at night, or in dense fogs, the speed of the engine, or distance it has travelled from the station. By the Same. This indicator consists of a screw working into a pinion on the axle of the driving wheel, which carries a spindle that works by means of a train of wheels, upon one that carries a hand or pointer, showing how many miles the engine has travelled from the station. Mr. Carrick recommends that, at each station, the engineer sets the pointer to zero, and thus he will know almost exactly where the train is, even in the darkest night or in dense fogs.

"*Description and Drawing of another Railway Indicator.*" By the Same. This is another form of the indicator. It consists in having studs fixed along the railway at each mile, which on the engine passing over them, come in contact with a bell crank, and ring a bell fixed on the locomotive. The engineer can thus count the number of miles passed over.

Monday, December 8.—John Beatson Bell, Esq., V.P., in the Chair.

The following communications were made :—

Notice relative to the properties of

Patent Intonaco Cement, with illustrative specimens. By Mrs. Margaret Henrietta Marshall, Millport.

It was stated that the principal claims to notice possessed by this cement, are its cheapness, hardness, and durability, and the almost boundless variety of purposes to which it may be usually applied. That in architecture, it is alike fitted for walls, flooring, ceiling, and pointing slates, which it unites into one solid immoveable body. That it sets in a few hours, and dries so rapidly, that a house plastered with it may with perfect safety be inhabited in eight days. That it is alike hard through its whole substance; and, even as exterior cement, in imitation of stone, has remained uninjured and unaltered in all weathers, never having been known to peel or throw off any salt from the surface. That it is such a slow conductor of heat, that iron of equal thickness, exposed to equal degrees, showed a balance of 6¼ in favour of the Intonaco, consequently it offers a very great security from fire. That as it shows at least as great a power of resisting damp, lathing may be entirely dispensed with, wherever it is used as wall plaster; and partitions formed of it, according to the plan of the patentee, only two inches in thickness, present a much firmer body, and more effectual deafening, than the 4½ inch double lath partitions at present in use; besides being cheaper;—and that no vermin of any description can penetrate or lodge in walls or partitions done with it. That this cement offers a perfectly new art of imitating marble, which, immoveably united to the surface of sandstone, and highly polished, will bear exposure to any weather. Every style of ancient ornamental flooting can be imitated to perfection at moderate cost. That it forms an entirely new ground either for mural, or easel oil painting: the finished paintings possessing all the advantages of fresco, united to greater depth and brilliancy, and incalculably greater ease of execution. That as a ground for gilding, it has received the highest approbation of practical men; and is ready for the gold in 24 hours after moulding or model.

Account of Experiments on Electro-Culture.—By Andrew Fyfe, M.D., F.R.S.E., Professor of Medicine and of Chemistry, University and King's College, Aberdeen.

In this paper the results of trials on the application of electricity to vegetation, as recommended by Dr. Foster, were first stated, the wires being applied to cabbages, &c. In these experiments Dr. Fyfe did not find the slightest benefit to accrue. At the time that the trials were in progress, experiments were also instituted with the view of ascertaining whether there was an electric current along the wire, which was done by the use of the gold leaf electrometer, and by delicate galvanometers. In all of these, there was not the slightest indication of electric current.

Dr. Fyfe's paper afterwards gave the results of trials on the application of galvanic electricity, this agent being applied in a variety of ways, to peas, beans, onions, potatoes. In some of these the galvanism was applied by sinking metallic plates in the ground, and connecting them with wires, sometimes sunk in the earth, at other times left above it, and in contact with the plants. In other trials the galvanism was applied by the use of batteries, with which galvanometers were connected; the trials, in some cases, being continued for several weeks. In all, not the slightest difference could be observed between the products of the galvanised and non-galvanised vegetable. In the case of the potatoes the products were, in one trial, as 37¼ for the galvanised to 33 for the non-galvanised. In another, it was as 46¼ for the galvanised to 51½ for the non-galvanised. Taking the average of all the trials, the results were as 101½ for the galvanised to 105 for the non-galvanised.

From the results of his numerous trials, Dr. Fyfe concluded that no benefit whatever was observed to follow the application of electricity, either by the mode recommended by Dr. Foster, or by galvanic electricity—at the same time, he stated, that though in these trials no benefit resulted, he was far from asserting that electricity would not be found beneficial; the subject was worthy of prosecution, and he hoped that others would be induced to prosecute it, and to give it the scrutiny to which it was entitled.

ATMOSPHERIC TRACTION.

The power employed in exhausting the Main Pipe compared with the power exerted by the Train Piston; Friction and Leakage being disregarded in both cases.

I presume that Mr. Haydon's formulæ* are general ones, i. e. independent of the dimensions of the tubes and pumps, as likewise of the length of the stroke of the pump and the number of the strokes; and that consequently I may assume, *for the purpose of explanation*, any dimensions, &c., which I find most easy to deal with, however extravagant such dimensions may otherwise appear.

The preliminary exhaustion I will suppose to be effected by means of a piston placed within the main pipe itself. To produce the degree of exhaustion assumed by Mr. Haydon, viz: one third of the atmospheric pressure, or 5lb. per square inch, such piston must obviously be moved along two-thirds of the length of the main; its motion terminating at the end opposite to that from which the train piston is to start.

The power, necessary so to move this piston, may be estimated as follows, (taking each side separately and considering only the effect upon one square inch).

Call the length of the main a, call $\frac{2}{3}$ of its length b, and $\frac{1}{3}$ of its length c, then $a = b + c$.

Opposed to the motion of this piston, through b, there would be the constant atmospheric pressure of 15lb = 15 b.

Assisting its motion throughout b, there would be a pressure varying from 15lb at the commencement, to 5lb. at the termination: if we call the *average* of this varying pressure x, then the assisting force would be $x\,b$, and the general expression of the resistance is 15 $b - x\,b$, or $(15 - x)\,b$, to be overcome in effecting the preliminary exhaustion down to 5lb pressure per square inch.

The train piston being now ready to start, the next object is to maintain in front of it, while it travels, the degree of exhaustion just specified, viz.: 5lb per inch; and for this purpose, I will suppose a second piston to be placed also within the main pipe, at a point some little in advance of the train piston, and that the power by which it (the second piston) is to be moved along the main, is so regulated as to draw it along exactly at the same rate as that at which the train piston itself travels, whereby the space between the two, may not become larger or smaller, as that, if it occurred would change the degree of exhaustion in front of the train piston.

The power necessary to move this *exhaustion maintaining* piston may be estimated as follows:

It must move through a, (the length of the main): opposed to its motion there would be a pressure at the outset of 5lb, but by the time the piston had moved through $\frac{2}{3}$ of the length of the main (or b) the pressure would have increased to 15lb. This varying pressure being precisely equal in continuance and intensity to the assisting pressure of the preliminary exhaustion, its *average* may like that be called x, and its total $x\,b$.

* Part 98, page 335.

This piston must be further moved through the remaining $\frac{2}{3}$ of the length of the main (or c) against an opposing pressure of 15lb $= 15\,c$, the sum of the opposing force is therefore $x\,b + 15\,c$.

To assist its motion there would be a pressure of 5lb throughout the length of the main $a = 5\,a$. The general expression of the resistance of this piston is therefore $x\,b + 15\,c - 5\,a$; and for both pistons $(15 - x)\,b + (x\,b + 15\,c - 5\,a)$ or $15\,(b + c) - 5\,a$: But $(b + c)$ being equal to a, therefore $15\,(b + c) - 5\,a = 15\,a - 5\,a = 10\,a$.

The power operating upon the train piston is $(15 - 5)\,a = 10\,a$; therefore, (leakage and friction excepted,) no power is lost.

It may be thought necessary to enquire, whether, if an air-pump be used, this reasoning still applies.

To take the secondary exhaustion first, I think that Mr. Haydon's formula is just as applicable to the supposed piston, as it is to that of the air-pump; as each stroke of the pump would be merely a diminished representation of the one long stroke of the supposed piston.

In respect of the preliminary exhaustion, it is most easy to form a judgement by making a calculation of the effect of one or more strokes of a pump of dimensions assumed with reference to convenience of calculation only. For instance; we may assume that the pump has twice the capacity of the main, in which case it would effect the preliminary exhaustion by *one upward stroke*. The power necessary to effect this stroke may be estimated as follows: The opposing power is $2\,a \times 15$. The necessary power is therefore $(2\,a \times 15) - (2\,a\,x) =$ The assisting power $2\,a\,x$, $(15\,x) . 2\,a$. And as $a = \frac{3\,b}{2}$, the power is $(15 - x) . \frac{(3\,b \times 2)}{2} = (15 - x) . 3\,b$.

Now as upon the other supposition the preliminary exhaustion of the main was found to require a power $= (15 - x)\,b$, there would be a loss in using the pump of $(15 - x)\,2\,b$; but this amount represents exactly the power consumed in exhausting the cavity of the pump itself, which by the supposition is twice the size of the main.

In my last communication I stated that the only loss (disregarding leakage and friction) was that of the power employed in exhauting the pumps and branch pipes; and the above reasoning confirms that view of the matter.

I may observe lastly that, with small pumps and branch pipes, this loss cannot bear more than an insignificant proportion to the whole power expended.

It has been argued that atmospheric traction is like traction by means of a highly elastic rope, which requires to be stretched, at the expense of much power, before it becomes rigid enough to overcome the resistance of the load, and which being so stretched, is assumed to afford no advantage over an ordinary rope.

Now it would be easy in this case to adopt an arrangement which would recover all the power employed in stretching the rope†. And in the case of atmospheric traction a mere glance at the subject shows that such a recovery of power must take place; for otherwise, the preliminary exhaustion being analogous to the stretching of the rope, the subsequent exhaustions, to complete the analogy, must require as much power as would be sufficient to drag along the train piston by means of a rigid medium; *i. e.* a power equal to that of the train-piston itself! a proposition all but self-evidently erroneous. The power acting upon the train-piston as previously shown being constantly $15 - 5 = 10$; while the resistance to the air-pump piston is 10 through one third only of its stroke, with an average of *about* 3 *during* the remaining two thirds of its stroke, making a total resistance equal to *about one half* of the power acting upon the train-piston.

E. H.

[We have to thank our correspondent for taking great pains to investigate the subjects of certain papers in this journal, and for communicating his observations in a most obliging manner. We cannot, however, carry our courtesy so far as to assent to his conclusions. His arrangement of a supposititious "exhaustion maintaining piston," "some little in advance of the train-piston," is wholly different from anything that occurs in practice. It does not appear how this exhaustion maintaining piston is itself to be moved—not by stationary air-pumps, for the degree of vacuum in front of it is supposed to constantly diminish, until the air actually recovers its natural density; and this could only take place on the supposition that the air-pump *ceases working* directly the train starts.

The mere consideration, that in the air-pump the air is alternately dilated, and condensed, ought of itself to shew that some power is lost, independently of leakage and friction. If the particles of air be at constant intervals moved closer together, and farther apart, than they are in their natural state, it is clear that *force* must be absorbed for the purpose. For to suppose that an elastic fluid has the power of contracting and dilating itself is to indue inert matter with an inherent power of motion.

The principles assumed in Mr. Haydon's paper were so entirely in the ordinary *routine* course of mathematical investigation, that no mathematician would dream of disputing the *nature* of the loss exhibited; all that can possibly be done is to question the *amount*. If our correspondent wish to do this, he must do it not as here, indirectly, but by directly showing some error in Mr. Haydon's paper. He must make no supposititious arrangements of pumps and pistons, but must follow the method of the paper in question, by taking the dimensions of the pump and tube, and the number of strokes to be *exactly what they are in practice*.

The illustration of the man drawing a weight from a well is accurate enough, except that the man's journeys would be less and less each time, while the stroke of the air-pump is always of the same length; the consequence would be that in the former case the loss of power might be made much less than it could possibly be in the latter. Our correspondent himself says, that there would be *some* loss in the former case,—that the power usefully applied would never exactly equal the power expended; the question therefore is, as we said, not one of principle, but a question of mere amount.]

† Suppose a weight is to be raised from the bottom of a well 100 feet deep, by means of an elastic rope 100 feet long, passing over a pully at the top of the well, and being drawn along horizontally by a man. Suppose the man found the rope to stretch to double its length; i. e. to 200 feet, by the time it began to lift the weight. Being so stretched, let its upper end (the 100 feet from the well head) be secured upon the ground, (by spiking or otherwise); and let the man then take hold of the rope close to the well head; the slightest force applied there will make the weight begin to rise; because the man has in his favour the reaction of the half of the rope which lies behind him, but as the weight rises, this half of the rope will shorten, and its reaction will diminish constantly till it ceases just when the man has moved 50 feet from the well head, raising the weight 50 feet.

In this operation however one half of the power, originally employed in stretching the rope, will have been recovered.

In like manner let the man make fast upon the ground the part of the rope which he now holds,—go back to the well head, and draw the rope forward 25 feet, raising the weight 25 feet; and he will further get back one quarter of the said power.

He may regain $\frac{1}{8}$ $\frac{1}{16}$ $\frac{1}{32}$ &c. so long as he goes on; whereby he may regain all b infinitesimal fraction.

THE PROPOSED EXPOSITION OF MANUFACTURES AND INDUSTRIAL ART.

The preparations for the proposed exposition of Manufactures and Industrial Art, in connection with the Manchester School of Design, under the direction of our talented townsman, Mr. George Jackson, are in a forward state, and the exhibition will be ready for the Christmas holidays. Mr. Jackson and his colleagues are gentlemen fully competent to the task they have undertaken, and their success so far has even exceeded their anticipations. It is now expected that every nook and corner of the Royal Institution will be required for the display of the articles, so numerous will they be. From the answers already received, it is expected that the contributions from the Potteries will be rich, indeed magnificent—several houses of eminence in the china trade having promised contributions of the highest class, and of considerable amount. From Stourbridge and Birmingham they have promises of an extensive collection in glass, comprising chandeliers and articles of general utility; and from the latter place there will be a considerable quantity of japanned goods, brassworks, and manufactures of other descriptions peculiar to the town. There will also be some very brilliant specimens, both in gold and silver, of the electro-deposit. From Coventry splendid specimens of ribbons and gauzes will be forthcoming, and watches equal to anything of foreign production. From Leicester a display of hosiery; and from different places in Nottingham a splendid collection of laces are promised. Sheffield is to contribute specimens of its steel and other goods, comprising grates, fenders, fire-irons, cutlery, &c. Glasgow is under contribution for carpets, and some magnificent articles of large dimensions woven in one piece are amongst the specimens. From Paisley, shawls, scarfs, and other woven fabrics peculiar to the district are bespoken. From Ireland specimens of linen are to be exhibited, manufactured from Irish-grown flax. London is to send silversmiths' goods, including splendid specimens of plate; and some magnificent collections of testimonial plate are on their way to Manchester from thence. Among the manufactures of our town an effort is making, and the contribution will include a large collection of printed cottons, de laines, and silks. The exposition of the latter description of goods will also include silks from Macclesfield, Spitalfields, and other places. The Council, we learn, have not restricted the exposition to articles of home manufacture only, but have induced several foreign houses to exhibit and forward specimens of their manufacture. As a favourable sample of the spirit in which they have been met on this point, we may mention that one house in London declined answering the application till a partner in Paris had been consulted. His reply was not very favourable, but he added, that in his opinion the Council had adopted "a principle with regard to this exposition that ought long ago to have been adopted on the continent, in allowing the foreigner to exhibit in competition, and that the expositions on the continent would never be successful till they adopted the same principle." The Council, however, confine the exhibition to the production itself, and do not contemplate exhibiting, as at the Parisian exposition, the means of production. With regard to the School of Design itself, it is expected that on this occasion it will fully bear out the anticipations which the public have been led to draw, and that the specimens will show the utility of such institutions like this, where they can be properly conducted. We are also glad to find that the prizes offered by the Council, to stimulate designers of the town generally, have had a good effect; and that the drawings sent in for competition are numerous, and many of them talented.—*Manchester Times.*

RAILWAYS NOW AT WORK IN THE UNITED STATES,

FITZWILLIAM MUSEUM.

The Syndicate appointed to report on the state in which the designs for the building are left, and of the engagements made with the contractors for the execution of the work, have reported as follows :—

"The Syndicate find by an examination of the drawings left by Mr. Basevi (which have been sent for their inspection by his brother, Mr. N. Basevi), that the designs for the greater part of the work remaining to be executed are in a forward state, but they conceive that these designs not having been perfected, require, for the completion of the work, the assistance of an architect of the same order as Mr. Basevi in professional eminence and skill.

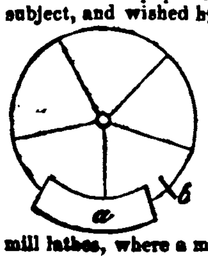
"The Syndicate think it highly desirable that the building should be completed with a close adherence to Mr. Basevi's intentions, so far as they appear in a settled form in his designs.

"The Syndicate have also ascertained, by inquiry of Mr. N. Basevi and Mr. Baker, the state of pending engagements with Mr. Baker, and the results of this inquiry will be laid upon the registrar's table.

"The Syndicate, considering the high professional character of Mr. Cockerell, and the confidence already reposed in him by the University, beg leave to recommend that Mr. Cockerell be appointed Mr. Basevi's successor as architect of the new Fitzwilliam Museum, with instructions to adhere as closely as may be to Mr. Basevi's designs in carrying on the work to its completion."

In accordance with that report a grace passed the Senate to appoint Mr. Cockerell architect of the Fitzwilliam Museum, in the room of the late lamented Mr. Basevi.

Newcastle Philosophical Society.—An excellent paper has been read by Mr. Armstrong (the inventor of the hydro-electric machine,) on the application of water pressure as a motive power, to be supplied from street mains. The lecturer illustrated his remarks by a model of a crane for lifting heavy weights, and he had the complete control of the motive power, and speed for raising, lowering, or turning round variable loads. He referred to a paper in the Mechanic's Magazine of April, 1840, on the subject, and wished his claim of priority of application of this power to be confirmed. The mechanical arrangement was very perfect. The lecturer exhibited also a machine for circular motion ; *a* a curved pipe, with water pressure beneath ; *b* a circular disc, or piston, with others similar to it, arranged at equal distances in the periphery, and they are, like the reefing paddles, made to enter edgeways into the curved pipe, and to turn transverse to act as pistons ; each successive piston entering before the preceding leaves the curved pipe. The machine is applicable to copper-mill lathes, where a motive power of amount is required at intervals, and the cost of power is estimated at only one-third the cost of manual labour.



MISCELLANEA.

Astronomical Observations.—A parliamentary document has just been printed, in answer to a return of Mr. Hume, for a copy of instructions to astronomers of the several observatories at home and abroad in the year 1837-8, with the number of volumes of astronomical observations made at each observatory since that year. It appears that no instructions were sent by the Board of Admiralty to the Astronomer Royal in 1837-8. One volume of astronomical observations is printed in each year by the Royal Observatory. A report is annually made in the month of June to the Board of Visitors by the Astronomer Royal on the state of the observatory, and communicated to the Board of Admiralty. It is added, that at the Royal Observatory at the Cape of Good Hope no astronomical observations have been printed since the year 1838, the astronomer and his assistants having been chiefly employed in the measurement of an arc of the meridian. Different volumes of astronomical observations made at Greenwich and elsewhere have been printed since 1837, under the superintendence of the Stationery-office.

St. Mary's Church, at Beverley.—A local paper says that the restorations of this fine edifice are progressing satisfactorily, and the work already executed is done in a substantial manner. A barrel drain of sufficient dimensions has been laid at a considerable depth round the church, which proves very efficient in keeping not only the floor of the nave and chancel, but the whole building perfectly dry. The flagged area and parapet wall, and the approaches to the five entrances, are finished. The foundations of the fabric have been carefully examined, and the basements of the buttresses, the walls, and their respective weather mouldings, repaired and restored to a considerable height; so that the stability of the structure may so far now be considered as secure as when first erected. The interior of the crypt is being proceeded with, and what has for ages seemed only a miserable-looking cellar, choked up with accumulations of soil, and bones and debris of every kind, already assumes a handsome appearance.

Present of Medieval Antiquities to the British Museum.—We understand that Lord Prudhoe, anxious for the formation, in England, of a public national collection in illustration of national antiquities, and persuaded that the British Museum is the best and most extensively available place of deposit for such a collection, has made an offer on subject to the Archæological Institute,—whose authority in such matters he desires to recognize and reserve. He proposes, we believe, to present to the Museum, through the medium of the Institute, and as a result of the meeting at Winchester, his collection o remarkable antiquities which were exhibited in the Museum on that occasion,—on condition that the trustees shall undertake to set apart a proper place for collections of the kind. Such is the report in antiquarian circles ; and we have reason to believe that the example of Lord Prudhoe has already been fruitful in other offers of a similar kind, in the event of the arrangement which is its condition taking effect. We have little doubt that a proposal of the kind will determine an arrangement for a separate assemblage and exhibition, in our great national institution, of the works of British and Mediæval Art : and the influence of the Institute will then have been early felt, in the formation, through their means and authority, of a department which has been so long felt to be a necessary feature of such an establishment. At the same time the Institute has no intention, while ministering to their larger object, to abandon the formation of similar collections for itself. Contributions to its library are, we are glad to hear, rapidly coming in ; and one of its projects is to take advantage of the opportunities afforded by its extended correspondence, in the collection of materials for local history. A large number of impressions from sepulchral brasses have also been presented ; and the Society purposes, we believe, to form, if possible, a complete collection of these memorials, for the sake of their valuable testimony on subjects of costume, family history, heraldry, and other antiquarian subjects.—'Athenæum.'

It is reported that an experimental squadron of steam vessels will put to sea to try their respective rates of sailing and steaming, and other features, as efficient and serviceable vessels of war, early in the ensuing spring, and that gunnery exercise will be a leading item in their trials, in order to ascertain which armament is best adapted for vessels of their class. The competing vessels named are the—

Vessel.	Tons.	Horse Power.
Terrible	1,847	800
Retribution	1,641	800
Avenger	1,444	650
Gladiator	1,167	4[illegible]0
Sampson (frigate)	——	450
Ardent (sloop)	——	200
Rattler (screw)	888	200
Scourge	1,124	420
Black Eagle	495	260

Early Painted Decorations.—Some curious remains of the early art of painting, as practised in England, have been lately brought to view, at Southerop, in Gloucestershire. The chancel of the parish church, of the Anglo-Norman era, requiring restoration, on removing the accumulated coatings of whitewash from the walls, it was discovered that it had been at one time a perfect gallery of scriptural and other subjects, not the smallest portion, from the roof to the floor, having been left unadorned. Most of these quaint designs were too far advanced in decay to be deciphered; but the Nativity, the Annunciation, and the Decapitation of St. John the Baptist, are still apparent, and show that the recluse and devout designers possessed all then known of art, as well as all the learning of the time. A remarkable device for the decoration of a sacred edifice remains in one of the deep recesses of the lancet shaped windows; it is the figure of a month, in a red tunic, shooting an arrow at a red squirrel in a bright yellow tree, the bow held in the right hand. The costume of this figure seems to make the date somewhere about the middle of the fourteenth century—five hundred years since.

Valuable Discovery.—A French mechanic formed the idea that by subjecting iron dross to the slow cooling process which is known to produce a total change in the nature of glass, a new and useful species of stone might be obtained; and as iron-dross, such as the large furnaces yield, is a wholly useless substance, the announced successful result of his persevering attempts cannot but be matter of great interest, more especially at the present time, when the smelting furnaces of England are in a hitherto unknown state of activity. The object which the Frenchman sought to accomplish was, to impart to iron dross the compactness and hardness of granite, and at the same time to save the cost and labour which the hewing of the real stone requires. To this end he contrived to let the iron refuse, while in a fluid state, run into iron forms, which were previously brought to a red heat by being placed so as to receive the superfluous flame which issues from the mouth of the furnace; and in order to insure the slow cooling, these forms are provided with double sides, between which sand is introduced, which is well known to be a bad conductor of heat; the whole is then brought again to a glow heat, and in like manner again cooled off. By this procedure, it is asserted, the ingenious discoverer has succeeded in forming paving stones, flags, large building block and even pipes, of any given form, of a degree of hardness and polish, equal, if not superior, to the best hewn natural granite, and at the most trifling conceivable cost.

The Iron Trade in America.—By an arrival from New York, on Monday, we have the following interesting particulars relative to the development of the iron trade there:—"The production of iron in Pennsylvania in 1844 was about 200,000 tons and it is estimated that this year it will amount to about 350,000 to 400,000 tons. It is, also estimated from good data that the total production of in the United States this year will not fall short of 700,000 tons, and that the consumption will amount to about 800,000 tons, leaving a deficiency, to be supplied by importation, of about 100,000 tons. We annex a table exhibiting the quantity and value of iron and steel of all kinds imported into the United States for the last sixteen years.

Aggregate Quantity and Value of Iron and Steel imported into the United States.

Years.	Tons.	Value. Dollars.	Per Ton. Dollars.
1828-29	36,314	2,417,292	66
1829-30	40,644	2,340,964	56
1830-31	51,571	2.235.363	49
1831-32	73,979	3,697,380	—
1832-33	80,289	3,371,867	—
1833-34	78,190	3,938,396	—
1834-35	59777,	5 710,193	—
1835-36	96,220	5,859,131	—
1836-37	102,866	6,363,188	—
1837-38	74,762	4,036,963	54
1838-39	115,637	6,688,598	57
1839-40	72,769	4.341,086	59
1840-41	112,111	6,020,416	44
1841-42	107,392	4,332,000	40
1842-43	37,405	1,665,651	43
1843-44	105,277	8,963,833	37
	1,261,074	63,837,526	50

This table shows that, notwithstanding the immense increase in the consumption of iron in this country, there has not been any very great increase in the importation, and that the supplies from our own manufactories have nearly kept pace with the increased demand for consumption.—The most extensive works in this country are those of the Mount Savage Company of Maryland. Its present capital is 1,500,000 dollars, with power to increase it to 5,000,000 dollars. Its stock is owned principally in Europe. These are the only works in the United States where railroad iron is manufactured to any extent, and it is calculated that 20,000 tons can be made in a year. Some of the eastern railroads now building are supplied with rails by this company. The mines of the Mount Savage Company, and in fact all the iron mines of Maryland, are situated in the Cumberland coal region, which, for the manufacture of iron, is said to be superior to any other."

LIST OF NEW PATENTS.

GRANTED IN ENGLAND FROM NOVEMBER 27, TO DECEMBER 24, 1845.

Six Months allowed for Enrolment, unless otherwise expressed.

John White, of Salford, Lancaster, engineer, for "certain Improvements in engines, machinery or apparatus for raising and forcing water."—Sealed November 27.

Peter Spence, of Burgh, Cumberland, for "Improvements in the manufacture of copperas and alum."—November 27.

Moses Poole, of Searle-street, Middlesex, gent., for "certain Improvements to hinder the oxydation of iron to all its various states of cast metal, steel, malleable iron, and also to render malleable iron more hard and durable." (A communication.)—November 27.

Eden Thomas Jones, of Bristol, manufacturing chemist, for "Improvements in the apparatus used in the concentration of sulphuric acid."—November 27.

William Maugham, of Newport-street, Surrey, consulting chemist, and Archibald Dunlop, the younger, of Upper Thames-street, gent., for "Improvements in the manufacture of ale, porter, and other fermented liquors."—November 27.

Edward Dell, of Woolwich, wine-merchant, for "certain Improvements in apparatus for heating and warming."—December 4.

Robert Rettie, civil engineer, of Glasgow, for "an Improved method of signalizing, or telegraphing on sea or land, preventing collision at sea, and giving signals of distress by improved burners with glasses coloured, and signal cards, applicable to railways in all the various departments, as well as preventing of accidents when the train is at full speed, showing the state of the tide in harbours, also the diurnal for railways, towns, villages, &c."—December 4.

William Gossage, of Neath, metallurgist, for "Improvements in obtaining products from certain ores and other compounds of certain metals."—December 4.

John Leslie, of Conduit-street, Hanover-square, tailor, for "Improvements in the combustion of gas."—December 4.

Moses Poole, of Serle-street, Middlesex, gent., for "Improvements in locks." (A communication.)—December 4.

James Meacock, of Kingston, Jamaica, merchant, for "Improvements in pulping, dressing, and sorting coffee."—December 4.

Archibald Dunlop, jun., of Thames-street, London, gent., for "Improvements in the manufacture of aerated waters."—December 4.

Henry Bessemer, of Baxter House, Old St. Pancras-road, Middlesex, engineer, for "certain Improvements in atmospheric propulsion, and in apparatus connected therewith, part, or parts of which improvements are applicable to the manufacture of columns, pipes and tubes, and other parts are applicable to the exhausting and impelling of air and other fluids generally."—December 5.

John Robert Johnson, Alfred-place, Blackfriars, chemist, for "Improvements in the materials employed in constructing and working atmospheric railways."—December 6.

Henry Heathcote Russell, of Millbank-street, Westminster, civil engineer, for "Improvements in constructing suspension bridges and viaducts."—December 6.

Josiah Wilkinson, of Lincoln's Inn-fields, gent., for "certain Improvements in filtering water and other fluids." (A communication.)—December 8.

Henry Augustus Box, of Great Titchfield-street, St. Marylebone, decorator, for "A new method of polishing, dyeing, and colouring marble, stone, and certain other materials used in the construction or decoration of houses and other buildings."—December 10.

Edward Green, of Wakefield, York, engineer, for "A new method of economising fuel, and certain improvements in retaining and applying heat for generating steam and heating water."—December 10.

Thomas Williams, of Norway-street, Middlesex, gent., for "a certain Improvement or improvements in wrenches or spanners."—December 10.

William Dines, of Oldston, near Dartmouth, Devon, Esq., for "Improvements in the making and fixing window glass."—December 10.

George Mordey Mowbray, of Paternoster-row, London, wholesale druggist, for "an Improved method of communication between the person or persons having the charge of a railway train and the controller of its motive power."—December 10.

Robert William Thomson, of Adam-street, Adelphi, civil engineer, for "an Improvement in carriage wheels, which is also applicable to other rolling bodies."—December 10.

Henry Lawrence, of Wigmore-street, Cavendish-square, gentleman, for "an Improved buckle, suitable for harness and other purposes."—December 10.

George Leach Ashworth, of Rochdale, Lancaster, cotton spinner, and Wilson Crossley, of the same place, manager, for "certain Improvements in machinery or apparatus for preparing and spinning cotton and other fibrous substances."—December 10.

James Garforth, of Dunkinfield, Chester, engineer, for "certain Improvements in machinery or apparatus for connecting of boilers, and other purposes."—December 10.

Alfred Vincent Newton, of Chancery-lane, mechanical draughtsman, for "Improvement in printing and dyeing various fabrics." (A communication.)—December 10.

Christopher Dunkin Hays, of Bermondsey, master mariner, for "Improvements in the construction and adaptation of apparatus for propelling and steering vessels on water."—December 10.

Charles Dowes, of Camden-town, gentleman, for "an Improved paper or material."—December 10.

William Mushet and Robert Mushet, iron founders, of Dalkeith, Scotland, for "Improvements in moulding iron."—December 10.

Thomas Victor Ailler, of Quai Saint Michel, Paris, gentleman, for "Improvements in breaks or machinery for stopping or retarding carriages."—December 10.

Frederick Gye, jun., of South Lambeth, for "Improvements in preparing aerated waters, and in vessels to contain aerated and mineral waters."—December 10.

Moses Poole, of Serle-street, Middlesex, gentleman, for "Improvements in apparatus to be used for drawing and marking." (A communication.)—December 10.

William Mac Naught, of Robertson-street, Glasgow, engineer, for "certain Improvements in the steam engine."—December 10.

Isaac Hawker Bedford, of Birmingham, for "Improvements in the manufacture of window and other glass." (A communication.)—December 12.

Moses Poole, of Serle-street, Middlesex, gentleman, for "Improvements in filling bottles and other vessels, and also in covering, stopping, or securing liquids and other matters in bottles and other vessels." (A communication.)—December 12.

Samuel Cunliffe Lister, of Manningham, York, gentleman, for "Improvements in carding, combing and spinning wool."—December 12.

Thomas Findler, of Flint, miller, for "Improvements in the construction and operation of certain parts of flint-grinding mills, and other grinding mills or machinery for grinding."—December 15.

John Robert Johnson, of Nelson-square, chemist, for "Improvements in purifying gas, and in the treatment of products of gas works."—December 20.

Henry Mandeville Meade, of New York, America, gentleman, for "certain Improvements in the manufacture of bread." (A communication.)—December 20.

George Fergusson Wilson, of Belmont, Vauxhall, gentleman, George Gwynne, of Regent-street, gentleman, and James Pillans Wilson, of Belmont, aforesaid, gentleman, for "Improvements in treating certain inflammable matters, and in the manufacture of candles."—December 20.

William Hannis Taylor, of Piccadilly, gentleman, and Francis Roubillac Conder, of Birmingham, civil engineer, for "certain Improvements in propelling."—December 20.

Jabez Church, of Colchester, gas engineer, for "Improvements in the manufacture of coke, and in the ovens for producing the same."—December 20.

John Blyth, of Limehouse, engineer, for "certain Improvements in diminishing the risk of accidental explosions of gunpowder and other substances which are liable to explode, or ignite by contact with fire."—December 20.

William M'Hardy, of Salford, for "certain Improvements in machinery or apparatus applicable to the preparation and spinning of cotton, wool, silk, flax, and other fibrous substances."—December 22.

Alfred Vincent Newton, of Chancery-lane, draughtsman, for "Improvements in combing wool." (A communication.)—December 22.

Samuel Heseltine, jun., of Bromley, Middlesex, civil engineer, for "Improvements in machinery or apparatus for dressing stones for grinding corn, grain, and other substances." (A communication.)—December 22.

Philip Smith, of High-street, Lambeth, lock-smith, for "Improvements in locks, latches, and other similar fastenings."—December 22.

CORRESPONDENTS.

Mr. Henry Carr, engineer of the Croydon Atmospheric Railway, in consequence of numerous inquiries, is anxious to state that the authorship of certain papers, which have appeared in this journal, with the initials "H. C." appended, is not to be attributed to himself.

Dr. Shoklitz, Limburg, Austria. On examining the invention, it appears to us so very impracticable, that we have not thought it worth while to give an account of it.

Next month, "Presbyterian Church, Dublin," and "Railway Key, Cardiff."

ON LIMES, MORTARS, AND CEMENTS.

From the Report to the Chamber of Deputies of the Commission appointed to consider the propriety of granting a pension for life to M. VICAT, *Engineer in chief, and Superintendent of Bridges and Highways.*

BY M. ARAGO.*

(*Translated from the French for this Journal.*)

Your Committee, from the time of their first sitting, have fully assented to the motive which suggested the proposition on which you are called to deliberate. They felt convinced that in submitting the *great discoveries* of our countrymen to the appreciation of the three constitutional powers of the kingdom, that in having recourse to all the solemnities of the law in regulating the remunerations which inventors may have deserved, they stimulate to the highest degree, and in the most beneficial manner the zeal, the ardour, the perseverance of men of genius.

We speak, solely of *great discoveries*. Respecting extensive works, however admirable in themselves, as this character does not legitimately belong to them, it does not appear our duty to invite the attention of the legislative Chambers.

These considerations mark out distinctly the course which we have to take. We have to examine whether M. Vicat is to be placed among the privileged men whom posterity will hold in remembrance; whether his works, when they came before the public, had the indisputable character of novelty; whether they possess general interest; whether, in fine, the results arising from them ought to take their rank among the brilliant inventions for which our country justly claims honour.

This brief preamble will justify the detailed observations which you are about to hear. We considered that in submitting to analysis the strictest and most minute a merit, so well recognised as that of M. Vicat, we should inspire a salutary distrust in those mediocrities who would have their names resound in this place. If the Commission have attained this end, they will, without doubt, have satisfied beforehand one of the objects of the Chamber.

MANUFACTURE OF HYDRAULIC LIMES.

Lime, whether in a state of purity, or, as is more usual, mixed with other substances, is the material used from the remotest times to bind together stones and all the constituent parts of buildings. If lime be not found in any part of the globe pure, the rocks from which it may be extracted—the calcareous rocks—exist almost everywhere. No mineral is so widely distributed by nature.

It is rare that calcareous stones are entirely pure, or exclusively composed of lime and carbonic acid. Their substance is usually made up of silex, aluminum, magnesia, oxyde of iron, manganese, &c. Thence the terms adopted by mineralogists of argillaceous, magnesian, ferruginous, or manganesian limestones.

These limestones furnish by roasting very different limes. Builders distinguish many kinds of them—rich lime—poor lime—hydraulic lime. Rich lime increases greatly in bulk when slaked; its weight is then more than doubled. This property would be very valuable in respect of economy did not rich limes remain a long time without hardening, especially in the centre of masonry, and particularly where they are kept from the action of the air; rich limes, moreover, are dissolved to their last particles in water frequently renewed; this solubility of the lime in time converts masonry into mere heaps of stones: quay-walls, for instance, which have been supposed to have been built of strong masonry, and with the greatest solidity.

Is it necessary to cite examples to shew that the rich limes will not harden without the action of the air? We may point to the fact that M. Treussart having had to reconstruct in 1822, at Strasburg, the foundations of a bastion built in 1666, found there the mortar as fresh as if the masons had laid it some few hours before. A similar circumstance was observed at Berlin by the architects who took down one of the pillars of the tower of St. Peter, built about 80 years ago.

Are we required to shew that the constant action of water dissolves rich limes in masonry? We choose among a thousand examples the demolition of the remains of the ancient sluices of the Vilaine. During this operation, it was found that, by the dissolving of the rich lime, there remained behind the revetement walls nothing but masses without cohesion, simple heaps of loose stones.

Poor or thin lime has all the defects of rich lime, and moreover, as its name indicates, but slightly increases in bulk. The use of it is therefore, as much as possible, avoided.

* Notices of M. Vicat's hydraulic lime, for resisting the action of water, will be found in the first volume of this journal, p. 4, and in vol. VI., p. 229.

Builders who desire to make their works lasting, must employ exclusively hydraulic limes, especially for foundations resting on a damp soil.

Hydraulic limes are those which readily harden under water. This property does not develop itself always in the same degree. The most valuable hydraulic limes begin to set the second to the fourth day after immersion; at the end of a month they are hard and quite insoluble; in the sixth month they assume the nature of certain *limestones*, a blow breaks them with a sharp sound, and the fracture has a laminated appearance.

The natural limestones are not distinguished in general from each other by any particular physical character of their texture, hardness, specific gravity, or colour, which will enable us to predict what kind of lime they will furnish. The rich, the poor, and the hydraulic limes are imperfectly white, grey, fawn-colored, red, &c. It is in the internal composition of rocks, in the nature and proportion of their constituent principles that the chemists have sought the real causes of the power of hardening under water (*hydraulicité*).

It has been long proved that the most pure limestones, the statuary marbles, primitive or saccharoid, the marbles of Paros and Carrara, always give by calcination the rich lime; it is also well known that the property of hardening under water is communicated to lime by particular substances contained in the material of the calcareous rock from which the lime is made. But what are these substances, and in what proportion ought they to exist in the limestone, to produce the requisite property in a sufficient degree? On this point opinions have long been divided.

Bergmann (for the greatest chemists have occupied themselves with the question,) attributed the characteristic properties of hydraulic limes to the presence in them of a small proportion of the oxyde of manganese.

Guyton-Morveau adopted the idea of his illustrious friend. It was evident, nevertheless, that the hypothesis did not afford a general solution: there are known to exist natural hydraulic limes in which there is no trace of the oxyde of manganese. It has even been stated that this oxyde does not possess the property assigned to it. A sluice constructed in Sweden, according to the notions of Bergmann, with a mortar composed of rich lime and manganese, was found so defective that it was necessary to destroy it a very short time after it was constructed.

The earliest investigations which we are acquainted with on the composition of hydraulic limes, date from the year 1756, that is, from the epoch when Smeaton proposed for bold task of building the Eddystone lighthouse. This great engineer then examined with the most scrupulous care the natural hydraulic lime of *Aberthaw*, Glamorganshire. This lime had in England a certain celebrity. Treated by acids, it left a residue "which *appeared* to be a bluish clay, weighing about $\frac{1}{8}$th of the total weight of the stone." The reddish colour which this residue acquired by roasting, induced Smeaton to think the calcareous rock of Aberthaw (it was already called *lias*) contained *iron*.

Saussure published in 1786, in the second volume of his celebrated travels, some observations tending to attribute the hydraulic property of the limes of St. Gingoulph, in Savoy, to the combined influence of manganese, quartz, and even clay, contained in the calcareous rocks of that locality. It must be added, for the sake of accuracy, that the illustrious naturalist leaves his opinions in the form of simple conjectures.

One more citation, and we shall have gone over the whole of the researches which preceded those of M. Vicat.

M. Collet-Descostils, Engineer of mines, having, in 1813, discovered a remarkable quantity of silicious matter in a very divided state in the lime of Senonches, attributed to the presence of silex, the hydraulic property, which is so energetic, and well known in this lime.

What was wanting in the conjectures of Smeaton, of Saussure, of Descostils? They wanted that which transforms simple conjecture into incontestible principles; they wanted the precision and clearness, the never-failing marks of established truths; they wanted to be resolved and simplified—to pass, in a word, by the impulse of a powerful hand, from the vague cloudy region of reveries into the place of practical truths.

In his first essays M. Vicat made use of synthesis; every one who had remarked how much the crystalline or nolecular condition modified the physical properties of certain bodies could not attach, but a limited confidence in the advantages to architecture likely to proceed from the chemical analysis of limes. The experiments of M. Vicat were directed straight to the object in view.

The natural limes of Senonches were the type of perfection. M. Vicat composed an *artificial* lime, superior to that of Senonches. He obtained this great result by calcinating, in proper proportions, chalk or pure lime, mixed with clay. By this experiment light succeeded to obscurity, certainty to doubt; the art of building had received the accession of an *admirable discovery*.

We do not suppose that this merit can be contested. We cannot believe that the desire, unfortunately too common, of robbing a contemporary of honor to the profit of the dead, will influence any one to exaggerate the value of the essays, hypotheses, and conjecture, previous to the labours of the engineer of the bridge of Souillac. It may be proved incontestibly that M. Vicat is not less really the discoverer in the subject of hydraulic limes than Newton was when he published the Theory of the Composition of White Light, or than Franklin was when he proposed lightning conductors to the civilised world. The great Smeaton essayed fruitlessly to render the rich lime hydraulic by the addition of clay without preparation; Smeaton mistaking, after repeated trials, the necessity of *roasting* the clay, showed, moreover, more clearly than all reasoning could do, the immense distance which separates simple appearances from realised and complete discoveries.

M. Vicat has carried out his felicitous investigations in all respects relating to the uses to which lime is appled in masonry; the art of burning lime, of dispelling, in the most effectual and economic manner, the carbonic acid, one of the constituents of calcareous rocks, is indebted for important remarks to the labors of our celebrated engineers; after the precise directions which these labours explain, there can be no hesitation as to the methods to be adopted to foresee at once what will ultimately be the qualities of any given samples of lime. To understand the processes which must be followed to slake limes of different sorts, we may consult with much profit the result of the experiments of M. Vicat; the choice of the materials which unite with limes of all kinds to form mortars will no longer be a matter of blind routine.

The necessity of being concise compels us to mention merely under this head the interesting researches of M. Vicat. We suppress, for the same reason, the analysis of the refined theoretical considerations, by the aid of which our engineer explains the gradual and prolonged action of limes on the substances with which they are combined in the mixing of mortar. We regret also to be compelled to refrain from the agreeable task of rendering full justice to the admirable experiments of M. Berthier, one of the best chemists of whom France can boast.

Cements.

M. Vicat has occupied himself with equal success in investigating the properties of *cements*.

Architects distinguish cements from mortars by their natural appearances. The sand contained in *mortar* exists there in the form of gravel more or less coarse, and more or less apparent. The composition of *cement* appears homogeneous, although it contains lime, silex, and alumina.

No substance has gained more celebrity among builders than that known at the present day as *Roman Cement*. This cement, called originally *aquatic cement*, was made in the year 1796 by Messrs. Parker and Wyatt. It was the result of subjecting to heat certain nodules of limestone of an ovoid form found in great abundance at some distance from London. Roman cement, mixed rather thick, solidifies in a few minutes either in air or water. There are certain works, the Thames Tunnel for instance, which could not have been executed without Roman cement. Under other circumstances this rapid solidification is a real obstacle; and in such cases it is necessary to substitute hydraulic lime, of which the price is much less.

Parker and Wyatt manufactured their cement, and found a sale for it throughout Europe; builders used it, but no one took notice of the real cause of its singular properties. The discovery of this cause belongs incontestibly to M. Vicat. We find, in fact, that after having indicated the proportion of clay which renders lime hydraulic, the skilful experimenter published in 1817 this categorical observation—

"When we increase the proportion (of clay) to 33 or 40 per cent., we obtain a lime which does not slake; but it pulverises readily, and produces, when wetted and mixed up, a composition which quickly sets under water."

The proportion of clay indicated is precisely that of the substance manufactured by Parker and Wyatt. M. Vicat made, then, from 1817, every kind, not only of hydraulic lime, but also of Roman cement.

The duty assigned to your Committee does not permit the citation of facts purely scientific; they therefore desire to remark that the discovery of our engineer respecting cements comes, in a great measure, under the description of practical applications. Here, as in the case of hydraulic limes, and as in other cases to be explained hereafter, geology, enlightened by M. Vicat as to the industrial value of limes containing a large quantity of clay, has directed its attention to these useful investigations, and the French builders, not long since dependent on England, have discovered a great number of places where they can prepare Roman cement. M. Vicat himself has pointed out more than 400. This new branch of industry is carried on with much success in many departements of France.

If the limits of this Report permitted, we could mention here many persons who have deserved great credit by the discovery of quarries of Roman cement, and, among others, a skilful engineer, whom the Chamber of Deputies reckons among its members, M. Lacordaire.

Pozzolanas and Tarras.

The natural pozzolanas, in the hands of ancient architects, tarras in the hands of mediæval architects, have played too important parts to have escaped the attention of M. Vicat. Despite all the difficulties of the subject, success, as regards practical results, has completetely crowned the patient and laborious investigations of the engineer.

The name of *pozzolana* is given to a volcanic substance found in great abundance in the neighbourhood of Pozzala, and of Rome.

Tarras is a conglomerate, also volcanic, found on the banks of the Rhine, and especially in the environs of Andernach.

To render rich lime hydraulic, it is sufficient to wet it in proper proportions with pozzolana or tarras. What more simple or convenient mode could be imagined? But in many localities the expense of conveyance renders it impossible to use either pozzolana or tarras. Many attempts have been made to prepare substances which possess the same properties. Chaptal thought he had resolved the problem by very much calcinating certain schists or ochreous clay. But even supposing the properties of tarras and pozzolana to be reproduced in this manner, the difficulty was only shifted. The schists experimented on by Chaptal are not common in France; and there is, moreover, in the operation recommended, even if ochreous clay be employed, a circumstance the very high temperature requisite, which opposes an irremediable difficulty.

M. Vicat resolved the questions into its elements. This solution is as follows:—

Artificial pozzolana superior, or at least equal to the best Italian pozzolana may be obtained by a simple manner of using clay of the purest kind. This method consists in *slightly* calcinating the clay, in merely driving off the water of combination, and always keeping the temperature between 600° and 700° centigrade (1·112° to 1·292° Fahr).

The mind rests with satisfaction on the solutions of problems of practical art when they possess this admirable simplicity. On the other hand, one is astonished to see an operation so easy that the workmen call it a *tour de main*, enrich a kingdom, or rather the whole world with a substance eminently useful, and which appeared as if it must inevitably remain the privileged property of a corner of the earth once the seat of volcanic eruptions.

We should fail of our duty if, after having cited the discoveries of M. Vicat in the difficult subject of pozzolanas, we omitted to mention that M. le General Treussart, whose premature loss the whole army deplores, has left a work on this subject filled with useful observations and valuable remarks.

The publications of M. Vicat have long since satisfied all the necessities of art, for the execution of works in fresh water, in canals, rivers, and streams. The sea water gave rise to grave difficulties which no one had anticipated. M. Vicat has the double merit of having pointed out the evil and indicated the remedy.

According to new and quite recent researches of M. Vicat, sea water has some tendency to decompose cements of every kind. It attacks indiscriminately those which contain rich limes or hydraulic limes, natural or artificial pozzolanas. This tendency results from the presence in the water of certain acids which have a great affinity for lime. M. Vicat has found the means of resisting this prejudicial effect and removing it. He is at this time preparing to point out the limes, pozzolanas, and cements which, prepared according to the old methods, will resist the destructive action of the sea; and with respect to others, to shew the modifications to which they must be subjected, to acquire the same power of resistance. It will be apprehended that in so nice a question M. Vicat will be in no haste to announce his discoveries. We may, however, state that the public will in a short time be put in possession of them. It is just to state that they already tend to the rejection of a certain kind of pozzolana proposed for the port of Algiers, and the employment of which has led to such disastrous consequences. The reserve wisely maintained by M. Vicat gives him the opportunity of supporting his system by decisive experiment: the *artificial* pozzolanas employed with so much success at Calais by M. Néhou, Engineer in Chief, are found to satisfy *fortuitously* the conditions, laid down by M. Vicat in his new labours, of preservation against the sea.

Statistics of Hydraulic Limes.

The materials for building recommended by M. Vicat did not meet with the usual fate of new things. The proofs of superiority were palpable, and the old system at once acknowledged itself vanquished. Scarcely had a few months elapsed after the publication of the memoir of the Engineer of the Souillac bridge before the artificial hydraulic lime was brought into use at Paris for quays, at the landings of the bridge of Jena, for the construction of four large *abattoirs*, and for the works on the Canal St. Martin.

Since then the artificial hydraulic lime has been less used; for it is now usually substituted for the natural lime of which the price is lower, and which possesses the same qualities. But we hasten to repeat the remark that it is principally owing to M. Vicat, that constructors daily avail themselves of new wealth in every part of the kingdom.

Our engineer had too much penetration to avoid the conjecture that if, according to his discovery, lime became hydraulic by the simple addition of clay, there must be innumerable formations of argillaceous lime-stones throughout the kingdom capable of affording hydraulic lime by roasting. The idea having taken possession of M. Vicat, he has for twelve years explored almost every one of our Departements. His publications under the modest title *Statistics of Hydraulic Limes*, have revealed this invaluable wealth in numberless localities where its existence was not even suspected. The Departements where natural hydraulic lime is found in the greatest abundance are Lot, Lot-et-Garonne, Tarn, Dordogne, Garel, Ardeche, Drôme, Gers, Charente, Hérault, Cher, Allier, Nièvre, Yonne, Côte-d'Or, Ain, Isere, Jura, Doubs, Haut-Rhin, &c. Of twenty-four Departements already explored, there are no more than six or seven, of primitive earths, where hydraulic lime is entirely wanting.

We proceed to relate two facts which exhibit in a striking manner what was the state of the knowledge of practical men respecting the wealth of our country in hydraulic limes when M. Vicat commenced his examinations for it.

When he visited Marseilles, a new basin was being dug. The contractors were at great expense to get rid of an immense quantity of calcareous refuse. On examination M. Vicat found that this matter would furnish sufficient hydraulic lime for the construction of the whole basin.

The following is a still more remarkable fact, especially when estimated by its consequences.—

At the time of constructing the canals of Bretagne there was great difficulty in procuring hydraulic lime. M. Vicat undertook the mission of visiting the localities, and almost immediately discovered in the quarries of Ponpean, near Rennes, between the beds of rich lime which had been worked from time immemorial, a bed of greenish marl known by the name *brule-mort-vert*, which the lime-makers rejected. This rejected bed, after the examination of M. Vicat supplied not only all the works of the Vilaine, and the canal of Isle-et-Rance, but has become the sole resource of that part of the kingdom for all hydraulic works.

Economical Considerations.

The price of lime almost always forms a considerable item in the cost of masonry. Limes have very different properties which determine the duration of works and the *mode* of executing them. In countries where lime is abundant and of good quality, the buildings last for ages without having required great expenses for their erection. In such districts habitations, even for the poorest classes, may be built with strict regard to healthfulness and preservation from accidents by fire, by the violence of storms, and the destructive effects of inundations and great rains. It is on account of such useful applications as these that the labours of engineers and chemists deserve the attention of the public authorities and the legislature. Let us consider for a moment this phase of the question: let us seek to value the number of the services which, in this respect M. Vicat has rendered to his country.

It was at Paris that the discoveries of M. Vicat first received a powerful impulse from the influence of M. Bruyere, it is at Paris that we find a valuation of the economy effected by these discoveries.

Before 1818 the hydraulic works of the capital were almost all executed in plaster or with rich lime. Thence arose the annual expense of numerous and costly repairs. From 1818, the date of M. Vicat's first publication, recourse was had to hydraulic lime. It is hydraulic lime which gives to new buildings an almost infinite durability.

The same solidity might have been obtained with the lime of Senonches; but the lime of Senonches conveyed to Paris costs 80 to 90 francs the cubic metre, while the lime from the quarries from which plaster is obtained, that lime which, before the researches of M. Vicat, was rejected as refuse, costs about 40 francs. This difference of cost reckoned for 37,000 cubic metres of lime, the quantity used in Paris from 1818 to 1841 in the construction of sewers, reservoirs, canals, &c. gives a total saving of more than 1,500,000 francs.*

One of the members of your Commission superintended part of the works of the fortifications round Paris. He has laid before his colleagues detailed tables, from which it is concluded satisfactorily that at Belleville alone during the years 1840-1-2-3-4 a saving of more than half a million [of francs] has been the consequence of using certain lime which was found on the spot, but which would have been considered of no value before the learned publications of M. Vicat.

We now proceed to offer some tables, in which the saving resulting from the labours of the celebrated engineer appear on the grandest scale.

Sluices and Barrages constructed in France in accordance with the laws of Aug. 5, 1821, and of Aug. 14, 1822.

NAMES OF CANALS.	Number of Sluices.	Number of Barrages.
Rhone and Rhine	162	
Somme	24	
Ardennes	49	
Isle	39	39
Aire and Bassée		
Bourgogne	191	
Nantes and Brest	234	
Isle-et-Rance	28	
Blavet	28	28
Arles and Bone	4	
Nivernais	114	
Berry	115	
Branch to the Loire	45	
Tarn	9	9
Oise	7	7
In accordance with the laws of July 3, 1838, and July 8, 1840.		
Marne and Rhine	180	
Branch to the Garonne	50	
Improvements of River Navigation.		
Branch to the Marne	14	
Charente	10	
Dordogne	9	
Tarn	6	6
Lot	80	47
Totals	1348	186

* About 60,000*l.* English. The metre is rather more than 3 feet 3 inches.—Ed.

LARGE BRIDGES OF HEWN STONE, &c.

To establish a comparison sufficiently exact between the cost of bridges erected on caissons and piles, and of those which, at the present day, are erected on a foundation in concrete, it will be necessary to take some unit of comparison which is independent of the number of arches and their size. We will choose the area of the surface between the parapets for our purpose.

Proceeding thus, it is found for bridges, where it has been possible to substitute the modern method for the ancient that the square metre costs, on the average, 1,312 francs.*

Now, for bridges erected under altogether similar circumstances, but on foundations in concrete, the square metre has cost, on the average 625 francs. The proportion of the expense of the old system to that of the new, is as 100 to 47. According to this calculation, if a bridge erected on foundations like those of Jena or of Sevres cost, on the average, 2,600,000 francs [104,000*l.*] a similar bridge built in the modern plan would not cost more than 1,222,000 fr. [48,880*l.*] consequently the saving would be 1,378,000 francs. Since 1818 there have been 19 great bridges built on foundations in concrete, which, therefore, may be reckoned a saving of 26,182,000 francs [1,047,280*l*].

Of bridges of the average size having a span of 15 or 16 metres for each arch the number is about 30. For each, reckoning in proportion there would be a saving of 235,000 francs, or for the 30 the saving would be 7,050,000 francs [282,000*l.*].

As for bridges of a single arch of 15 to 20 metres span, there have been constructed more than a thousand during the interval of five and twenty years on royal highways and departement-roads. In each of these the average saving by the substitution for coffer dams of hewn stone with concrete, in the foundations has been 25,000 francs, or for the whole 25,000,000 [1,000,000*l.*].

Suspension Bridges.

Prior to July, 1843, there were authorised to be constructed 327 suspension bridges of one, two, three, or four spans. If we calculate each to have a span of 100 metres [325 feet English], each costing 100,000 francs [4,000*l.*], deducting from this sum 30,000 francs [1,200*l.*], the cost of the platform and means of suspension, there remain 70,000 fr. for the foundations and masonry. Experience having showed that for bridges, as for locks, the expense has been reduced more than one half, there would be grounds for reckoning here a reduction still more considerable; still, we will estimate it at one half, and then the saving will be 22,890,000 fr.

Recapitulation of the Economy effected.

	francs.	
Weirs	67,850,000	
Barrages or sluice gates	18,600,000	
Locks, &c.	20,000,000	
Large bridges	26,182,000	
Common bridge	7,050,000	
Single-span bridges	25,000,000	
Suspension bridges	22,890,000	
	182,072,000	[£7,282,880]

Other constructions in which economy has been effected but without sufficient documents to shew the actual amount are,

1. Wooden or iron bridges, on foundations of masonry.
2. Bridge of a single arch, of from 6 to 10 metres span.
3. Marine quays, dikes, basins, &c.
4. Foundation of public and private buildings in towns.
5. Military Works.

It is important to remark, that we have not taken into account the question of time. Now, in these matters, time is money, and becomes, financially speaking, a consideration of the highest importance. The new system of foundations allows the execution of works to be done in one or two years that formerly took five or six. There is therefore in this respect also a considerable saving.

One conclusion springs out of all the preceding evidence—it is that supposing the constructive arts such as they were before 1818, the period of the discoveries of M. Vicat, the greater part of the important works in course of execution would have stopped by the considerations of time and expense.

If we did not estimate, how much the remuneration demanded will acquire value from the imposing manner in which it is granted, we should have omitted all these sums and the accompanying remarks. In a purely financial point of view, what are 6,000 francs pension beside the colossal economies for which the country is indebted to the labours of M. Vicat?

The Works of M. Vicat compared with those of the Ancients

Certain of the learned profess an admiration, absolute, passionate, for the monuments of antiquity. According to them, the Greeks and Romans had discovered everything in the constructive arts. The solidity of edifices yet remaining show that the moderns are the real disciples. M. Vicat has simply *re-discovered* the methods practised in Egypt, at Athens, at Rome, of which the remembrance was lost in the times of barbarism.

Although we do not perceive any injury that these reflections will do

* About 4*l.* 0s. 6. per square foot.

to the labors of M. Vicat—although the discovery of lost truth seems to us altogether similar to the discovery of a new truth—your Commission has devoted itself to a minute examination of the pretended superiority of the ancients over the moderns in the art of building. We have examined, moreover, whether this superiority can be maintained on reference to the progress due to the discoveries of our illustrious engineer.

"Some of the Roman mortars have lasted eighteen centuries. A great number of modern buildings are in a deplorable condition!"

This comparison is essentially erroneous. To give it any value we must draw a parallel between none but the greatest monuments of the two epochs. The results will then be very different to those on which the learned support their position.

The ramparts of the Bastille were of extreme solidity even in the centre of the masonry. It was necessary to use gunpowder to destroy them. Gunpowder was also found necessary a few years ago to destroy at Agen the ruins of a bridge built about the year 1200. M. Vicat himself ascertained that the mortar of the bridge of Valentré, built at Cahors in 1400, surpassed in hardness that of the ancient theatre, of which the ruins are seen in that town.

Ancient architects, like modern, built according to the nature of the materials at their disposal, and also according to finâncial exigencies, either edifices which were indestructible, or with the same exterior forms, temples, palaces, and houses, without solidity. The constructions of the latter class rapidly disappeared. The others alone have resisted the ravages of time and the violence of the seasons. The blind admirers of bygone ages, have they forgotten the words of Pliny, "The cause from which at Rome so many buildings fall is the bad quality of the cement."?

If, as it is pretended, the Romans knew certain methods of preparing good mortar, we ought to find this substance in all their public monuments with qualities almost identical. Now this is not even the case in comparing different parts of the same edifice. The Commission have remarked in many publications of M. Vicat's experiments which throw great light on this subject; those, for instance, made with mortar taken from different points of the bridge of Gard; these experiments give resistances varying in the proportion of *one to three*.

Those who devote themselves to these comparisons should remember that time acts unceasingly in foundations on the hardness of mortar. The mode of action by which this *conglomerate* hardens—acquires adhesiveness—is still a matter of controversy among the learned. But no one can deny that there are circumstances under which it is impossible for this mysterious action to continue for a long series of ages.

It would seem forgotten, that in considering the knowledge of cements in the art of building, we are not reduced to simple conjectures. Vitruvius, contemporary and architect of Augustus, has left a detailed account of the precepts in use among the builders of Greece and Rome. These precepts are far from justifying our unreserved admiration of the ancients.

The ancients were not in possession of any exact notion concerning the chemical modification that calcareous stone undergoes in the kiln, a modification by which its friability is so much increased. Neither did they know anything of the kind of action which restores to the disintegrated molecules of this stone converted into lime, the adhesion and hardness of which they had been deprived by heat. The efforts of Vitruvius to give a plausible explanation were ineffectual. The same was the case until the chemical discoveries of Black respecting carbonic acid, with the attempts of the most illustrious successors of Vitruvius, Scamozzy, Philibert Delorme, Perrault, &c.

One single word will disabuse all those who persuade themselves that the theoretic errors of these great architects are of no consequence. Take the instance of Philibert Delorme: to arrive at a maximum of solidity in edifices, he thought it necessary that the lime should be taken from the same bed of limestone as the materials of the masonry. This direction, if it had been followed out, would have involved an enormous increase of expense.

Builders who regulated the choice of their lime by the colour of the rock from which it is obtained; who were not acquainted with any natural hydraulic lime: who were lavish in mixing with their lime broken pottery and brick rubbish, cannot, without great injustice, be compared with modern constructors. Putting aside the excellent observations on the properties of *natural pozzolanas*, on the possibility of using this material to make enormous artificial blocks to be sunk in the sea, we find that the Romans have taught us nothing essential in the art of building.

For the rest, every attempt to exalt the merit of the ancient in the constructive arts only redounds to the merit of M. Vicat. The best mortar extracted from Roman monuments has, after two thousand years of antiquity, a hardness precisely equal to that which M. Vicat obtained with good limes in the short period of a year or eighteen months. In applying the comparison to average resistances, the advantage greatly preponderates for the modern mortar.

Opinions of Chemists and Builders on the Labours of M. Vicat.

The importance of M. Vicat's discoveries is palpable. For about a quarter of a century all builders have taken advantage of them: now, in such matter, it must be readily understood that it must rest with the actual practitioner to pronounce a definitive judgment. Nevertheless, not to neglect any kind of information, the Commission have thought it right to gather the opinions of chemists and engineers, who are occupied, with the greatest success, in the application of science to the arts. In this examination we have met with the most flattering recognitions of the labours of the celebrated engineer; no one appears to have contested their novelty.

Is the first memoir of M. Vicat on the production of artificial hydraulic lime presented to the Academy of Sciences? That learned body decide on the motion of MM. de Prony, Girard, and Gay-Lussac, that the memoir shall appear in the celebrated collection entitled *Receuil des Savants étrangers*. To this mark of approbation, the greatest that academic commissions ever give, was soon added a proof of esteem sought for throughout the world; the Academy named M. Vicat one of its correspondents.

The Council of Bridges and Highways, called upon at the commencement of 1818, to declare its opinion on the artificial formation of hydraulic lime, declare, by their organ, the accurate and skilful M. Bruyere, "that the advantages of the new method were innumerable, that they dispensed with the costly employment of real pozzolanas, and that of stones of large dimensions, lavishly used in modern buildings, in spite of all the examples to the contrary afforded by the Romans and Goths." "We may predict," adds the sagacious Inspector-General, "that some years hence, no other mortar will be allowed in public buildings. When M. Vicat made known the first part of his statistical labours on the hydraulic limes of France, the Academy decreed to him one of the medals founded by Montyon.

Let us take the opinion of M. Berthier, the most competent judge of the labours of M. Vicat who could be found in the whole world. "The researches of M. Vicat on limes and mortars ought to be placed in the rank of the best works due to members of the *corps* of bridges and highways. His discovery relative to the manufacture of artificial hydraulic limes is of the highest importance . . . . In making it public, M. Vicat has acted the more nobly, because he might have made a considerable fortune either by selling the lime or by securing a patent of his invention."

M. Dumas, (we will quote only those of the greatest celebrity in science) declares in his *Chimie Appliquée aux Arts*, that the solution of the long debated question of hydraulic limes is due *entirely* to the labours of M. Vicat. In speaking of artificial pozzolanas, the illustrious chemist observes, "It is, however, from labours in the laboratory that M. Vicat has been led to the important discovery with which he has enriched the arts. The state in which he found the question renders the discovery the more remarkable."

We could borrow proofs equally flattering from a host of writers, and especially from two excellent articles by M. Chevreuil, inserted in the *Journal des Savants*. These opinions, notwithstanding the high authorities from whom they emanate, ought not, doubtless, to prevent the commission from making the minute enquiry of which the Chamber has heard the results, but your commission, since they have by their own researches been led to the opinions professed by the Academy of Sciences, and the judgments of Gay-Lussac, of Berthier, of Chevreuil, of Dumas, of Bruyere, desire to avail themselves of a circumstance which proves they have not erred.

Conclusion.

To resume;

M. Vicat was the first to demonstrate that the properties of natural hydraulic limes depend on *clay* distributed throughout their substance, that is, on a particular action which silex united with alumina exercises on lime when these substances are brought by heat to a proper state.

M. Vicat has been the first to make hydraulic lime of all kinds, not only in small quantities in the laboratory, but in large quanties for the foundations of his bridge of Souillac. The piers of this noble bridge rest on a foundation of concrete formed with artificial hydraulic lime. Since the labours of M. Vicat, means have been found of procuring, whenever it is necessary, lime, which readily sets in water.

M. Vicat has liberally given his discovery to the public. It is certain that if he had secured by a patent the privilege of making the artificial hydraulic lime, this engineer would have acquired an immense fortune.

The first discovery of M. Vicat has faded, if the expression may be permitted, beside the important results deduced from it. We have seen this indefatigable engineer traversing France step by step, seeking beds of calcareous marl, clay formations in which were united naturally in proper proportions, the constitutive elements of hydraulic limes; we have followed him during twelve years in this search which has become so successful that there are now known on French ground by the sole labours of M. Vicat 900 quarries capable of furnishing hydraulic limes, while before there were reckoned only eight or ten. M. Vicat has so well appreciated the honour of having discovered and placed in the hands of constructors, such wealth hidden in the bowels of the earth, or been rejected at its surface, that in order to complete this work he has recommended the advancement to which his standing and merit give him claims uncontested and incontestible.*

The works of M. Vicat on *pozzolanas* have been equally decisive. They have proved that the parent clays afford artificial pozzolanas superior, or at least equal to the Italian; and as nature has distributed clay with a kind of profusion on the surface of the globe, nothing prevents us at the present day from easily obtaining excellent pozzolana in every region.

France, which before the time of M. Vicat, was tributary to England for Roman cement, could now supply the wants of the whole of Europe.

The general system of foundations, by means of concrete, dates from the

* M. Vicat, appointed divisionary inspector under M. Dufaure, has requested to remain with his rank of engineer in chief to continue the investigation which he has so felicitously commenced.

discoveries which we have analysed, and particularly from the admirable works of the bridge of Souillac. Engineers, to their honour, never refuse to assign a large share to M. Vicat of the success which they obtain, even when circumstances permit them to have recourse exclusively to natural hydraulic lime, and natural pozzolanas. Thus, for example, on the occasion of the entirely successful completion of the new basin for repairing vessels at Toulon, founded 42 feet above the level of the sea, the able director of these works, M. Noel, wrote on the 24th of April last to the Under Secretary to the Department of Public Works; "At a time when the law respecting M. Vicat is about to be discussed, it will not be superfluous to bring to your knowledge a fact which gives a new importance to the labours of the illustrious engineer who has done so much for the advancement of our art."

Thanks to the laborious and patient researches of M. Vicat, works once deemed *impossible*, are executed at the present day safely in every part of the kingdom, and without requiring enormous expenses.

We will not repeat the numerical computations already given respecting the economy effected in public works by M. Vicat's invention. Those computations should be retained in every mind. It would, in fact, be difficult to cite a discovery which, in the short interval of 26 years, has produced such colossal and useful results.

The Commission are unanimously of opinion, that in voting, without some modification, the law which has been proposed by the Minister of Public Works the justice rendered to M. Vicat would not be complete. They would desire that the pension of 6,000 francs should be accorded more explicitly under the title of a *National Recompense*. This is the only change of which the Government proposition appears to us susceptible. We trust that the Chancellor, adopting our opinions respecting the services rendered to the country by M. Vicat, will assent to the amendment which we have the honour of suggesting, and which has already received the sanction of the Minister of Public Works.

ATMOSPHERIC TRACTION.

SIR—Since the appearance of Mr. Haydon's paper in your November Part, I have been inclined to pay some attention to the atmospheric system. The favourable results actually obtained after so few attempts led me to expect some error in the numerical example appended to the forementioned paper, especially when the length of the formula and the difficulty of substitution were taken into account. I made several attempts with the formula as it now stands, but in every case arrived at different results, and each of them at variance with that deduced from the work done each stroke. One source of error seems to have arisen from taking $R = 99$, instead of its exact value $\frac{1053909}{1067374}$ for if $R^n = \frac{1}{3}$ we get $n = 111$ or 87, nearly according as the former or latter is used. I was surprised at the difference in the results, but it teaches us how careful we ought to be to ensure *approximations in our results*. In my application to the example at Dalkey, I shall suppose the whole length of the connecting pipe to be used for propelling the train, as local circumstances compelled them in that instance, to place the engine at an inconvenient and extravagant distance from the main tube.

Let w_n denote the work done during the nth stroke of the air pump.

W_n denote the work done at the end of the nth stroke.

W'_n denote the work done during the motion of the train, their having been n strokes of the air pump before the train started.

W, the useful effect communicated to the tube piston.

Then it is found by Mr. Haydon, that

$$w_n = 15\,a\,k\,R^{n-1}\left\{1 - \overline{n-1}\log_e R + \frac{S-A}{A}\log_e\frac{S-A}{S}\right\}$$

$$W_n = 15\,a\,k\left\{\frac{1-R^n}{1-R}\left(1 + \frac{S-A}{A}\log_e R\right)\right.$$

$$\left. - \left(R\,\frac{1-R^{n-1}}{(1-R)^2} - \frac{\overline{n-1}\,R^n}{1-R}\right)\log_e R\right\}$$

$$\text{Where } R = \frac{B+C}{A+B+C} \text{ and } A+B+C = S$$

$$\therefore (1-R) = 1 - \frac{B+C}{A+B+C} = \frac{A}{S}, \text{ or } \frac{S-A}{S} = R,$$

$$\therefore w_n = 15\,a\,k\,R^{n-1}\left\{1 + \left(\frac{S}{A} - n\right)\log_e R\right\} \qquad \text{(A)}$$

$$W_n = \frac{15\,a\,k}{1-R}\left\{1 - R_n + R_n\log_e R^n\right\} \qquad \text{(B)}$$

after the proper substitutions have been made.

The correctness of the simplification may be tested in the following manner: $W_n - W_n - 1 =$ work done at the nth stroke—that done at the end of the $\overline{n-1}$th.

$$= \frac{15\,a\,k}{1-R}\left\{1 - R^n + R^n n\log_e R - (1 - R^{n-1} + \overline{n-1}\,R^{n-1}\log_e R)\right\}$$

$$= \frac{15\,a\,k}{1-R}\left\{R^{n-1} - R^n + \left(-n\,(R^{n-1} - R^n) + R^{n-1}\right)\log_e R\right\}$$

$$= 15\,a\,k\,R^{n-1}\left\{1 + \left(\frac{1}{1-R} - n\right)\log_e R\right\}$$

$$= 15\,a\,k\,R^{n-1}\left\{1 + \left(\frac{S}{A} - n\right)\log_e R\right\} = W_n = \text{work done during the}$$

nth stroke. Let n have such a value that $R_n = \frac{1}{3}\,m$ then $n = 87$ nearly.

$$W_{87} = \frac{15\,a\,k}{1-R}\left\{1 - \tfrac{1}{3} - \tfrac{1}{3}\log_e 3\right\}$$

$$= \frac{5\,a\,k}{1-R}\left\{2 - (1{\cdot}098612)\right\} = 5\,a\,k\,\frac{S}{A}({\cdot}90138771)$$

$= 720\ S \times 90138771$ lb. raised one foot.

Where $S =$ vol. of the tube and air-pump cylinder expressed in feet.

$W_{87} = 720 \times 10673{\cdot}74 \times {\cdot}90131771 = 6{,}927{,}242.$

$W'_{87} = 5 \times 176{\cdot}7 \times 8588 = 8{,}335{,}720.$

$W = 10 \times 176{\cdot}7 \times 8588 = 15{,}174{,}926.$

$W_{87} + W'_{87} = 15{,}274{,}926 =$ work done.

$W = 15{,}174{,}996 =$ useful effect of work done.

Subtracting, $87{,}972 =$ loss.

Hence the loss is about $\frac{1}{170}$ of the power given out by the engine.

Let $B + C = V =$ vol. of tube to be exhausted; $v =$ vol. of air-pump cylinder; $S = V + v$.

$$W_n = \frac{15\,a\,k}{1-R}\left\{1 - R^n + R^n\log_e R^n\right\}$$

$$= 15\,a\,k\,\frac{(V+v)}{v}\left\{1 - R^n + R^n\log_e R^n\right\}$$

$$= 2160\,(V+v)\left\{1 - R^n + R^n\log_e R\right\}$$

Where V and v are expressed in cubical feet.

$$W'_n = 2160\,R^n\,V\log_e\frac{1}{R^n} = -2160\,R^n\,V\log_e R^n.$$

$$W = 2160\,V\,(1 - R^n)$$

$$W_n + W'_n = 2160\,(1 - R^n + 2160\,v\left\{1 - R^n + R^n\log_e R^n\right\}$$

$$\therefore \text{Loss} = 2160 \times v\left\{1 - R^n + R^n\log_e R^n\right\}$$

For the loss in the Dalkey line we have $= 2160 \times 134{\cdot}65 \times \frac{1}{3}\,({\cdot}90138771) = 720 \times 134{\cdot}65 \times {\cdot}90138771 = 87{,}387$ lb. raised one foot high.

This agrees very nearly with the former result, and therefore we may suppose that the necessary loss is correctly determined.

This we see varies as the volume of the air-pump. If W_n be a maximum

$$\frac{d\,W_n}{d\,n} = 0$$

$$0 = R^n - 1\log_e R\,\left(1 + \left(\frac{S}{A} - n\right)\log_e R\right) - R^{n-1}\log_e R, \text{ or } 0 = \frac{S}{A} - n,$$

$$n = \frac{S}{A} = 79 \text{ nearly.}$$

$R^{79} = \frac{11}{30}$ nearly, which agrees with Mr. Stephenson's experiments.

It may be observed that the above formulæ are true, for positive integral values of n. By examining the diagrams which accompany the Report to the Directors of the Chester and Holyhead Railway, it will be found that the pressure of the air in the pump became equal to the pressure of the atmosphere sooner than we should have expected from theory. This would no doubt be caused in some measure by the heat developed during compression, but before the stroke commenced, the pressure in the pump cylinders generally exceeded that in the branch pipe—so that probably more air rushed into the pump each time than was sufficient to restore the equilibrium with the main tube and its retreat being cut off by the valve, it was expelled by the piston.

I remain,
Your obedient servant,
F. BASHFORTH.

St. John's College, Cambridge, Jan. 15, 1846.

[It may be as well to inform the reader who is not acquainted with mathematics, that the object of Mr. Bashforth is not to controvert the principles of Mr. Haydon's paper, but to effect simplifications by which the arithmetical computations are greatly facilitated. We are, we believe, indebted to these gentlemen for the only accurate mathematical investigations of a very important subject, hitherto published.]—ED.

REVIEWS.

A Treatise on the Steam Engine. By the Artizan Club. Part XVIII. Dec. 1, 1845: Longman, 4to. pp. 16.

This work which has several times been the subject of our reviews is now drawing to a close. Of the twenty-four monthly parts in which it is to be completed, three-fourths are now published. It cannot be denied that a vast mass of information is collected in this work, though some portions might have been omitted without harm. Of the mathematical investigations, parts are of a very doubtful description, and there is not much in the theoretical portion of the work which possesses originality. With respect to the practical views, however, the cause is very different. The writers have a way of looking right at practical questions which is exactly suited to the nature of the subjects; so that even when we dispute their views we are compelled to confess that they are fairly set before us.

The present number is illustrated by a large plate of details of the West India Mail Packets Clyde, Tweed, Tay, and Teviot, exhibiting in a very clear manner the forms of the cylinder and slides, the metallic packing, &c. The most interesting subject treated of in the letter press is a comparison of the merits of the principal forms of *direct action engines* which are divided, into five classes. 1. The Gorgon; 2. the double cylinder; 3. the steeple; 4. the double cross-head; 5. the oscillating. We will give part of the observations made on each class.

1. *The Gorgon Engines* (those which have the connecting rod between the piston rod and the crank). "The objections to the Gorgon plan of engine are numerous and weighty. In the first place, only a very short stroke is attainable by this plan of engine; and although we are not of the number of those who subscribe to the doctrine, that expansion can only be productive of its proper efficacy in a long cylinder, yet we believe that an engine of a moderate stroke will work more steadily and smoothly than when the stroke is short and the reciprocation rapid. There is, moreover, a great waste of steam at the ends of the cylinder when the stroke is short; and although the amount of this loss cannot be great, yet it is too great to be altogether disregarded. We do not attach the importance attributed by some to the deranging influence of a short connecting-rod upon the slide valve, but we attach a good deal of importance to the increased friction consequent upon the thrust, when the angle the connecting-rod makes is great,—not on account of the power absorbed, but on account of the difficulty of keeping the bearings from heating. To *this* objection it is no answer to say, that the friction of a direct-action engine is as little or less than that of a beam engine; the vice being, that the friction is not fairly distributed, but so concentrated at particular points as to be productive of injury in engines of the common proportions.

"There is, however, a far more serious defect of the Gorgon variety of engine than any we have yet mentioned. It involves the use of a large paddle-wheel by the elevation of the shaft, rendered necessary to afford room for the stroke; and the largeness of the wheel gives too great a velocity to the float boards, by which means a considerable proportion of the engine power is dissipated. There is nothing better known, than that in all cases where there is a great disparity between the speed of the wheel and the speed of the ship, a large amount of the power is wasted in throwing the water back from the wheel, instead of being employed in forcing the vessel forwards; and in the Gorgon plan of engine, as applied to ordinary sea-going steamers, a serious loss from this source must be perpetually going on, or else the engine must be working under its proper speed and power. These objections apply to all short connecting-rod engines, of which the stroke is small and the shaft high; and in our eyes, they carry sufficient weight to justify the condemnation of this species of engine *in toto*."

Several varieties of Gorgon engines are then brought under review—those by Boulton and Watt in the "Centaur," by Miller and Ravenhill in the "Eclair," by Fairbairn and Co. in the "Odin," &c. The first introduction of the Gorgon class is attributed to Messrs. Seaward, and the same defect is alleged against every one of the numerous varieties—that of having the shaft too high. The next classes treated of are

2. *The Steeple Engine*, "which is the invention of Mr. David Napier has the merit of being very compact and effectual, and in the case of river vessels, offers advantages which have led to its extended adoption. The protrusion of a large portion of machinery above the deck is, however, much objected to in the case of sea-going vessels, and Messrs. Tod and Macgregor now give the preference to the double cross head engines in such cases. It is a fault, we conceive, to make the air-pump with the same stroke as the cylinder. Where the air-pump bucket moves with a great velocity, the valves strike so forcibly as to wear themselves out very soon. The injury might, however, be mitigated by the use of the Cornish equilibrium valve, both for the delivery valve and the air-pump bucket."

3. *The Double Cylinder Engines.* "Of this plan of engine we cannot approve, and we think Messrs. Maudslay would act wisely by giving it up in favour of some less precarious arrangement. The Siamese plan involves an increased leakage, increased friction, and increased radiation, while the grand purpose of direct action—saving of room—is only imperfectly fulfilled. Should either of the pistons leak steam, moreover, or either of the stuffing boxes leak air, a twist must be given to the parts of the engine, such as would arise if there were more pressure upon one half of a piston than on the other. Such a strain cannot, in our judgment, fail to be sooner or later injurious. The arrangement also involves the use of a low condenser which the air-pump cannot thoroughly drain, and the pitching of the vessel, by causing the water to run from one end of the condenser to the other, sometimes causes the air-pump to make an ineffectual stroke while at other times the air-pump is choked with water, which it can only with difficulty deliver, and fractures occur in consequence."

A long description is then given of the engine of the Ellen Mac Gregor. A very decided preference is given to the fourth and fifth classes above all the rest, and as the treatment of the question involves points long disputed among engineers, we will at the risk of making a rather long extract, give the decision with some few omissions.

4, *The Double Cross-head Engines.* "The nature of the arrangement in the double cross-head engine will be made manifest by a reference to the engines of Messrs. Bury or Messrs. Fawcett. From the top of the piston-rod a cross-head and side-rods proceed as in side-lever engines; and from the lower ends of these side rods other side-rods ascend to a cross-head, situated above the other cross-head, and which, by means of a short arm, communicates with the crank. By this expedient, the benefit of a long connecting-rod is gained without the disadvantages incidental to the plans already mentioned. There is only one air-pump in Messrs. Bury's engine, but it is double-acting, so that, in effect, it is equal to two. A common objection to this description of pump is, that the air accumulates underneath the piston; but it will be remarked, that a provision is made to counteract this tendency, the bulk of the air-pump piston being made to travel past the port, so as to expel air as well as water. We may here remark, that it appears expedient in this engine to avoid injecting from the bilge into the lower condenser, as coal-dust and other foreign matters might be drawn into the air-pump chamber, which would resist the descent of the piston, and probably occasion fracture.

"In Messrs. Fawcett's engine there are two air-pumps, which are wrought by independent bell-cranks off a crank in the intermediate shaft. The inferior cross-head is made in the form of a cross, from the ends of which two rods proceed to a cross-bar working vertically in guides on each side of the cylinder, the effect of this arrangement is to bring the centres of the rods on each side of the cylinder in the same plane, whereby the twist incidental to an overhanging pin is avoided. Messrs. Fawcett have, we understand, since this design was made, more nearly approximated to Messrs. Bury's arrangement; and we believe their engines are likely to become a type which many will follow and many more approve."

5. *Oscillating Engines.* "The most plausible objection to the oscillating engine that we are aware of is, that the cylinder and stuffing-box will speedily become oval, on account of the pressure necessary to communicate motion to the cylinder. The existence of a tendency of this kind cannot be disputed; but it is so small in amount as to be imperceptible in practice; and although, after a lapse of years, it has been found that oscillating cylinders became slightly oval, yet the amount of ellipticity is, for the most part, actually less than is found to exist in the cylinder of common side-lever engines, after the same amount of wear. This, indeed, if the question be considered attentively, is by no means surprising; for the common parallel motion, if in the least degree out of adjustment, will exercise a most severe pressure upon the cylinder; whereas the maximum pressure that can be exerted on the oscillating plan is only that requisite to overcome the friction of the pivots on which the cylinder oscillates, of which the amount is insignificant. Upon the stuffing-box, indeed, the tendency to wear oval may be more operative, but, to counteract this tendency, it is made of unusual depth, and a very substantial brass bush is fitted into its interior portion. The piston rod, moreover, is made of cast steel; and, with these precautions, oscillating engines are found to work, for a number of years, without inconvenience from the causes mentioned.

"Many nautical men, and some engineers, have objected to oscillating engines on account of the movement of the cylinder, which, they imagine, would become a formidable evil in the case of a vessel rolling heavily at sea. These objectors do not seem to have remarked that the rolling of the cylinder is neither dependent upon, nor proportionate to, the rolling of the ship, but is regulated exclusively by the movement of the piston; and we really do not see why a mass of matter, in the form of a cylinder, should be more formidable or intractable in its movements than a similar quantity of matter in the form of a side lever, or in any other shape whatever.

"It has also been objected against the oscillating engine, that the eduction passages are more tortuous than in common engines, so that the steam gets out of the cylinder less freely. We do not believe such to be the fact, if the comparison be made with the common run of marine engines; and in practice, no diminution of efficacy from this cause is appreciable. The fact is, all the objections that have been raised to the oscillating engine are merely hypothetical; they are anticipations of defects to be found out in large engines on the oscillating plan, and would probably be plausible enough to carry some weight, were it not the fact, that they have been completely controverted by experience. The remark, indeed, is heard sometimes even yet, that the oscillating method may do very well for small engines, but is of doubtful efficacy for large ones. But the definition of large engines has been continually changed, to escape the contradiction experience afforded, and that size is, in every case, decided to be large, which just exceeds the size of the oscillating engine last constructed. It is plain, however, that the grounds of this scepticism are being fast contracted; and, indeed, we think it requires a little controversial intrepidity to set down engines of 62-inch cylinders, which is the size of those of the "Black Eagle," as among the number of small engines. And if engines of this size are found to operate well—and those of the "Black Eagle" have been found to perform most satisfactorily—it really appears to us impossible to suppose that engines of 5 or 10 inches more cylinder would not be found correspondingly effective."

The points here discussed are many of them of that complicated nature, that independent reasoning will not suffice for the decision of them. The ultimate verdict must depend on a much more extended experience than we at present possess. However, notices such as the above, in which engines of each kind are examined together and their defects compared, have the happiest effect in removing prejudices.

Weale's Quarterly papers on Engineering. Part IX, quarto, p. p. 240. 23 engravings. Weale, High Holborn.

The present Part of Mr. Weale's series of magnificently printed and illustrated volumes, is that for Michaelmas 1845, but the publication of it has been unavoidably postponed to January 1846, owing, as it is stated, to "the engagements in Railway matters of two of the gentlemen contributors." There are four papers in the present number; of which the first and third may be considered together, as both are chiefly of a historical nature; the subjects of them being respectively "the Progress of Machinery and Manufactures in Great Britain, from the earliest times to Queen Elizabeth," and "a memoir of the Thames Tunnel. Section II., by Henry Law." The first of these papers gives a historical account of the progress of the arts, year by year, in England; the principal enactments affecting manufactures and inventions, the importation of foreign improvements, &c. Some of the notices are very curious and interesting.—In 1404 we find Henry IV. ordaining "that none henceforth shall use to multiply gold or silver, nor use the craft of *multiplication* under the pain of felony." The paper closes with an account of the disputes between Elizabeth and her Parliament, respecting the royal, fondly-cherished, privilege of granting patents for monopolies.

Mr. Law's paper is also interesting, and will be very acceptable to those who feel the value of tracing the *history* of Engineering. This branch of knowledge is much neglected at the present day; we seem content with ascertaining the actual state of Engineering, and care but little to know how and by whom the advancement of practical science has been effected. The paper on the Thames Tunnel supplies a very important point in the annals of mechanics. It details in distinct and forcible language the wonderful skill and patience by which the difficulties attending that great work were overcome, and deserves to be read with the greatest attention.

The second paper is entitled "*Practical and Experimental Researches in Hydraulics*, by R. H. Peacocke, E. C.;" the object proposed is to suggest formulæ for calculating the discharge of water from pipes, &c. The first investigation which the author makes, tends to show that the curve which water assumes when discharged from a pipe is not a parabola. It may be as well to remark, *in limine*, that the form of the curve in which water actually falls is never taken to be exactly a parabola; because it is natural to conclude that if a projectile *in air* do not describe a parabola neither will falling water. Mr. Peacocke, suggests a formula for calculating the curve of falling water in the following terms;

"The hydraulic curve consists of ordinates of a parabola plus, (sometimes minus) a certain constant quantity which increases arithmetically as the corresponding abscissæ increase." p. 3.

It is not very easy to see how a "certain *constant* quantity" can increase arithmetically; and we find out afterwards that this quantity is no *factor* at all, but something to be simply added to, not multiplied by, the length of the ordinate. We apprehend Mr. Peacocke's meaning to be—that his curve is found by adding to, or substracting from, the ordinates of a parabola, quantities proportional to the corresponding abscissæ. For instance, in his first experiment he substracts from each ordinate the decimal part .07 of each corresponding abscissa, in the second experiment he substracts ·09 of each abscissæ, &c. But one great defect which seems fatal to his formula is, that it leaves quite undetermined *what* proportions of the abscissæ are to be substracted. These decimal parts .07, .09, &c., are wholly empirical, and only suitable for the *particular* cases to which they are respectively applied. He, himself says, of his "factors," as they are termed throughout,

"In Experiment	1.	The factor is	—.07.
"	2.	Ditto	—.09
"	3.	Ditto	—. a minute quantity not ascertained
"	4.	Ditto	+.03
"	5.	Ditto	0

On comparison of these factors, and consideration of them with reference to the lengths and diameters of the tubes, and the amounts of "head"—*it is not observable that the factors follow any definite law;* though it is probable that a greater number of experiments would have proved the existence of a definite law. But the farther prosecution of the subject in that way, though it would have been interesting, was not necessary to my present purpose."

So that we really cannot see in what way we are the wiser for his experiments. In two out of five of them he does not determine any "factor" whatever, and in the remaining three the factors apply only to the particular cases and suggest no general law.

It is important to remark that Mr. Peacocke merely observed the form of the curve near the orifice. His experiments for the determination of the curve do not extend to a fall of four feet below the discharge pipe. Now it is very possible the proposed formulæ may represent a curve, resembling that of falling water near its source, but widely diverging from it at a great distance from the source; for with short lengths of the curve, errors would not be easily detected. It may readily be conceived that by Mr. Peacocke's system of "factors" (determined, it is to be observed, separately for each case,) he may get a formulæ which coincides with the results of his experiments as far as they extend, but *not* much farther;—and we must be excused for adding that it is also possible to conceive the existence of a formula of entirely different shape, and involving altogether different functions, which would represent the form of the curve both near and at a distance from the origin.

The experiments are followed by an examination of formula, proposed by Mr. Smeaton, M. Prony, Dr. Young, Chevalier Dubuat, M. Eytelwein, &c. for the discharge of water. The following conclusions are ultimately made.

"1st. How nearly the experiments are a mean of the two extreme formulæ, namely, those of M. Eytelwein and M. Genieys.

2nd. How nearly the experiments are a mean of the two next formulæ, namely, those of Mr. Smeaton and Chevalier Dubuat.

3rd. How very nearly the experiments are a mean of the two most accurate formulæ, namely, those of M. Prony and Dr. Young.

I think no scientific man will, after satisfying himself that my calculations are correctly made from M. Eytelwein's and M. Genieys' directions, make use of either of these gentlemen's formulæ."

Having some curiosity to know on what data the condemnation of Eytelwein's formulæ, which has considerable reputation, was founded, we turned to Mr. Peacocke's examination of that particular formulæ, and found that he had by his own showing, taken the value of one symbol at one-fourth of that intended by Eytelwein. He says that Dr. Young understands the symbol *d* in the formulæ "to signify the diameter, (of the discharge pipe) while I understand it to mean the hydraulic mean depth, or *one-fourth* of the diameter of the pipe," and then adds in a note that he finds on reference to the original work in German, that Dr. Young is right, but that he himself was misled by the Encyclopædia Britannica.

"I have, since this essay was in type, referred to M. Eytelwein's original work in German; and have found that *d* signifies *the diameter*, consequently the writer in the Encyclopædia Britannica has (unintentionally of course) mis-stated M. Eytelwein's formula."

The paper certainly evinces great labour, but such an error as the above is rather a serious one; and the writer must not be surprised to find that in a subject which has baffled the sagacity of the acutest philosophers, the proposition of new empirical formulæ will be regarded with distrust, unless they be supported by a weight of testimony far exceeding any hitherto collected.

The last paper is a report of the Institute of France, on M. Arnolett's system of Atmospheric Railway. This paper is translated and prepared for publication by Mr. R. Mallet, A B. CE., who prefixes an introduction explaining "the views and objects" which influenced him in publishing the report in English. After assigning various reasons, he brings forward the following in a paragraph by itself.

"My principal inducement, however, has been to make readily available to the English engineer the mathematical notes of M. Lamè, appended to the report of the commission."

Now when we find, as we presently shall, that these "mathematical notes" are not only incorrect, but that there is scarcely one line free from gross errors, we can scarcely be expected to give great credit to Mr. Mallet, for his judgment in selection. It is necessary to state that M. Lamé's investigations exclude the supposition of leakage in the main pipe: the reason, stated in the body of the report, is that "as this defect of the apparatus and the loss of power which it occasions have not yet been sufficiently considered, we shall neglect it in comparing the two systems."

We take the first dozen lines of the "notes" as a sample of their general character. The object is to calculate the power required in the *preliminary exhaustion* of a tube of the length Λ and section S, from a density H to a density η.

"We will assume the tube to have a fixed bottom, taken for the origin of x, and that it is closed towards its other end by a moveable piston, P, beyond which the tube is indefinitely prolonged.

We readily perceive that the power sought is equal to that which will be required to draw out the piston P, placed originally at a distance $x = \frac{\Lambda\eta}{H}$, from the fixed bottom to the distance Λ. H being the density of the air contained in the tube of the length $\frac{\Lambda\eta}{H}$, let p be the elastic force of this air for any length, x; we then have

$$p = \frac{\Lambda\eta}{x} \text{ or } H - p = H - \frac{\Lambda\eta}{x}$$

and the power sought will be given by the definite integral.

$$\int_{\frac{\Lambda\eta}{H}}^{\Lambda} S\left(H = \frac{\Lambda\eta}{x}\right) dx = S\Lambda\left(H = \eta - \eta \log. \frac{H}{\eta}\right). \quad (1)\text{"}$$

In this calculation we first of all observe that the alternating action of the air-pumps, and the influence of the external valves (those through which the air is expelled from the pump) are totally neglected. But the whole amount of error is not perceived till we come to see to what use this formula (1) is applied. The conclusion from it is thus expressed, at p. 14. "Hence we conclude that in the English system, the available power expended, however the engine work, is exactly equal to the work done."

Now the full force of the reasoning amounts to this—the passage quoted above, and commencing "we readily perceive that the power sought is, &c." assumes that the *power expended* may be measured by the *useful effect produced*: having made this assumption, M. Lamé gets a formula from it, which he concludes that *the power expended* is equal to the *useful effect produced*, that is—he assumes a proposition in order to prove the truth of it.

The mathematical reader will have no difficulty in seeing that this logic is as bad an example of reasoning in a circle as can possibly be found. But we want, if possible, to convince the *un*mathematical reader—for it is he who is most likely to be injured by errors so gross as this appearing in a work like the "Quarterly papers." M. Lamè totally overlooks the loss arising from the employment of an elastic agent for communicating power. This simple consideration, as we said last month, will shew that the power expended cannot be mathematically equal to the effect produced—the alternating action of the pump-piston alternately dilates and condenses the air in the pump—dilates it while draining it from the main tube — condenses it while expelling it into the external air. Consequently all the component particles of the air in the pump are first drawn further apart, and secondly are brought closer together, than they are in their natural state. Now to suppose that *no* force is expended in thus continually altering the constituent arrangement of the particles of air is equivalent to asserting that the change takes place spontaneously, that the molecules can of themselves approach and recede from each other—that is, that they have a kind of vitality in them, an inherent power of moving themselves.

It may seem bold to attack opinions sanctioned by such high authority as that of M. Lamé; but philosophy does not recognise the weight of personal testimony. It is the obvious duty of the reviewer to point out errors wherever he finds them, and his duty is only increased in importance where errors seem confirmed by the celebrity of their advocate. The proposition of M. Lamè, to somewhat vary the view of it, may be stated thus:—The requisite exhaustion *might* be produced in the tube by moving a piston within it through a certain distance; and hence the force required is the same whether the effect be produced by this hypothetical arrangement, or by that *really* employed in practice. That is, provided the result be the same, the means of effecting it are matters of indifference! Now this assumption that no more force is lost by the use of air-pumps than by an arrangement more direct, but entirely imaginary, what is it but an assumption of the very question in debate, namely, whether the power, expended by the air-pumps &c., be equal to the useful effect? It is clear that the mechanical means by which the effect is produced cannot be neglected in the calculation, for it would be easy to contrive machines which would effect the requisite exhaustion with a loss of 99 per cent of their power.

It is very true, that the investigation of Mr. Bashforth, in another page of this number, shews that the loss under consideration is but *small*; but the mathematical truth remains independent of the actual amount of the loss. Whether that amount be 1 per cent. or 99 per cent., the fact remains the same, that mathematics founded on the assumption that the effect produced is equal to the power expended must be erroneous.

If any confirmation of this opinion were requisite, the following extract, from the "notes" of M. Lamè, almost immediately following the one made above, is perfectly conclusive:—

"Thus the power expended to form the vacuum in the tube before the starting of the train is to the whole power as (2 — log. 3) is to 2, or since the hyperbolic logarithm of 3 is = 1.09861 — the time of working of the engine is to the time of transit of the train as 2 is to 1.09861, that is to say, a little more than double, or more exactly, as 9 : 5."

Here it is asserted, that for a working pressure of 10 lb. to the square inch, the preliminary exhaustion will be *always* $\frac{4}{9}$ of the whole power expended. And it is particularly to be observed, that this conclusion is independent of the length of the main tube, or the size of the air pump; whereas, in truth, the power expended in the preliminary exhaustion depends most materially on the relation between the solid content of the pump and that of the tube. Every tyro in pneumatics knows that the density of air in an exhausted receiver depends on a formula in which the number of each stroke appears as a *power* or *index*. For instance, if the capacity of the pump and receiver *together* were to the capacity of the receiver alone as 20 : 19, the density after the first stroke would be expressed by $\frac{19}{20}$; after the second stroke by the square of $\frac{19}{20}$; after the third by the cube of $\frac{19}{20}$; after the fourth by the fourth power of $\frac{19}{20}$...... after the hundredth by the hundredth power of $\frac{19}{20}$. Now these considerations, which are to be found in every elementary book on pneumatics, are totally neglected by M. Lamè, not only in the passage here quoted, but throughout his investigation.

The "mathematical notes" next discuss "M. Arnollet's system," in which magazines of power are obtained by the exhaustion of large air-tight reservoirs. The mathematics are here founded on the same reasoning as before—that is, the alternate action of the pump and the proportion of its size to that of the tube are quite left out of sight. It would be worse than useless to quote conclusions obtained under these unsatisfactory circumstances.

What adds greatly to the regret, excited by finding these calculations in a report by a commission of the Institute of France, is the circumstance that M. Arago's name is attached to the report.

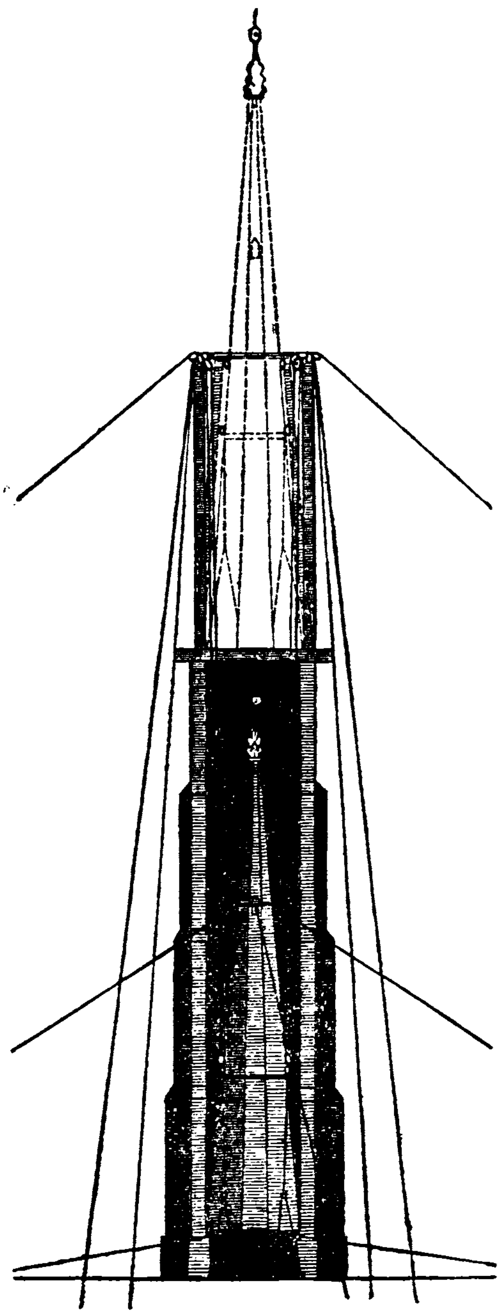
Engineering seems fated to be particularly unfortunate, in being obscured by incorrect mathematics. Were the confused heaps of mathematical symbols which beset the path of the engineering student merely worthless, we would not say one word respecting them. They might safely be consigned to oblivion. But, unfortunately, these errors have the most pernicious effect on those who are least able to discover them. Mathematics of the very worst kind are constantly receiving the highest sanction when applied to engineering. In any other department of science the authors would infallibly meet with condemnation. We can only give general advice to the student who is likely to be affected by these evils, —never to take on trust any mathematical conclusions except those sanctioned by time, and embodied in works of accredited authority: respecting all new investigations, we recommend him to reject them altogether until he feels his physical views sufficiently matured to enable him to investigate and confidently decide for himself.

RAISING THE SPIRE OF A CHURCH.

(From the American *Franklin Journal.*)

"*Account of the Raising of the Spire of the Nativity, in Spring Garden, Philadelphia county.*" By N. Le Brun, Architect.

The Doric tower on which this spire was raised, faces the east, and is 90 feet in height; it is strengthened at the angles by four buttresses, projecting at the base four feet; the projection of these buttresses is diminished at four stages in their height. The interior figure of the tower at the base is a square, but mid-way it assumes the figure of an octagon by gathering over the brickwork at the angles; the whole forming a construction of the most solid character. The octagonal spire, which was finished complete in front of the tower previous to rising, is 80 feet high, including its crowning ornaments; its width at the base is 12 feet 6 inches.



The spire was raised by means of two derricks situated on the north and south wall on the top of the tower, and placed about 18 inches behind the front posts of the spire, or about 3 feet back from the front of the tower, and were 13 feet, 6 inches apart, allowing about 6 inches on each side between them and the spire. Their feet were made convex and fitted into corresponding cavities worked in the oak sleepers which were securely bolted down into the sills of the spire, which sills were themselves secured to the tower by 1½ inch rods 36 feet long, and built in the angles of the tower walls. To avoid all the strain being thrown on the top of the walls at these points, diagonal braces were placed, extending 40 feet down the tower, and as an additional precaution to prevent the derricks from slipping at the heels, they were connected by lashings fastened to iron bolts passed through them,—the heads were connected by two tackle blocks, which were only of use to keep them in their position till the spire was being raised. The guys from each of the derricks, extended in three directions over the neighbouring commons.

The spire was connected with the derricks by four double lashings, (each end of which was fastened to one of the spire posts at the foot,) and two spans; the belt, which connected the spans, was 30 feet high above the base of the spire, (being about 5 feet above the centre of gravity) and passed through the straps of the purchase blocks. The falls from the treble blocks on the derricks to the leading blocks, were in the interior of the tower, and the two capstans used, were placed in the main story of the church, and were each manned by twenty men. Attached to the base of the spire were three guys, and at about 25 feet from the head were four more guys, all secured to guy posts.

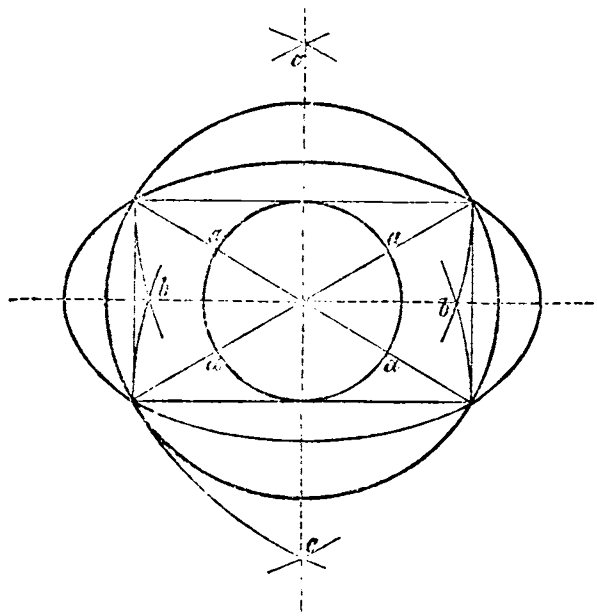
All the arrangements having been made with the greatest care, on the 10th of February, at two o'clock in the afternoon, the raising was commenced, and it was performed with the greatest ease. The spire was kept plumb by the management of the guys attached to it. As the derricks were but 42 feet high, and the belt to which the purchase blocks was fastened was 30 feet from the base, (at which height the distance from each derrick head to the spire would be about 3 feet,) there would be but 6 feet between the blocks when the spire would be raised;—they would thus necessarily have lain almost horizontal, and caused a great strain on them; to avoid this strain, as the raising was progressing, the north and south derrick guys were slackened to make the purchase blocks work more perpendicularly.

When the spire had been raised to its proper height in front of the tower, the two west derrick guys were worked by two crabs to draw over the derricks and swing the spire to its destined position. It had been deemed most prudent to work them in that manner, as in the hauling in of the back guys in the usual manner, an oscillatory motion might have been communicated to the spire, which would have rendered it difficult to manage at this most critical moment. The raising lasted an hour and thirty minutes, and thirty minutes were required to secure it firmly to the sills on the tower by the iron straps;—thus the whole operation occupied two hours.

METHOD TO PROJECT CIRCLES ISOMETRICALLY.

By Thomas Prosser, C.E., New York.

Fig. 1. Draw the two Isometrical diameters; (*i. e.* the two exi-conjugate diameters of the ellipse which is to represent the circle,) unite their vertises so as to form a rectangle with its diagonals; circumscribe the whole with a circle passing through each angle of the parellelogram, the sides of which will thus form chords to its segments; with the chord of half the arc of a lesser segment as radius, describe another concentric circle cutting the diagonals of the rectangle, at *a, a, a, a*.



From each angle of the rectangle as centres, and with its largest side as radius, describe arcs cutting each other within the rectangle as at *b, b.*

From the same centres, and with the diagonal of the rectangle as radius, describe arcs on the opposite side of the figure, as at *c*, *c*.

From each of the points *a*, *a*, *a*, *a*, as centres, describe arcs passing through the vertises of the isometrical diameters which are on the same side of the conjugate axis, but on the opposite side of the transverse one. From the points *b*, *b*, and *c*, *c*, as centres, describe arcs in continuation.

REPORT FROM THE INSTITUTE OF THE FINE ARTS ON PUBLIC COMPETITIONS.

"Gentlemen—Competitions in art are now so frequent and so fully responded to that, without sound principles in their management, they must necessarily be very injurious to the artists, however advantageous they may appear to the public; for instance, in the case before us, if 1,000*l*. has to be competed for, and fifty artists enter the lists and spend 1,800*l*. of money and an amount of time equal to twenty-nine years of human life, as this inquiry will demonstrate, they evidently lose 1.800*l*. and the whole of that time, unless there is compensation by reputation, by acquired knowledge which may be turned to account, or in the sale of the competition pictures. If wholesome condition of public taste, good sense in the arrangements, and strict justice in the awards at competitions, would, in some measure, afford this compensation, but the usual modes adopted in these trials of skill afford none; on the contrary, they are attended with many circumstances that embitter the feelings, aggravate the sufferings, and injure the reputation of enthusiastic competitors. Such a course must ultimately be injurious to the public as well as to the artist. The system has indeed much of the excitement and immoral tendencies of a lottery.

In order to arrive at a better principle, we have inquired into the results of various competitions in different ages, and in several countries; we have endeavoured to trace the amount of competency in the judges and of equity in the mode of arrangement, or of good faith in the superintending authorities. Among the ancient Greeks various plans were adopted, according to the more or less popular political institutions of the community. Where the arts flourished most, public opinion, in whatever form expressed, was the basis of public patronage. In some cases the community, considering the competing artists most interested in a fair decision, actually left that decision to them; in others the opinion of the people was paramount; but even then suggestions from the artists were attended to with deference and respect, and not disregarded or condemned as is too often done among us. When Phidias and Alcamenes competed for a statue to be placed on a column or other elevated situation, at first sight all opinions were in favour of Alcamenes, but Phidias demanded that both figures should be placed at the intended elevation, previous to the award being made. This was done, and such was the consideration of perspective effect by the one artist and its neglect by the other, that the people no sooner saw them at their required elevation, than they changed their opinion, and decided in favour of Phidias. In this instance it is clear that the judges, *i. e.* the public, were not fully competent to their task, but it is also obvious that such artists as Alcamenes would have been equally unfit or even worse; for, in all probability, relying on their practice and skill, they would not have taken the trouble to raise the competing statues to the proposed elevation, and in all likelihood they would have been more tenacious of a first opinion than the people were.

In the case of the citizens of Cos choosing a statue of Venus from two by Praxiteles, so far from delegating their judgment to artists, they selected, from a motive of delicacy, that which the technical connoisseurs denounced as inferior. Posterity has decreed that in this, good sense triumphed over conventional excellence.

Much has been said of a mode of deciding some competitions among artists in ancient Greece, in which the competitors were each allowed two votes, under the notion that in the ballot, each would give one vote in favour of his own performance, and the other to the best of his rivals; as though all the candidates, after indulging a selfish conceit, would, as soon as that first impulse was gratified, become perfectly candid; as though the act performed by one hand, and its motive, were unknown to the other? Unless they were strictly honourable and impartial, it is more likely that they would give both votes to their own work, or the second vote to the most unlikely rival; thus might the least talented stand at the head of the poll: we have been informed of occurrences which confirm this opinion. On one occasion at one of our distinguished institutions, a candidate was elected to an important office, for which he was so totally unfit, that the self-degraded electors had to request their own nominee to resign; on another, an individual of considerable reputation, after proposing and making a warm eulogy of a friend's qualifications, was proved, by the unanimity of the votes in favour of himself, to have sacrificed that friend to his own conceit. If candidates are honourable and true, one vote is as good as two; and so it would be if they were all selfish and cunning.

Early in the fourteenth century, a very important competition took place at Florence, between Bruneleschi, Donatello, Ghiberti, and four other eminent sculptors; for under good and honourable regulations, the greatest were not loth to compete. Subjects, to be executed in bronze, for the ornament of the gates of the Baptistery of St. John, were confided to their emulation, each being provided, at the public expense, with every convenience of studio, furnace, and other accommodation, that could ensure success, and a sum for personal expenses. Having done so much for the comfort of the artists during the period of their exertions, a competent tribunal next received the consideration of the Florentines; thirty-four men of taste and talent, some artists and some amateurs, were appointed judges to determine which was entitled to especial admiration, and public employment. Their votes were divided, and no decision obtained from them; but the magnanimous candour of Bruneleschi and Donatello, who had each the same number of votes as Ghiberti, at once settled it in his favour, and proved the tribunal incompetent: those generous rivals saw no room to doubt his superiority in that contest; and posterity has sanctioned their opinion. The incompetency of this tribunal was, however, but negatively bad; it allowed the scales of justice to remain in doubtful suspension, but it did not actually reverse its tendency, and cloud the prospects and fame of a deserving candidate. A similar diffidence, or modest ignorance, was remarkable when Leonardo da Vinci, and Michael Angelo Buonarotti, made their great trial of skill at the Council Chamber; the splendour of the one did not eclipse the majesty of the other, as the success of one man's talent invariably smothers the fame of every other in our modern competitions.

In France, during the period of religious animosity, from the reign of Francis the First to that of Louis the Fourteenth, public competitions were often productive of fine works, as the best portions of the palace of Fontainebleau, and the beautiful square of the Louvre attest. In those instances, native talent, both Catholic and Protestant, in worthy emulation, stands triumphant amidst the performances of foreign rivalry. The same system was resorted to for the east front of the Louvre, and the award of superior merit was in favour of Claude Perrault, the physician and mathematician, but a corrupt court, where the spirit of intellectual freedom had not survived that of anarchy and rebellion, could not rest satisfied with the result of competition and public opinion. Louis the Fourteenth endeavoured to set aside the design of Perrault, and invited Bernini, the fashionable Italian architect and sculptor of the day, to visit his court and design something worthy the magnificence and splendour of that pompous monarch. Princely honours attended on the foreign artist in his progress to the French capital, but Colbert found it advisable to lean towards the popular opinion: the king relented, Bernini retired with the same affected magnificence that accompanied his arrival, and the design of Perrault, the masterpiece of that era, before which even Whitehall sinks in comparison, was completed, at once a monument to French taste and a trophy to public opinion.

Under Napoleon, competition was far from pure. The jury of artists for the Decennal prizes adjudged the great prize for a subject of ancient history to Girodet, for a scene of the Deluge. The emperor was disappointed: he had expected that prize to be given to his first painter, David, for the intercession of the Sabine women between their enraged relatives and their Roman husbands. The judges could not indeed be induced to convict themselves of incompetency in that decision; but, to conciliate the sovereign, in the next trial, they conferred the prize for a modern subject on David's coronation, and not on the plague of Jaffa, by Gros, which they individually preferred. A sad example of artists, eminent for talent and character, rendered dishonest by the interference of a potentate.

At the present time in France, where artists constitute an influential portion of the intellectual aristocracy (the aristocracy of talent and professions); where authority and intrigue are variously apportioned, no one competition is of much importance, for the effect of a partial decision by the court party, is frequently neutralised by an equally unsound award in favour of the injured artist, by some municipality of opposition politics, to whose prejudices an appeal is made, and who have in their gift a provincial commission.

In our own country, competitions are very unsatisfactory, and frequently alike absurd and unjust: in that for the Nelson memorial, the vacillation of the committee in setting aside their first hasty award, and advertising a new contest and exhibition, with their final confirmation of that first very doubtful judgment, compromised the dignity of the committee as much as its taste, and unnecessarily increased by many thousands of pounds the expense (besides trouble) of the artists. That competition was fatal to the confidence of artists in a tribunal of amateurs of rank and fortune, but that of the Royal Exchange with a tribunal of artists was still worse: the jury of three eminent architects, refused any premium to the design which they acknowledged to be the best, under the plea that it could not be built for the sum stipulated; nor was that decree reversed when contractors of reputation offered to undertake it under securities; but they gave the premiums to other candidates, whose designs they declared to be quite impracticable. They were next requested to prepare a design themselves. It is understood, that two of those three judges, after examining and condemning all the designs, actually consented to do so, but the unseemly proceeding was checked by public opinion. The ultimate competition was between two architects of considerable and nearly equal influence among the civic authorities.

The recent competition exhibitions at Westminster Hall, for the decoration of the Parliament Houses, were at first hailed as the beginning of a better system, more intellectual and pure; but up to the present time, the results have led only to disappointment among the great body of the candidates, and growing indifference in the public. Some artists, after being rewarded the first year, had their works treated as unworthy even to be publicly exhibited at the second, whilst others have been appointed for actual employment on one trial, or even without passing through the prescribed ordeal at all. Several who have appeared honourably and with general approbation at all the exhibitions, have been utterly neglected or discarded by the royal commission, although the leading object of its appointment was the encouragement of native talent in the higher walks of art, and the commissioners had pronounced the works of many of those artists "highly creditable to the country."

The whole of the evidence on competitions, tends to prove that in respect of matters of art, a competent tribunal and equal justice have scarcely ever been obtained. In questions of taste, there is indeed so much room for doubt, that prevarication and partiality are less obvious and disgraceful than in simple questions of property, and yet the injury done to the sufferers is far greater where professional reputation as well as fortune is involved. Why should not artists, whose fame and means of existence are at stake, have as good protection from a committee of taste, as persons in trade are sure to find in a court of justice? Why are not committees, like judges and juries, responsible fer their proceedings, either to a higher tribunal or to public opinion? Why are they not, in like manner, obliged to examine and consider both sides of the question? Our juries are selected for their impartiality, and every accident in that respect is rectified, by allowing each contesting party to challenge the jurors: no false delicacy towards jurymen is allowed to weigh against the welfare of the parties before the court and the strict rules of justice. To see that they attend to their prescribed duties, and that the evidence is fairly placed before them, and not to interfere with the verdict, a judge presides who, after a long career of study and experience, is placed above ordinary rivalry and contention, in circumstances that render character, especially for impartiality and judgment, to him, all-important. Should he, forgetful of his high responsibility, lean unduly to one side and misdirect the jury, an appeal lies to a higher Court, where his error or misinterpretation is sure to be severely discussed, and, if a case is made out, the trial is set aside or the verdict is reversed, without the least complacency for his authority and feelings. Thus is the property of the humblest trader protected; thus the life or liberty of the poorest wretch accused of crime, is held paramount to all considerations of rank and station. In questions of property, every possible discussion has long been afforded; witnesses are examined, cross-examined, and re-examined, by contending advocates. The same protection has of late years been granted to persons criminally indicted.—And why should this wholesome respect for mutual rights be denied to men of intellectual pursuits—authors or artists, who embark fame and fortune on the tide of public competition? Why should those to whom they entrust all that is precious in their estimation, think lightly of their responsibility. Something like the system of judge and jury, or an assimilation to the best of our prerogative Courts can alone render competitions among artists fair, honourable, and efficient, and give to the emanations of genius their proper value among us.

In the case immediately before us, it is proposed that a prize of 1,000*l*. be given to the artist who, in general competition, shall produce the bes painting 12 or 15 feet one way, and 10 or 12 the other; the subject is defined, and, in several points, the precise mode of treating it. With so great a temptation, it is reasonable to suppose that many will overlook the expense, trouble, disappointment, and serious inconveniences that await all but the one fortunate candidate; it is reasonable to suppose that fifty artists may risk comfort and reputation in the attempt. We feel assured that the gentlemen who propose this competition, besides the desire to obtain as fine a picture as possible, are anxious to make it worth while to men of talent and character to vie with each other in honourable emulation. They would evince generous delicacy towards the less successful artists who gave proof of high talent in the contest; for their object is not to encourage speculators to make a heedless dash at the 1,000*l*., nor can they wish for a gaudy meritricious picture, but one wherein the subject is fully considered, the character of each figure is faithfully studied and pathetically delineated;—where the action of all is in due relation one with the other, and the whole is combined into a rational and picturesque composition. Such are the essentials of high art; they are best attended to in the simplest and least expensive materials, such as involve a larger outlay of mind in proportion to that of money. Thus may the best results be obtained with as little injury as possible to the candidates, as all virtuous and religious men must wish to do.

We now proceed to state the artist's case in two ways:—first, as it will stand if the advertised regulations are carried out; and next, as it would be, if our suggestions were adopted, supposing in either case the number of candidates to be fifty.

Fifty finished paintings, varying from 12 feet by 13 to 15 feet by 12, would involve the artists in expenses (actual outlay) from 30*l*. to 40*l*. each; average, 36*l*.; total in money, 1,800*l*.

In time expended, average 7 months; total 29 years; which, at the low estimate of 150*l*. a-year amounts to 4,350*l*., making the whole outlay equivalent to 6,150*l*.; a positive loss in the aggregate of 5,150*l*. beyond the prize of 1,000*l*.

As pictures so large, all of a given subject, peculiarly treated, and blighted by the vulgar stigma of defeat, stand no chance for sale, but really become a trouble and a nuisance to the artists, we may fairly say that in the aggregate this loss is wholly unmitigated, and that ten such speculative competitions would be equivalent to a loss among them of 50,000*l*. or 1,000*l*. each, or in other words, a total loss of two hundred and ninety years of human life, and 8,000*l*. of the artists' money.

By the mode we would suggest, the loss on the present occasion may be reduced to about 300*l*. in money and 17 years of time; that is, compared with the above, a saving of 525*l* in money, and of nearly 12 years of time and exertion, whilst four or five paintings and twice that number of artists would be held up to distinction, instead of one, who in the ordinary way, engrosses admiration.

On a plan somewhat similar to the double competiton trial, adopted by the French institute at the election for students for residence at Rome, w would have two exhibitions; thus, supposing the number of competitors to be as above, fifty. The first exhibition would be of 50 cartoons, half life size, and 50 studies, of half figures, life size. From these, eight or ten should be rewarded with preliminary prizes. To each the sum of 40*l*. or 50*l*. should be paid, *i. e.* an equal portion of 400*l*. These distinguished candidates are then entitled and invited to compete with each other for the ultimate object. Thus the final great struggle would be between these eight or ten, and the second exhibition would consist of their eight or ten cartoons and studies from their first exhibition, and eight or ten finished pictures full size.

Four or five prizes should be awarded in this competition according to the number of good productions, *i. e.* 200*l*. among them. Thus four or five would receive 40*l*. or 50*l*. each, and as many would have 80*l*. or 100*l*.

Of these twice rewarded four or five, by the final decision, one would receive the great prize of the remaining 400*l*. in addition to his previous rewards, amounting together to 480*l*. or 500*l*. Surely the honour and advantages of such a victory, if properly awarded, would satisfy an ambitious enthusiastic artist. Could any one, amidst the honours and comfort of the glorious harvest, envy his less successful rivals the small return their gleanings had procured them?

By this arrangement the outlay of money and time of the competitors would be,

For 50 cartoons, average 13*l*. and 3 months each	Total £650	and 12½ years.
50 studies, average 8*l*. and 14 days	400	— 2
8 or 10 (say 9) paintings, at 25*l*., and 5 months' average	225	— 2¾
General Total	£1,275	—17¼ years.

Let us now consider the best mode of awarding the prizes, and the way to secure a competent tribunal, without which no good result can be depended on. Much of the difficulty comes from the uncertainty of what is considered excellence in art; some adjudging by the dictates of common sense, untutored to the technical rules of art, others guided almost entirely by conventional technicalites. Again, personal or professional prejudices have not been sufficiently controlled by principles or by responsibility.

The following regulations appear to us entitled to consideration and adoption, viz. the judges should consist of *three*, elected by the parties interested in the purchase; and *three* elected by the artist competitors; in all six persons. They should be elected by ballot after nomination: at least, this rule should be strictly observed in respect to those who represent the artists.

Each of the judges should separately, from others, examine and criticise the performances, and write his opinion of each, and of every work of art; and, naming those which he considers entitled to distinction, give his reasons for that opinion.

These written opinions to be given in previous to the opening of the exhibition to the public; but the result not to be confirmed until a certain number of days after its closing. Then the judges should, for the first time, meet and discuss each other's opinions, and the merits of the competitors; and, recording their matured judgments, decide by the majority; the contrary opinions being also recorded, in order that public opinion be not smothered, as it now usually is, under respect for a supposed unanimous decision.

Gentlemen.—Your committee beg to observe that, in this inquiry, they have considered it of the utmost importance to discuss both sides of every question, and on several occasions, its members have abandoned old favourite views, when the evidence or the argument outweighed a favourite prejudice; they are therefore the more confident in their anticipation of this report meeting with favourable attention, and serious consideration at your hands, and they sincerely hope it may eventually lead to changes equally advantageous to artists, and to the public; to the establishment of regulations more consistent with the immutable principles of equity and good sense, than those which have too often rendered competitions illusive and hurtful; and they trust that apparent difficulties in the operation of a wholesome system, will not weigh against the best interests of humanity, and the progress of the Fine Arts.

French Railways.—The *Journal des Chemins de Fer* publishes the receipts of the French railroad companies for the year 1845, by which it appears that the railroads have produced sufficient to pay a dividend of 6 per cent. on the amount of capital subscribed, besides a prospect of a considerable increase in future years. "This result," observes the journal, "without being extremely brilliant, is sufficiently favourable to encourage investments in railroad speculations; for not only is the increase of the receipts certain, but a reduction in the expense of working them may be expected."

MODEL OF THE PARTHENON.

The principles of pure taste are best taught by examples. One single specimen of the sublime and beautiful will exhibit the nature of it more clearly than whole folios of discussion about the abstract idea. It is for this reason that we must look to the actual restoration of works of ancient architecture, to their original purity as the principal means of elevating the public taste. That architecture has made rapid advances during the last few years, and has attained a higher position than it formerly held in popular estimation, is undeniable; but it is still far from its true place, and not until the works of the architect become, as they once were, works of national importance, not until architecture be restored to perfect purity and be thoroughly purified of all taint of barbarism and all the stains contracted during the debasement of the arts, will those who labour now so zealously for the Revival of the Art, have thoroughly accomplished their great task.

The Parthenon is universally esteemed by the architectural student as *the* exemplar of one of the two great modes of architecture recognized amongst us. The perfection of Classic Art—the complete realisation of its true principles—the last appeal of architectural discussion must be looked for amongst the ruins of the Acropolis—whatever disputes we may have respecting the true spirit of classic architecture must be ultimately settled by reference to this great authority. So that it is impossible to overrate the importance of ascertaining clearly the precise nature of the original architecture of the Parthenon. It is the highest architectural Pandect; the true and right understanding of the code of laws which it embodies must be the sole foundation of all modern Commentaries.

In examining the results of Mr. Lucas's talent and labours now deposited in the British Museum, we criticise a work which is calculated to work an important effect on the public taste. The model of a restoration of the Parthenon, placed where it is universally accessible, affords to the people a type of that of which they possess no actual specimen—pure Grecian architecture. Of the thousands who will inspect this model, there will be scarcely one, even of the most unrefined and uneducated, who will not be led to admire the wonderful beauty of the temple represented—for this is the distinguishing feature (is it not, rightly considered, the being criterion?) of perfect architecture, that its beauties are apprehended by the simplest understanding, and yet for their full appreciation task the energies of the most erudite observer. It may well be imagined that many of those who look with admiration on the representation of the masterpiece of Grecian art will enquire how it comes that we have nothing so perfectly beautiful in our country, as we may reasonably hope that the eye becomes more and more familiar with the principles exhibited in the Parthenon, it will grow more and more dissatisfied with those of modern works in which these principles are most flagrantly violated.

We intend to confine our notice of Mr. Lucas's works to the architectural considerations. A criticism of the elaborate sculpture which the models exhibit does not come immediately within our province, except in so far as the arrangement of the sculpture affects the architecture of the building.

With respect to the external architecture of the Parthenon there are happily but few opportunities for controversy. The remains are in a sufficiently perfect condition to exhibit in a clear and indubitable manner, all the great features of the exterior of the temple. With respect to the interior, however, our knowledge is not so satisfactory. Time and violence have worked so busily within this glorious fane, that now the best evidences of the original design are often no better than mere conjectures. We know the interior of the building was divided into two great chambers, the Opisthodomus or treasury to the west, and the chamber which contained the great statue of Miverva, to the east; but few traces remain of the architecture of these two great divisions of the temple.

In the restoration by Mr. Lucas, the roof of the Opisthodomus is supported from the ground by Ionic columns; the roof of the principal or eastern chamber is supported by a double order of columns, the lower tier Ionic, the upper Corinthian, and for this arrangement Mr. Lucas assigns the following reasons in a small octavo volume, entitled *Remarks on the Parthenon, being the result of studies and inquiries respecting that noble building.*

"In the restoration of the interior, I have adopted that view of the case which is set forth in the seventh volume of the Museum writings, published by the Trustees. Mr. Cockerell has, in that volume, given a restoration which is mainly based on the discovery I have alluded to, of the Corinthian capital in the eastern chamber;* and supposing that this beautiful combination contains the result of all the information on this branch of the subject, I had implicitly adopted it; considerable difference of opinion, however, exists as to the propriety of placing the Doric order over the Corinthian, as Mr. Cockerell has done, or even using the Corinthian at all with propriety. This objection was urged with great force by the celebrated Sicilian antiquary, Le Duo di Serradifalco, on his recent visit to this country. Col. Leake's observations, however, appear conclusive as to the Corinthian order; the Doric over it does not appear to rest on any sure data, as in the Walhalla the caryatides are used instead of the Doric. As this restoration is purchased by the trustees of the British Museum to illustrate the Elgin Gallery, I consider it needful this work should have the advantage of all the recent information that has resulted from the excavations and discoveries of King Otho; and by the kindness of Col. Fox and Major Parker, I am placed in correspondence with the architects of the Walhalla, and also those now employed by the King of Greece at Athens, so that all information will be exhausted in the restoration of the interior. In Inwood's folio work, published in 1827, is engraved plate 22, a portion of a Corinthian capital that was brought by him from the Parthenon, and which he considered a fragment of one of the lower tiers of columns of the interior; and of the fragment, and his restoration from the same, an etching is here presented. †

In regard, however, to the roof of the chamber being open over the statue of the goddess, that question has been much discussed; and it appears probable that the aperture over the statue was filled with some transparent substance, conducing alike to the double purpose of the protection of so costly a work, and rendering its effect mysterious.

NOTE.—The following communications on the subject of the interior of the Parthenon have been obtained from Athens, through the influence of Sir Edmund Lyons, the British Minister at that Court, from Mr. Pittakis, the present Curator of the Parthenon; and also from Mr. George Finlay, who is esteemed a great authority on this matter.

Questions submitted to Mr. Pittakis by R. C Lucas.

1st.—Is the capital of a Corinthian column which Col. Leake alludes to in his work, as having been found in the eastern chamber of the Parthenon (and on which discovery Mr. Cockerell has based his restoration of the lower tier of columns in the interior of the Parthenon) in Athens; or can any account be given of it?

2d.—Can any data be given for the upper tier of columns or support to the roof of the eastern chamber? Mr. Cockerell has used the Doric placed over the Corinthian in his restoration.

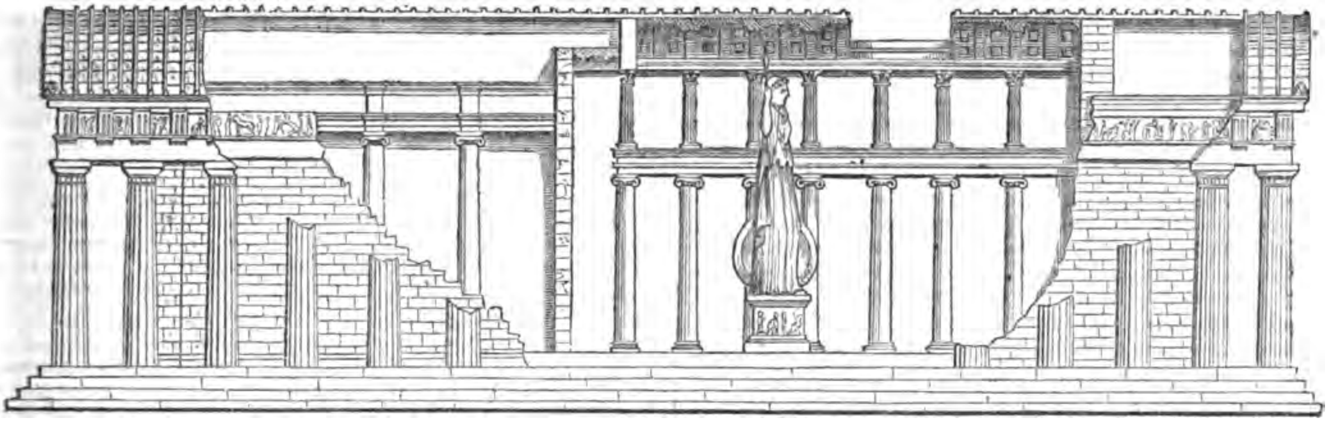
Mr. Pittakis's Answer to Mr. Lucas's Inquiries.

In answer to the first question, around the altar, which was the ancient Hecatompedon, the soil of which is lower than the rest of the Parthenon, appear signs of double columns. The first, which Mr. Cockerell saw, are about three feet in diameter; and thus it has been supposed, wrongly, I think, that those small columns supported the roof of the temple; but when the mosque, which stood on the south side of the temple, was knocked down and cleared away in 1844, traces of columns of five feet in diameter were discovered on the flooring, and are still visible; these columns, which, from their size, were able to support the weight of the roof, were up to the half the height of the Temple of the Doric order; above them was another tier of columns of the Ionic order; so that the lower tier was Doric, and the upper Ionic. The same order of architecture prevailed in the Temple of Minerva. The traces of the Doric order appear in two places, and I have shown the same to several travellers, particularly to Mr. Bracebridge, who may assist in this explanation if referred to. As for the upper range of columns, they were certainly Ionic. This I have ascertained from fragments of this order which I have found in the different excavations I have superintended in the Parthenon; and I also believe that the traces of those columns which Mr. Cockerell gave were made in the time of the Romans, when the Parthenon was restored; and I have found in excavating up to the present period four pieces of the frieze of the Roman era, and they made use of the same upper tier of column—that is, Ionic. As to the second question, six traces of the stylobates exist towards the south of the Parthenon, and four on the north side; but they are of the Roman epoch, as I said before.

I do not agree with Mr. Cockerell in placing the Doric order on the Corinthian; and, if I may be allowed to offer my opinion, I should

* Note.—(From Col. Leake's Work, vol. i. page 334, Second Edition.)—In the eastern chamber of the Parthenon, a Corinthian capital has been found of such dimensions as leads to the belief that the columns were of that order. The smallness of their diameter leaves little doubt that there was an upper range, as described by Pausanias at Olympia, and as still exemplified in one of the temples at Pæstum. In the interior of the temple of Phygalia are two new varieties of the Ionic order, one of which by its helices and leaves of acanthus must be considered as the order afterwards called Corinthian. It proves, therefore, this order was employed in the time of Pericles; in fact, Vitruvius gives the honour of its invention to Callimachus, who lived about that time.

† This restoration, Inwood himself says, is merely ideal. He observes, that there is a peculiarity in the fluting, being different on different sides of the volute. This peculiarity exists also, according to Mr. Cockerell, in the fragments of Corinthian capital in the Temple of Apollo Epicurius, at Phygalia, which was built by Ictinus; but it does not appear that the fragments were similar in other respects, and, even if they did, there is no argument for a range of Corinthian columns in the Parthenon, for in the other temple (that of Apollo, at Phygalia,) the Corinthian column was a solitary one. In "this" case, there is no doubt whatever that the column was a "single" one (not one of a range), and its office was to support the south end of the cellar.



say, that in ancient times, when good taste prevailed in Greece, the Greeks never made use of the Corinthian order to support weights, because this order is only an imitation of flowers, and naturally cannot support anything heavy; they, therefore, used Tripodes, or other architectural ornaments; and used the Corinthian for small, pretty, elegant buildings, such as the Tomb of Lysicrates; but the Romans lost this fine idea, and made the Temple of Jupiter Olympus of the Corinthian order, as also the Gate of Adrian.

From Mr. Finlay to Sir Edmund Lyons.

My dear Sir Edmund,—I have read over Mr. Lucas's questions and Pittakis's replies, and which I now return. The question is one of evidence, and I am not aware that enough exists to decide on how the Parthenon was roofed, or how that roof was supported. There were certain columns; but the very vagueness of Pittakis's conjectures, about which are the Roman restorations, show how much uncertainty reigns concerning the subject. The Corinthian was just as much used to support an entablature as any other order from its earliest existence, as may be proved from many Attic examples.

This subject, therefore, has been discussed, and it appearing probable that in the recent excavations the foundations of the old Parthenon, that exist on the site of the present building, have disclosed traces of the Doric columns that supported the former building; as five feet in diameter is too great for the required height of the lower tier of columns in the interior; and the evidence for the Corinthian order appearing conclusive for the upper tier, as the fragments that Inwood discovered in the Parthenon, from their size, must have belonged to the upper tier, and the size of the Ionic according with the required size of the lower tier, this restoration is now completed with the lower tier Ionic, and the upper of the Corinthian order.

From the above extracts it is obvious that traces of the interior arrangement of the Parthenon are so indistinct as to leave the matter at least a fair subject for controversy. In the sixth volume of the large work published by the Trustees of the British Museum as a catalogue of the Ancient Marbles in the Museum Collection, Mr. Cockerell confesses that the orders of the columns are not clearly ascertainable. We have endeavoured to collect all the principal facts and arguments respecting the internal architecture of the Parthenon, and give them in this place, because, as had been said, no subject can be so important to the architectural student as a precise knowledge of the construction of the great type of Grecian architecture. The reasons for supposing a double tier of columns in the cella of the Parthenon seem to resolve themselves into these two.

1. The presence of the fragments of a Corinthian capital delineated above.

2. Indications in the floor of the interior that columns once stood there of so small diameter that if of proportionate height they would not have reached the roof.

We propose to examine each of these reasons separately. With respect to the first it may, we think, be safely pronounced that the fragments of the Corinthian capital belong to a far more ancient date than the erection of the Parthenon. In Inwood's large folio work, he gives an ideal restoration of the capital to which these fragments belonged, but whether his restoration be correct or not, this is certain that enough of the fragments remain to show that they are to be assigned to an epoch when the arts were in a very different state to that manifested in the building of the Parthenon. Inwood indeed gives a collateral testimony in favour of the hypothesis of a double tier of columns which appears at first very plausible, but which on examination will not be found to have much weight in it. He says that there is a certain peculiarity in which this fragment resembles another found in the temple of Apollo, near Phigalia, which temple was built by the architect of the Parthenon—Ictinus. The point of resemblance between the fragments is this—it is observed in each volute that it is not fluted in the same way on both sides. It does not appear that the resemblance extends any further than this—that the general form and indications of date are the same in both capitals. But even supposing that the similarity were carried much farther than it really is, what does the argument amount to? In two different temples built by Ictinus, we find two columns somewhat resembling each other. But surely this is no proof (of itself) of the existence of a double tier of columns in the Parthenon. For in the other temple built by Ictinus (that at Phigalia), it has never been even surmised that there was a double tier of columns. *Here* it is quite certain what were the purposes and situation of the Corinthian column. It is stood near one end of the cella and midway between the lateral walls, and supported the roof from the ground. It has never been questioned that this column was a *single* one, not one of a range bu standing in the isolated position described, and supporting the centre of the roof by itself. In the case of the Parthenon, however, the circumstances are altogether different, for there the fragments are so small that they could never have belonged to a column which discharged the same office as that at Phigalia. The argument seems therefore reduced to this—if an analogy be made between the two cases, we must infer the use and situation of the one column from the use and situation of the other: and yet from the different sizes of the fragments it is impossible to conceive that they belonged to columns which discharged the same offices.

So that even if it be conceded that the Corinthian column was actually made use of at the Parthenon, the accidental presence of two small fragments seems but scanty data for the supposition of a whole order. To the objection that the Parthenon fragments are of a date anterior to the temple itself, it may be replied that perhaps some of the materials of the old Parthenon were used up in the construction of the new. (For the Parthenon now existing is the second temple built on the same site; its predecessor, the ancient Hecatompedon having been destroyed during the invasion of Xerxes, and the stones of it having been carried away to make military fortifications.) Now it is scarcely to be supposed, the old temple having been violently destroyed, and the materials of it used for fortification, that at a subsequent period part of those materials (namely, the columns and their capitals) would be found so perfect as to be worthy of being used again in the building of the new temple, which was to be the wonder of Greece. There is every reason for thinking that the Athenians were determined that the new Parthenon should be, what in truth it is, the most perfect specimen of Grecian art. The construction and decoration of it taxed the energies of the greatest artists and sculptors of that age, and not only the Athenians but the whole Grecian race looked to the perfect completion of it with the greatest interest. Is it then to be supposed that the poor economy of using up old materials would be readily allowed under any circumstances? And is it not in the highest degree improbable that columns would be employed which in the important points of their orders and their dates differed from the other columns of the temple, and which had moreover suffered all the mutilations inevitable in the rough usages of warfare?

2. The second argument for the upper tier of columns is that traces have been found in the pavement, from which it is concluded that columns of small diameter once stood there—so small that the columns could not have

been high enough to reach the roof. This certainly is a more formidable argument than the last; it shows that if columns corresponding to these indications actually existed, there must have been another order of columns or some other architectural members between them and the roof. This conclusion seemed perfectly unavoidable when Professor Cockerell wrote; but we seem now relieved from all necessity of a supposition of the kind by the subsequent discovery of traces of larger colums *which would have reached the roof*. There seems no reason whatever for supposing that these columns rather than the small ones were vestigies of the old Hecatompedon. It may be conceded that such traces would remain of the foundations of the first building as would exhibit the position of its columns; and there is no great improbability in supposing that these traces would not be wholly effaced by the erection of the new Parthenon.—We ourselves have repeated experience of the same state of things in our own mediæval edifices. But there seems no reason for preferring the small columns to the large ones as having been those actually constructed in the new Parthenon. If either set of remains are to be assigned to the previous building, we have a perfect right to choose which we please—so that there is no absolute *necessity* for supposing that the small columns rather than the large were those of the Parthenon.

But there are several general considerations of a very weighty nature which lead us irresistibly to choose the larger columns reaching from the pavement to the roof as the set actually belonging to the Parthenon. In the sixth volume of the work on the Museum collection of marbles, already referred to, Mr. Cockerell gives a representation of the interior of the temple restored; his drawing resembling the illustration of the present article, excepting in the orders of the columns. Now it will be observed that in Mr. Cockerell's drawing, and also in the woodcut here given, the ower order of columns of the cella are between *two and three times* the height of the upper order. It seems to us perfectly impossible that such an arrangement could have actually existed. The upper range of columns would be considerably less than half the size of the lower range, and consequently one of these two things must have occurred—either the upper columns must have been constructed in total defiance of all due proportion of their height to their diameter (a deformity which such an architect as Ictinus could never have permitted), or else the columns of the upper tiers must have been of less diameter as well as less height than those of the lower tier—an arrangement as awkward and ungraceful as can possibly be imagined; for the intercolumniation ought to be proportionate to the diameter of the columns, and here we should have the large columns of the lower tier and the small upper columns arranged at the same distances from each other.

This objection appears perfectly fatal to the existence of the upper range. It may be added that, viewed quite independently, the second tier of columns is but a poor make-shift contrivance for getting additional height, and one which we should never attribute to the architects of the Parthenon. The whole building—that is, where the architecture is clearly determined—exhibits a perfect simplicity and oneness of design, totally at variance with this supposition, for which we have shewn that there is no *absolute necessity*, and against which there are so many powerful *a priori* arguments. In the exterior of the temple the columns were all of one order, and all supported the roof from the ground: if, in examining Mr. Lucas's beautiful model, the observer will imagine that the same arrangement was observed in the interior of the building, he will, we think, be disposed to agree with us, that the beautiful symmetry and unity of the whole is greatly enhanced on this supposition.

If we suppose the great chamber of the temple supported by a magnificent range of lofty columns rising to the roof, the mind instantly pictures a noble interior, harmonising in its severe and simple beauty with what the eye has been taught to expect by surveying the exterior of the building. If, on the contrary, we suppose in the interior a range of diminutive columns supporting others still smaller than themselves, our preconceived notions of the dignity and simplicity of the Parthenon are entirely overturned, and we are forced to allow that the Greeks themselves gave a precedent for the later parodies and barbarous adaptations of their beautiful architecture.

There is good reason to hope that before long this matter will be settled beyond all dispute. Mr. Lucas is far too energetic a lover of the arts to leave his task half done. He purposes to show shortly the very scenes of which he has furnished so admirable representations, for the purpose of examining, in the minutest manner, all that remains of the Parthenon, and of clearing up, as far as possible, all controversies respecting it. All disciples of true architecture will await the true result of his mission with interest, as tending to elucidate points of the very highest architectural importance. It may not be inopportune to call to remembrance that the distinguishing characteristic of Grecian architecture is *unity* and *simplicity*, and that therefore, in all cases of doubt, we should lean to the opinion which favours the simplest form. In nothing is the *simplex munditiis* so admirably developed as in pure classic art, as distinguished from the subsequent imitations of it; and therefore it is by following up those traces which are indicative of the greatest simplicity, that difficulties are most likely to be unravelled. With this hint we quit the subject, thanking Mr. Lucas for the valuable information which he has personally communicated, and congratulating him cordially, not only on the accession of fame which his models will win for him, but on having completed a work which will have the most powerful effect in elevating the public taste for *true* classic architecture.

ON SACRISTIES.

Very little has ever been said on the subject of Sacristies, or, as they are more usually called now, Vestries, in the Ecclesiologist. Yet it may be doubted whether such an appendage is not absolutely necessary to a church; from the impossibility of dispensing with its use, if the Divine offices are to be performed with any ceremonial, not to say decency. For not only is a receptacle required for the ornaments of the altar, the church, and the clergy, but it can scarcely comport with seemly reverence for any change of vestment to take place in the presence of an assembled congregation: the high pews in the chancel, which used often to hide this process in mean country churches, having by this time pretty generally disappeared; and the device of screening off a part of the area of the church being now fitly regarded as an expedient scarcely justifiable under any emergency.

It is not difficult to derive a general rule for the right position, and for several important details of the arrangement of Sacristies from observation of our old churches. For although existing ancient examples are far from numerous, yet in a large proportion of untouched chancels, we may observe unmistakeable traces of Sacristies which have been destroyed. From these we deduce that the proper situation of a Sacristy is on the north side of the chancel, towards its eastern part. The reasons for this position are obvious: it is near the altar (to the service of which the Sacristy, like the rigidly prescribed *Diaconicum* in a Greek church, more especially belongs); the door into it falls conveniently between the end of the northern stalls and the steps of the sacrarium, the south side being pre-occupied by piscina, sedilia, and the priest's entrance; and perhaps its presence, always rather intrusive, is less so on the north than it would be if it marred the southern prospect of the church, which in our climate is, as a general rule, in an inoffensive sense, the *show* side.

Ancient Sacristies remain in the above situation at S. Nicolas, Southfleet, Kent; S. Swithin, Leadenham, Lincolnshire; S. Mary, Reigate, Surrey, where there is a north chancel-aisle; S. Andrew, Backwell, Somerset. Sacristies in the same position once existed in SS. Mary and Michael, Trumpington; All Saints, Teversham; S. Mary, Fen Ditton, Cambridgeshire; S. Mary, Stone, Kent; and S. John, Shottesbrook, Berks. These examples are taken at random. External corbels on the north chancel-wall; the absence of windows in that part; the presence of a north chancel door, generally blocked, (in addition to the priest's door), the outer mouldings of which will often be found to be not of an external character; and foundations discovered in digging graves; reveal the former existence of a Sacristy, and are peculiarities not explained by any other supposition. In some few cases these may be traces of a chantry chapel; much more generally, however, of a Sacristy, allowed to fall to ruin, or destroyed, by the holder of the great tithes. Again, chantries, more especially detached ones, belonged generally to manors, and contained monuments, for the sake of which they have been preserved. Chantries also opened to the church by arches, not by a small door; so that we may conclude the marks mentioned above to be true signs of a Sacristy, not of a chantry chapel.

Before we leave the question of position, we must condemn the practice of some architects who, having partly received the rule we are laying down, have placed their Sacristies at the *western* part of the north side of the chancel, in the angle between the north aisle and the chancel. Certain advantages seem to be gained by this alteration: it is particularly convenient for a concealed winding staircase to the pulpit; it avoids an awkward corner on the outside; it allows of the door being placed so far west as not to interfere with the altar space, which is felt to be a gain now, considering that so many lay people resort to the Sacristy. Nevertheless, independently of the argument from authority, we prefer the old arrangement, by which the proximity of the Sacristy to the altar is maintained, the east window of the north aisle is preserved, a better distribution of light in the chancel is gained, and the stalls on the north side are left free. In a word, we think it will be *felt* that this arrangement harmonizes more with the disposition and keeping of an old church; and very often the feeling of a thoughtful observer of our old churches is worth attention, even though he may find it difficult or impossible to describe in words the nature of, or the reasons for, his impression.

We are aware that examples may be found of Sacristies built in the middle, and not at the eastern part, of the north side, as at S. Margaret's, Leicester, where it occupies the middle of the three bays composing the north chancel-aisle; or even of Sacristies in the middle bay of the south side, as at All Saints, Maidstone, Kent; but this is the case, perhaps exclusively, in Third-Pointed churches, and those of a more dignified kind than the class we are now considering. The eastern end of the north side will be found, we believe, the usual place in moderate churches of the Middle-Pointed period.

Another position, sometimes chosen in modern times, is to be severely reprehended. The Sacristy ought not to be eastward of, or behind, the altar, whether it be made by advancing the altar and reredos and leaving a screened space between it and the east wall, as at Holy Trinity, Cambridge, or by building a semicircular apse for it, as at Emmanuel church, Camberwell. We are aware that some have held that the apsidal Romanesque churches in this country were originally so fitted: at S. John, Little Maplestead, Essex, the arrangement remains: we answer, that even were this the case, which we do not believe, both the Romanesque style and the apse itself have passed away, and the Camberwell parody perhaps did not deserve mention.

Having thus settled the right position of the Sacristy, we will mention a few further particulars respecting this part of a church. We believe that generally it *ought* to have a lean-to roof, to distinguish it from a chantry, which, more often, if not always, has a gable. We are not sure that a separate gable is ever to be recommended, where there is no altar; for example, in aisles: the picturesqueness of three gables is, we are confident, a snare to some of our best modern architects. Still, if the Sacristy runs at right angles to the axis of the church, instead of parallel to it, a gable may be allowed; but this arrangement is not to be encouraged.

The details in the Sacristy may be of a less ecclesiastical character than those admitted into the church itself. Authority for this is found to a limited degree in the instances above; the church of S. Mary, Oberwesel on the Rhine, and S. Leonhard, at Frankfort-on-the-Maine, are examples in point. It may be questioned whether this licence is to be extended to more dignified churches. We cannot object to a fireplace and a chimney in a Sacristy: let them be boldly and undisguisedly treated. Still we are not sure that a too secular style has not been sometimes admitted.

Respecting large or town churches, the rules are not so stringent. In these the Sacristies may be in any convenient situation; of course, nearer the altar than otherwise. Thus at S. Mary, Redcliffe, they are on the north side, and have an upper story of rooms fitted for residence; in the abbey church of S. Mary, Tewkesbury, they are beautifully vaulted apartments to the south. In such churches the Sacristy ought to glow with colour and ornaments no less than the more sacred parts of the building. The Sacristies at S. Miniato, Florence, and Sta. Maria Gloriosa de' Frari, Venice—the first south of the south chancel-aisle, the latter south of the south transept—are remarkable examples. S. Anastasia, Verona, has a noble Sacristy, north of the north transept. The Duomo, at Milan, has Sacristies north and south; an arrangement adopted, not unhappily, in S. Paul's, London. At Cologne they lie to the north; and the detached Sacristies at S. Peter's, Rome, lie also to the north of the north transept. On the whole the north, for dignified churches also, is the better side. The Vestries of the churches in London built after the great fire—which provoke many a sneer from superficial observers for their supposed *comfort*—are rather to be regarded as instances wherein the architects have mastered the true idea of what they were building; placing it where most convenient, fitting it for its various uses, (unfortunately not solely religious ones,) and making it a not unworthy appendage to their costly churches. It was neither practical skill, nor boldness, nor *animus* that was wanting to our then architects. The Paganism of their age spoilt it all.

And this consideration leads us naturally to observe the importance of an architect's clearly mastering the idea of what he is going to design before he begins. There is no part of a church which has not its peculiar use, and ought not therefore to have a peculiar character. One does not see how a northern or southern porch could be otherwise than a gabled building, with its axis at right angles to the church. Again, nothing can be more distinct, or peculiarly appropriate to its use, than the character of a chapter-house. Similarly, a chantry, or an aisle with eastern altar, would seem to require a gabled roof: a lean-to roof, again, befits the subsidiary use of a Sacristy. The selection, then, of the detached chapter-house form for the Sacristy at a new church at Keswick, and at S. John Baptist's, Eastover, was a great mistake arising from a want of discrimination between the two kinds of building. But a less pardonable confusion of ideas is to be observed in the restoration of S. Martin's, Canterbury, where a nondescript building, part aisle, part chantry, is added as a Sacristy, and a cellar for the stove, towards the western part of the north side of the chancel. It is a great mistake also to build parvises for Sacristies. The position is most inconvenient, besides that the parvis had, and might have again, an appropriate use. Nor can this use of an ancient parvise be well defended, even where the sacristy has perished. This was the case at Kemerton, Gloucestershire, and led perhaps to the blocking up of the priest's door in that church. We have seen a modern design in which the chancel is raised and a Sacristy formed like a crypt below it. It is conceivable that great peculiarity of site might justify this arrangement; but it is not to be recommended.

It will be at once seen that if our observations be true, few devices are more essentially objectionable than one we have often deplored; namely, the use of a building, opening to the church, aisle-wise or chantry-wise, by an arch, and parclosed off for a Sacristy, the organ perhaps being placed above. It is altogether a confusion of ideas.

Any secular uses of a vestry are so incompatible with the religious ones, that we cannot conceive any arrangement which shall unobjectionably suit the two combined. We have confined ourselves to pointing out the best course to adopt with reference to the Sacristy considered only in its higher use.—*Ecclesiologist.*

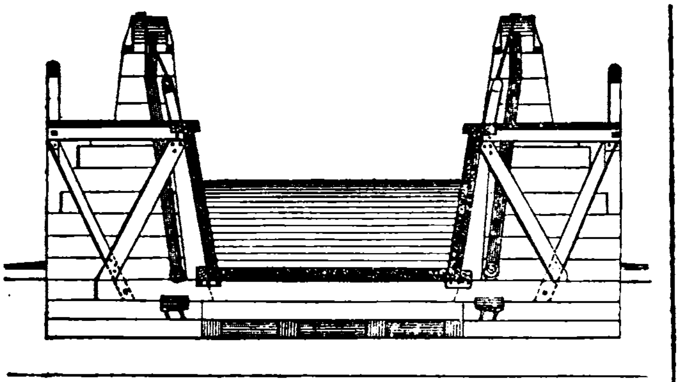
SUSPENSION AQUEDUCT OVER THE ALLEGHENY RIVER, PITTSBURGH.

This work, recently constructed under the superintendence of John A. Roebling, the designer and contractor, has supplied the place of the old wooden structure which originally was built by the State of Pennsylvania at the western termination of the Pennsylvania Canal.

The Council of the city of Pittsburgh, by whom, in consequence of an arrangement with the State, the tolls on this aqueduct are of late received, and who are bound to keep the work in repair, decided on re-building, and after considering various plans, adopted that of Mr. Roebling, and entered into contract with him to re-construct the communication, for the gross sum of 62,000 dollars, including the removal of the old ponderous structure and the repair of the pier and abutments; a very small sum indeed for a work of such magnitude. As this work is the first of the kind ever attempted, its construction speaks well for the enterprize of the city of Pittsburgh.

The removal of the old work was commenced in September, 1844, and boats were passed through the new aqueduct in May, 1845.

This work consists of 7 spans, of 160 feet each, from centre to centre of pier. The trunk is of wood, and 1,140 feet long, 14 feet wide at bottom, 16½ feet at top, the sides 8½ feet deep. These as well as the bottom, are composed of a *double* course of 2½ inch white pine plank, laid diagonally, the two courses crossing each other at right angles, so as to form a solid lattice-work of great strength and stiffness, sufficient to bear its own weight, and to resist the effects of the most violent storms. The bottom of the trunk rests upon transverse beams, arranged in pairs, four feet apart; between these, the posts which support the sides of the trunk are let in with dove-tailed tenons, secured by bolts. The outside posts, which support the sidewalk and tow-path, incline outwards, and are connected with the beams in a similar manner. Each trunk-post is held by two braces, 2½ × 10 inch, and connected with the outside posts by a double joist of 2½ × 10. The trunk-posts are 7 inches square on top, and 7 × 14 at the heel; the transverse beams are 27 feet long, and 16 × 6 inches; the space between the two framings is 4 inches. It will be observed, that all parts of the framing are double, with the exception of the posts, so as to admit the suspension rods. Each pair of beams is supported on each side of the trunk by a double suspension rod of 1⅛th inch round iron, bent in the shape of a stirrup, and mounted on a small cast-iron saddle, which rests on the cable. These saddles are connected, on top of the cables, by links, which diminish in size from the pier towards the centre. The sides of the trunk set solid against the bodies of masonry, which are erected on each pier and abutment as bases for the pyramids which support the cables. These pyramids, which are constructed of 3 blocks of a durable, coarse, hard-grained sand-stone, rise 5 feet above the level of the sidewalk and tow-path, and measure 3 × 5 feet on top, and 4 × 6½ feet at base. The side-walk and tow-path being 7 feet wide, leave 3 feet space for the passage of the pyramids. The ample width of the tow and foot-path is therefore contracted on every pier, but this arrangement proves no inconvenience, and was necessary for the suspension of the cables next to the trunk.



The caps which cover the saddles and cables on the pyramids rise 3 feet above the inside or trunk railing, and would obstruct the free passage of the tow-line; but this is obviated by an iron rod which passes over the top of the cap, and forms a gradual slope down to the railing on each side of the pyramid.

The wire cables, which are the main support of the structure, are suspended next to the trunk, one on each side; each of these two cables is exactly 7 inches in diameter, perfectly solid and compact, and constructed in one piece from shore to shore, 1,175 feet long; it is composed of 1,900 wires of ⅙th inch thickness, which are laid parallel to each other. Great care has been taken to insure an equal tension of the wires. Oxidation is guarded against by a varnish applied to each wire separately, their preservation, however, is insured for certain by a close, compact, and continuous wrapping, made of annealed wire, and laid on by machinery in the most perfect manner. A continuous wrapping is an important improvement, which, in this case, has been for the first time successfully applied.

A well-constructed and well-wrapped cable presents the appearance of a solid cylinder, which in strength greatly surpasses a chain, made of bars of the same aggregate section or weight. It is not only the great relative strength of wire which renders it superior to bar iron, but its greater elasticity, which enables it to support strong and repeated vibrations, add still more to its value as a material for bridge building.

The extremities of the cables do not extend *below* ground, but connect with anchor chains, which, in a curved line, pass through large masses of masonry, the last links occupying a vertical position. The bars composing these chains average 1½ × 4 inch, and are from 4 to 12 feet long; they are manufactured of boiler scrap and forged in one piece without a weld. The extreme links are anchored to heavy cast-iron plates of 6 feet square, which are held down by the foundations, upon which the weight of 700 perches of masonry rests. The stability of this part of the structure is fully insured, as the resistance of the anchorage is twice as great as the greatest strain to which the chains can ever be subjected.

The plan of anchorage adopted on the aqueduct varies materially from those methods usually applied to suspension bridges, where an open channel is formed under ground for the passage of the chains. On the aqueduct, the chains below ground are imbedded and completely surrounded by cement. In the construction of the masonry, this material and common lime mortar have been abundantly applied. The bars are painted with red lead. Their preservation is rendered certain by the known quality of calcareous cements to prevent oxidation. If moisture should find its way to the chains, it will be saturated with lime, and add another calcareous coating to the iron. This portion of the work has been executed with scrupulous care, so as to render it unnecessary on the part of those who exercise a surveillance over the structure to examine it. The re-painting of the cables every two or three years will insure their duration for a long period.

Where the cables rest on the saddles, their size is increased at two points by introducing short wires, and thus forming swells, which fit into corresponding recesses of the casting. Between these swells, the cable is forcibly pressed down by three sets of strong iron wedges, driven through openings which are cast in the side of the saddle.

When the merits of the suspension bar were discussed previous to the commencement of the structure, doubts were raised as to the stability of the pyramids and the masonry below, when unequal forces should happen to disturb the equilibrium of adjoining spans. It was then proved by a statistical demonstration, that any of the arches with the water in the trunk could support an extra weight of 120 tons, without disturbance to any part of the work. In this examination, no allowance at all was made for the great resistance of the wood-work and the stiffness of the trunk itself. During the raising of the frame-work, the several arches were repeatedly subjected to very considerable unequal forces, which never disturbed the balance, and proved the correctness of previous calculations.

The stiffness and rigidity of the structure is so great, that no doubt is entertained that each of the several arches would sustain *itself* in case the wood-work of the next one adjoining should be consumed by fire. The wood-work in any of the arches separately may be removed and substituted by new material, without affecting the equilibrium of the next one.

The original idea upon which the plan has been perfected, was to form a *wooden trunk*, strong enough to support its own weight, and stiff enough for an aqueduct or bridge, and to combine this structure with wire cables of a sufficient strength to bear safely the great weight of water.

The plan of this work, therefore, is a combination which presents very superior advantages, viz., *great strength*, *stiffness*, *safety*, *durability*, and *economy*.

This system, for the first time successfully carried out on the Pittsburgh aqueduct, may hereafter be applied, with the happiest results, to railroad bridges, which have to resist the powerful weight and great vibrations, which result from the passage of heavy locomotives and trains of cars.

Remark.—The quantities in the following table are calculated for a depth of water of 4 feet, which has been in the aqueduct ever since the opening. The depth contemplated was 3½ feet; a greater depth is at present required on account of the raising of the bottom of the canal by bars and sediment, which have to be removed before the level can be lowered.

Table of Quantities of the Aqueduct.

Length of Aqueduct without extensions 1,140 feet.
Length of cables, 1,175 feet.
Length of cables and chains, 1,283 feet.
Diameter of cables, 7 inches.
Aggregate weight of both cables, 110 tons.
Section of 4 feet of water in trunk, 59 sup' feet.
Total weight of water in aqueduct, 2,100 tons.
" " one span, 295 tons.
Weight of one span, including all, 4[illegible]0 tons.
Aggregate number of wires in both cables, 3,800.
Aggregate solid section of both cables, 53 sup. inches.
" " anchor chains, 72 sup. inches
Deflection of cables, 14 feet 6 inches.
Elevation of pyramids above piers, 16 feet 6 inches.
Weight of water in 1 span between piers, 275 tons.
Tension of cables resulting from this weight, 392 tons.
Tension of one single wire, 206lb.
Average ultimate strength of one wire, 1,100 lb.
Ultimate strength of cables, 2,090 tons.
Tension resulting from weight of water upon one solid square inch of wire cable, 11,800 lb.
Tension resulting from weight of water upon one square inch of anchor chains, 11,000 lb.
Pressure resulting from weight of water upon one pyramid, 137½ tons,
" " " " one superficial foot, 18,400 lb.

COLOGNE CATHEDRAL.

It appears from the forty-ninth Report of the Committee of the Society for the Restoration of Cologne Cathedral, that the advance made during the period embraced in the present Report consists, on the south side, in the additional height to which the pier of the transepts have been carried. In the same part, the western entrance has been completely vaulted in, and the eastern begun to be so. A great quantity of stone is lying ready cut for the work, and still more is expected from the quarries, in order, if possible, to vault-in the middle space also before the end of the year.

Similarly, only somewhat further, advanced are the works in the north transept. Here the three spaces are for the most part already vaulted over, and they will at all events be quite completed in the course of the present autumn.

The works in the northern nave aisle were put in activity immediately after the illustrious visit of Queen Victoria, it being necessary that the old roofing should be retained till up to that time. This has now been removed, and scaffolding is in course of erection in order to set to work upon the new vaulting. Seven bays of original vaulting, as is well known, already existed on the north side; so that there remained but five to construct. But on the removal of the old roofing and woodwork, the south-eastern pillar of the seventh bay was discovered to be built of brick in the most slovenly and insufficient manner. The groining bands and ribs of tuffstone springing from it were in the same way most meanly put together, the lines broken so as to form polygons, and the joints very faulty. Still, supposing this defect could have been partly discovered from below by the naked eye, and the conclusion thence arrived at that this vaulting was of later origin than the other portions of the beautiful vaulting of the cathedral, with which it admitted of no comparison, this would not have prevented it from being retained from antiquarian considerations, had the previously-concealed pillar proved at all adequate to support the pressure of the mass rising from it to the additional height of ninety feet and more.

This not being the case, this pillar and the vault belonging to it had to be given up to destruction. This is at present being accomplished, and the construction of the remaining spaces of vaulting suffers some delay in consequence. In general, the works will be carried on uninterruptedly with about four hundred men. Meanwhile the supply of stone is by no means kept up with the regularity to be desired, notwithstanding the arrangements have been entered into with ten different contractors. There is considerable difficulty in procuring stone of good quality in a sufficient quantity; and even were these stones obliged to be delivered in all at once according to given dimensions, the due succession would not be always observed, as the quarry-men work out the material only as it can be procured to best advantage from the rock.

At a previous meeting of the Committee, the following order of the King of Prussia was read:—

"I have received the report of the Central Restoration Society's operations during the last three years, transmitted to me the 2nd of last month, and have taken cognizance of its contents with true satisfaction. From it I perceive with pleasure the constantly growing sympathy for the grand object of the Society in most of the provinces of Germany, and am much gratified in recognising the credit which the Society's Committee has gained itself by its wise and strenuous conduct of the concerns entrusted to its care. The judicious administration and application of the resources placed at its disposal are sufficiently attested by the performances of the Society during the short period of its existence. These fully answer every reasonable expectation, and justify a still higher confidence in the successful prosecution of this sacred and noble work. To promote this success to the utmost of my power and with undiminished interest, forms one of the objects to which my life will be devoted."

FREDERICK WILLIAM.

Sanssouci, Sept. 1, 1845

To the Central Society for the Restoration of Cologne Cathedral.

The total receipts of the Society amount to about 22,180*l.*

BROAD AND NARROW GAUGE EXPERIMENTS.

We are indebted for the following particulars of the experiments made before the *Gauge Commissioners* to the Morning Herald, at present the official account has not been published.*

On Saturday morning, January 10, two more experimental trips were made on the broad gauge (the Great Western Railway) in the presence of the Gauge Commissioners; the weather was rather unfavourable, the morning being dull and damp, and very little wind stirring until the afternoon. The Hercules was again selected for the purpose; it is a powerful engine, having connected wheels 5 feet in diameter, cylinder 16 inches, stroke 18 inches, and weighs 22 tons. At 7h. 52m. 24s. she started from the one mile post, Paddington, with a train of 18 trucks, coal-laden, an additional tender, and a first class carriage, which was occupied by Sir F. Smith, Professor Barlow, Mr. Watson, Mr. Saunders, secretary to the company, Mr. Harmer, and Mr. Gibson; on the engine were Mr. Brunel, engineer of the line, and Mr. Gooch, superintendent of the locomotive department. This experimental train was driven from Paddington to Didcot, a distance of 52¾ miles, where it arrived at 10h. 19m. 38s. having made stoppages at Ealing, Southall, West Drayton, Slough, Maidenhead, Twyford, and Goring. For the exact time of arrival and departure from the several stations the reporter has been indebted to Mr. Seymour Clarke, the principal superintendent of the line, and it is as follows:—

Miles from Paddington.		Arrival. h. m. s.	Departure. h. m. s.	Stoppage. h. m. s.
	Paddington	..	7 52 24	—
5¼	Ealing	8 4 53	8 7 42	0 2 49

44¾	Goring	10 0 8	10 2 0	0 1 52
47½	Wallingford-road	10 9 30	—	—
52¾	Didcot	10 19 38	—	—
		Total stoppage ..		0 26 55

The distance was accomplished in 2h. 27m. 14s., or at a rate of 26·75 miles an hour. The weight of train propelled, exclusive of the engine, was 204 tons 18 cwt. 1 qr. 3 lb. Soon after the arrival of this train at Didcot, the Ixion, a powerful passenger engine, having driving wheels 7 feet in diameter, came up with a train of 15 trucks, laden with coal, to be attached to the train of the Hercules, making in all 28 trucks and one first class carriage. After all matters were arranged this leviathian train proceeded on its journey; its weight, length, and the time it passed the different stations, are given from the same authority as that of the down trip:—weight 406 tons, 3 cwt. 1 qr. 10 lb.; length of train, 232 yards.

	From Paddington. Miles.	h. m. s.

Arriving at the 1¼ mile-post from Paddington	—	3 39 0

Performing the journey in 2h. 16m. 45s., at an average rate of speed of 23 miles an hour.

The duration of this trip was 54 minutes, 6 seconds, which shows a speed of upwards of 47½ miles per hour. The maximum rate, between the 18th and 19th mile-posts, was somewhat above 54 miles per hour.

NARROW GAUGE EXPERIMENTS.

The experiments for testing the tractive capacity of the narrow-gauge engine commenced on the 30th Dec. last, upon the Great North of England line, between York and Darlington. The distance run was that between the first and forty-fourth mile-posts—viz. 43 miles. This piece of railway has been selected in consequence of its being nearly a direct line throughout its whole course, and from the very easy character of its gradients. The engine selected is a new one, recently constructed, made at the celebrated locomotive establishment of Mr. Robert Stephenson. She had been running for about a week only, and had not made any except experimental trips. Her performances were considered to be so good that she was fixed upon as the champion for the narrow-gauge interests. She is a six-wheel engine, with outside cylinders; has 6 feet 6 inches driving wheels, and the top of her boiler is about 7 feet 4 inches from the rails.

The hour fixed for the starting of the train was nine o'clock. There were present to witness the experiment Professor Barlow, Professor Airy (two of the gauge commissioners); Mr. Watson, the secretary to the commission; Mr. G. Hudson, M.P.; Mr. Richardson, the mayor of York; Mr. Brunel; Mr. C. A. Saunders, the secretary of the Great Western company; Mr. Gooch, superintendent of the locomotive department in the same company; Mr. Bidder; Mr. Cabry, the engineer of the York and North Midland; Mr. Harrison, the engineer of the Great North of England; Mr. W. Stevenson, of the Great Western Company; Mr. Wyndham Harding; Mr. Berkeley of Mr. Robert Stephenson's establishment, and several other scientific gentlemen.

The weight of the train was 50 tons only, and that of the engine and tender together about 28 tons. The weights of the experimental trains

* The first experiments were made in the middle of December last on the Great Western Railway. The Hercules locomotive engine was selected for the purpose.

upon the broad gauge were (exclusive of engine and tender) fixed at 80 tons, 70 tons and 60 tons, but the actual tonnages were 81 tons 18 cwt., 71 tons 12¾ cwt., and 61 tons 0 cwt. 2 qrs. It will be seen, therefore, that the experiment upon the narrow-gauge line, the particulars of which we are about to detail, has no parallel working upon the broad-gauge railway; and that whatever the value of the result, it can be recognized only when the broad-gauge engine shall have taken the same reduced tonnage for the same distance.

STARTING.—At 9h. 7m. 15s. the train started from the station in order to proceed to the first mile-post, from which it had been understood the experiment was to commence. Upon the Great Western line the experimental trains left the Paddington terminus, and were brought to a stand-still at the first mile-post. This, however, was not the case this morning.

The train passed the—

The train stopped at the Darlington station at 10h. 27m. 20s. It will be seen that the 43 miles were performed in 1 hour, 13 minutes and 53 seconds, or at the rate of nearly 35 miles per hour. The maximum speed (between the 5th and 6th mile-posts) was nearly 53 miles per hour, and the minimum rate rather more than 25 miles per hour. The average speed of the 80-tons train (exclusive of the engine and tender) upon the broad-gauge line was 47·5 miles per hour, and the maximum speed 55 miles per hour. There was, however, one thing greatly against the narrow-gauge experiment of this morning, viz.—the wind. When the train left the York station the weather was not at all unfavourable; the horizon promised rain, but very little wind was stirring. Up to the 10th mile-post the result promised to be pretty good; the last three miles had been done at about 52 miles per hour, and the narrow-gauge party calculated that the 43 miles would be got over in about 52 or 54 minutes. On reaching the 10th mile-post a heavy westerly wind came suddenly down upon the carriages, taking them obliquely in the direction the train was going. The effect was felt in less than a minute—the wind reduced the speed from 50 to nearly 30 miles per hour. There could be no doubt about the cause of retardation, because from the 10th mile-post the progress of the train was slow or fast in proportion to the length of embankment, open country or cutting. Immediately the engine entered a cutting, the increase of velocity was most sensibly apparent. If she entered a cutting of a couple of furlongs in length or 30 miles an hour, she dashed out of it at 38 or 40, and before another couple of furlongs had been run upon an embankment exposed to the gale the speed became reduced to 30 miles per hour.

The return trip commenced at 12h. 8m. 15s., and the train reached the first mile-post from the York station at 1h. 32m. 8s., performing the 43 miles in 1 hour, 24 minutes and 53 seconds, or at a speed of about 30 miles per hour. A stoppage took place in this trip for water, by which two or three minutes were lost.

The experiments were resumed on the following day.

The experiments yesterday with the 50 tons trains were considered so inconclusive, in consequence of the high wind which prevailed, that it was determined to repeat them to-day. The hour appointed for leaving the station was 9 o'clock. The train left at 9h. 2m. 10s., accompanied by Professor Barlow, Professor Airy, Mr. Watson, Mr. Brunel, Mr. Saunders, Mr. Gooch, Mr. Bidder, Mr. Wyndham Harding, Mr. Berkeley, Mr. Cabry, and about a dozen other gentlemen. The day was a favourable one. There was a slight breeze to the north, and the rails were in a fair condition. Contrary to the practice observed in the experimental trips on the Great Western Railway, the train did not stop at the first mile-post, and commence its experimental trip from a state of rest. Instead of doing this, it passed the post at the rate of about 8 miles per hour. The following is the working of the train for the 43 miles,—that is, measuring from the first mile-post out of the York station to the mile-post on the York side of the Darlington station:—

	h.	m.	s.	Time each mile in seconds.		h.	m.	s.	Time each mile in seconds.
Passed 1st mile-post at	9	6	30	—	Passed 23rd mile-post at	9	33	20	72
2	9	8	30	120	24	9	34	38	78
3	9	10	0	90	25	9	35	48	70

14	9	22	49	70	36	9	49	5	82
15	9	23	59	70	37	9	50	24	79
16	9	25	8	69	38	9	51	44	80
17	9	26	18	70	39 } 40 }	9	54	12	148
18	9	27	28	70					
19	9	28	38	70	41	9	55	30	78
20	9	29	48	70	42	9	56	48	78
21	9	30	59	71	43	9	58	10	82
22	9	32	8	69	44	6	59	58	108

The time occupied in performing the distance yesterday was 1 hour, 13 minutes, 53 seconds, or at the rate of something less than 35 miles per hour. It will be seen that to-day the same distance was accomplished in 53 minutes, 28 seconds, or at rather less than 48 miles per hour, the maximum speed, between the 5th and 6th mile-posts, being nearly 55 miles per hour. The wind of yesterday may therefore be considered to have offered a resistance equal to above 13 miles per hour.

The return train with the 50 tons left Darlington station at 11h. 21m. 0s., and passed the first mile-post at 11h. 22m. 18s. The following is the working of the engine:—

	h.	m.	s.	Time each mile in seconds.		h.	m.	s.	Time each mile in seconds.
Passed 1st mile-post at	11	22	18	—	Passed 23rd mile-post at	11	51	28	77

22	2	37	44	82	44	3	8	8	[illegible]

From this table it is seen that with good weather to-day, the same engine upon the same line, and going over the same gradient (for curves there are none), took 80 tons 43 miles in 58 minutes, 30 seconds, or in 15 minutes, 23 seconds, less than she took 50 tons yesterday with a side wind against her.

THIRD DAY.—In consequence of an accident by the engine running off the rails, the experiments could not take place.

FOURTH DAY.—Two more experiments were made with the goods train of 200 and 400 tons respectively. The engine employed was the Hercules. She is a six-wheel coupled engine, with 4 feet 6 inches driving-wheels. Fire-box, 60 feet surface; tubes, 900 feet; cylinder, 15 inches; stroke, 24 inches; weight, 20 tons.

The engine started from the first mile-post beyond York at 9h. 36s., made seven stoppages, amounting to 40m. 50s., and arrived at the 43rd mile-post at 12h. 31m. 40s. The actual time of running, therefore, was 2h. 14m. 20s., or upwards of 18 miles per hour. The return trip from Darlington was with 400 tons, the train being above 300 yards long. The train left the 44¾ mile-post at 2h. 5m. 5s., and arrived at the first mile-post at 4h. 22m. 24s., without making any stoppages. This gives something like 19 miles per hour. The following is the working of the engine with the monster train, viz. 47 wagons.

	m.	s.		m.	s.
1st mile performed in..	4	6	24th mile performed in	3	1
2	2	20	25	2	50
3	2	10	26	2	50

19	2	4	42	3	0
21	2	30	43	3	0
22	3	25	44	3	20

It will be seen that the maximum speed was nearly 30 miles per hour.

THE LATE ACCIDENT UPON THE NORFOLK RAILWAY.

At an inquest commenced in December last, in consequence of a fatal accident on the Norfolk Railway, considerable interest was excited on account of the contradictory opinions expressed by two gentlemen of the highest eminence for their knowledge of engineering—General Pasley and Mr. Bidder. General Pasley did not hesitate to assert in his evidence that Mr. Bidder had, in the course of his examination, expressed opinions "quite erroneous and *contrary to the first principles of mechanics.* It is of the highest importance to the engineering profession to ascertain the truth respecting several very important views propounded during the inquest.

It does not lie within our plan to give a detailed account of the accident, it will be sufficient for our purpose to state simply that it arose from the engine running off the rails. The following extracts from the evidence of Mr. Bidder embody the notions which General Pasley declared to be contrary to sound philosophy.

"The inclination of the line where the engine had run off was 1 in 100. The permanent way was as good a piece as any in England. It was constructed on a chalk embankment, the most favourable soil for such work. At the point where the engine left the rail the embankment was raised about five feet above the ordinary surface of the earth. The chalk in the embankment was used in large lumps, and he thought the late wet weather would have no effect upon it. On examining the engine he found the steam-regulator indicated that *the steam had been turned off suddenly*, the effect of which would be precisely similar to that which had been described by the previous witness. The speed of the engine would be more retarded than the carriages, and the train would urge the engine on, forcing it off one side of the rail, and the carriages on the other. He attributed the accident to the impropriety of the engine-driver *proceeding at a very high velocity and suddenly shutting off the steam.* Moreover, the line near Thetford being under repair, it required particular caution in passing over it, and if the deceased did not exercise that precaution, it showed a great want of care on his part. He had no means of judging the exact speed the engine was going, but his opinion was, that it must have been *very great, far beyond that of the proper speed*, viz., 30 miles an hour."

The evidence of the next witness examined after Mr. Bidder is important, not for matters of opinion but matters of fact; for it appears that he distinctly stated the circumstances on which Mr. Bidder founded his opinion to be, in reality, quite different from those under which the accident took place. Coleman, the chief guard of the train says, that "no alteration was made in the speed more than usual," that the speed of the train "up to the period of the accident *did not exceed 35 miles an hour,*" and that "he had travelled on the line frequently as fast as he did on Wednesday." He says also that just before the accident, the engine gave a "tremendous jump;" that he could see distinctly what the engine-driver was doing, and that "the moment the engine jumped, Pickering turned round and looked on one side, and *then* cut off the steam." He swore positively that "Pickering *did not* shut off the steam *until after the engine had jumped off the rails.*"

The evidence of Major-General Pasley is as follows.

General Pasley—My opinion is, that owing to the peculiar construction of the engines, like the one that met with the accident on the Norfolk line, they are not the most suitable to the narrow gauge, as they do not admit of any great speed without danger. They are perfectly secure on the narrow gauge at a certain rate. For instance, the distance from the Harsling-road station to Thetford is eight miles, and 26 minutes is allowed to accomplish that distance. The distance and time noted in the Norfolk Railway Company's time-bill can be travelled over without any excessive speed. If by any extraordinary neglect 10 minutes should be lost between those two stations, there is 16 minutes to go the eight miles, a rate of 30 miles per hour.

Coroner—Can you account for the broken chair, which was 22 feet from the sleeper, that was cut apparently by the engine when it got off the rail?

General Pasley—I should say that the chair was broken by the motion of the engine. If it was defective before, the motion might contribute to its breaking entirely.

Coroner—What description of engine was it that met with the accident?

General Pasley—One of most extraordinary length of such a length as was never used on the narrow or any other gauge before. If you will allow me, I will mention a circumstance respecting these peculiar class of engines. Some months ago there existed doubts as to the safety of express trains to travel by, and knowing that oscillation of carriages was no proof of danger, or that their steadiness ensured perfect safety I determined to ride upon the engines, with a view of more easily detecting their unsteadiness—their oscillating indicating danger. I travelled lines in different parts of the country, and the only engine I found having such an oscillation was one on the South Eastern Railway, called the White Horse of Kent, manufactured by Mr. Robert Stephenson, and of the same peculiar construction as the one that went off the rails on the Norfolk line. I went on that engine at the rate of 44 or 45 miles an hour, and at that speed she rolled something like a ship at sea. The oscillation, when the train is going at such a rate, indicates a danger of running off the rail. I told the engine-drivers and other authorities that if they ran 50 miles an hour, like the express trains on the Great Western Railway, the greater likelihood of the engines rolling over. I have stated that opinion to the Gauge Commissioners. The difference between the engine you have alluded to as manufactured by Mr. Robert Stephenson and those employed on the Great Western, is thus—The narrow gauge not offering so great a diameter of boiler as the broad, Mr. Stephenson, to remove the obstacle, constructed the long-boiler engines to equal them in power, and they have failed in the purpose for which they were intended. The long boiler engines, which Mr. Stephenson persevered in, are four or five feet longer than those of original construction, the smoke box overhangs the fore wheels, and the fire-box and dome the hind wheels, which will cause them to oscillate. I think such an engine as the one in question can go at 30 or 35 miles an hour, and I think I have gone at 45 miles an hour upon them; but when they approach 50 I think they are unsafe, and that is an opinion not hastily formed. I have mentioned it frequently to engineers and superintendents of railways, as well as to the Gauge Commissioners. The Great Western Railway has been worked by engines of one pattern for the last five or six years. The motive for forming the long-boiler engine was to gain a larger evaporating surface, and thereby obtaining greater power of steam. That however has failed, owing to the tube at the fore part of the boiler being so far distant from the fire-box, and not being exposed to the full action of the heat. The engine on the South Western, Manchester and Birmingham, and Grand Junction Railways, of the make of Messrs. Sharp and Brothers, with boilers of moderate length, have equal, if not more power, and are capable of going at any speed they will admit of, providing the ground is in good order. I think these long boiler engines, if they are going at a rate exceeding 40 miles per hour, are liable to oscillate and run over the line. The cause is the defect in their formation. It is the wheels huddled together, or the axles under the boiler, that gives so much overhanging dead weight at each end, which I have not found with any other engines but those of Mr. Stephenson.

Coroner—Did you ever anticipate an engine of this description meeting with such an accident?

General Pasley—The fact is, I did not expect such an accident could have taken place. I did not think that such an engine could have gone at the speed it did in running off the line. It is a rule with engine drivers to shut off the steam on a descending gradient, and in all my journeys in railway travelling I never found them neglect doing so. I have frequently informed the engine-drivers of these engines of the danger they were incurring when driving them at a rate verging upon 50 miles per hour. In the north of England, however, I remember being on one of Mr. Stephenson's long-boiler engines, and two pair of the wheels were coupled together, and in riding upon it I felt more secure than I would upon the two other ones, as the coupling produces steadiness, and consequently safety. I wish to explain why I consider that the sudden shutting off of the steam could not have led to the accident—the grounds upon which I differ with other opinions. When the steam is shut off suddenly, more especially on a descending gradient, the momentum will drag the tender and carriages for a considerable distance, and presuming that the engine should become detached from the tender, its impetus would carry it far in advance; so much so, that the train would fail in overtaking it. The engine would proceed faster than the carriages. In order to show you the effect of suddenly shutting off the steam, I was lately on an engine on the Bristol and Gloucester Railway with Mr. Connell, the locomotive superintendent, the Gauge Commissioners being in the train, when I desired a greater speed to be put on, and then requested the steam to be turned off suddenly. It was done so, and not the slightest effect was produced. Again, on the Great Western Railway I was on an engine with Mr. Brunel—two tenders attached and a goods'-train of 2,000 tons, with a speed of 30 miles an hour. I desired Mr. Brunel, when they had to stop at a station, to shut off the steam suddenly a minute before the breaks were applied. It was done frequently, and not the least effect felt. The tender did not crowd upon the engine, and neither did the wagons crowd upon the tender. In short, shutting off the steam produces no effect, unless the breaks are applied, more especially in descending an incline of 1 in 200. At the New Cross incline, which is 1 in 100, the trains are always stopped by turning the steam off suddenly, and applying the breaks immediately, and if the cause of the accident was really the shutting off the steam, accidents would be constantly occurring at New Cross. Whenever there was a necessity for such a step I should have no hesitation in adopting it.

Coroner—Then, Sir, you quite disagree with Mr. Bidder's opinion as to the cause of the accident?

General Pasley—I consider Mr. Bidder's opinion perfectly erroneous; at the same time I wish to observe that Mr. Bidder is a gentleman of much ability, but in this case I think he is much mistaken; his opinion is contrary to the first principle of mechanics. The dimensions of the engine are 19 ft. 6 in. in length, without the foot-plates which the engine-driver and occasionally the stoker stand upon, which gives about 2 feet more. The distance from the centre of the front and hind wheels is 10 ft. 3 in., so that the smoke-box is projecting before the fore wheels, and the fire-box and dome overhanging the hind wheels. In all engines, before Mr. Stephenson took out his patent for the construction of the long-boiler engines, the hind wheels are in the rear of the fire-box and dome, and consequently there is no overhanging dead weight at the rear of the wheels. When I first saw the engines I thought them very good in travelling at a moderate rate, but I now see no advantage in their construction or improvement. The fore part of the boiler being so far from the fire-box, the tubes being so much distant, the engines do not afford the power that was expected from them. The engines of Sharp, Brothers, and Co., with moderate length boiler, possess equal or greater power, and are free from danger.

Coroner—Are there any signal posts to denote gradients.

General Pasley—After the first accident on the Eastern Counties Railway, the Earl of Dalhousie wrote to the board desiring that all the inclines should be marked out with posts, which had been done to guide engine-drivers; for at the accident at Littlebury, on that line, the superintendent of the locomotive department, who was on the engine, and the driver, were really descending a gradient without knowing it.

Coroner—Mr. Bidder has told us that on gradients of 1 in 200, engines are in the habit of travelling at the greatest velocity?

General Pasley—Then that is contrary to my general experience. I never travelled an incline but that the steam had been partially or perfectly shut off. It is a general rule to shut it off on going down an incline. I do not think that on a gradient of 1 in 200, engines are in the habit of running at the greatest possible velocity.

Coroner—Then we perfectly understand you to say, that shutting off steam in descending a gradient would not cause an engine to stop?

General Pasley—Certainly, if the breaks were not applied. If the decline is 20 miles in length, it will not stop until it comes to a level. It is the source of gravity. Its momentum forces it along.

The learned Coroner proceeded to sum up the evidence, and after commenting on the principal facts as related to the unfortunate occurrence, remarked upon the wide contrast of opinion entertained by Major-General Pasley and Mr. Bidder. It was for the jury to determine, knowing well that they would so decide as would ensure the public every safety.

The verdict was "Accidental death, caused by the imprudent conduct of the engine-driver in going at an excessive speed."

General Pasley, on his return to town by the last train, rode on the engine of the Eastern Counties Company, one of the same description as those that ran off the rails at Littlebury and Waterbeach, built by Stothart, Slaughter, and Co., in order to test its capabilities. The speed on one portion of the line between Bishop's Stortford and Stratford was for a short time upwards of 45 miles an hour, and the engine rode very steady; and in two or three instances, on nearing a station, he directed the engine-driver to turn the steam off suddenly, full a minute before the breaks were put down, and not the slightest effect was produced.

The reply of Mr. Bidder appears in the form of an advertisement, published in the *Times*, from which we make the following extracts:—

"The substance of the evidence which I gave was to the effect, that by the sudden shutting off of the steam of the engine, the carriages were no longer drawn by the engine, but that the engine was propelled by the carriages, and that this, in combination with other circumstances which (as I then stated) might not occur once in a thousand times, had, on this occasion, the effect of forcing the engine off the line.

"The grounds upon which I formed this opinion are based upon what I must still believe to be a well-established law of mechanics—viz., that in any system of bodies moving together, if there be no resistance, or if the resistance of each body be in the like ratio to its weight, when the motive power ceases to act upon them, these bodies will exert no influence upon each other in any direction, but if the resistance to the motion of the bodies in front be greater than that which is required to sustain the motion of those which are behind, the retardation of the former will be more rapid than that of the latter, and will be impelled by them, and *vice versâ*.

"Applying this to the case of a railway train in motion, we have this fact for our guidance—that an engine requires from 7 to 12 lb. per ton more to sustain its motion than the carriages—it must inevitably follow, that the effect of suddenly shutting off the steam causes the carriages to overtake and impel the engine forward, as stated by me in my evidence."

It certainly must be conceded that assuming with Mr. Bidder, the resistance to motion to be 7 to 12 lb. per ton more for an engine than for carriages, the carriages will exert a pressure against the engine when the steam is suddenly cut off. But the misapprehension on which General Pasley grounded his censure of Mr. Bidder appears to be this—that he presumed Mr. Bidder's notion to be that the carriages acted on the engine not by a continuous pressure, but by impact or collision. There is no ground however for supposing that Mr. Bidder entertained this idea. At the same time while defending him from the charge of having erred in the first principles of mechanics, we do not hesitate to deny the possibility of the accident having arisen from the causes assigned by him.

It appears from the very careful and elaborate experiments of M. de Pambour, that the friction of an engine when not drawing a train (the case here supposed) is about 14 lb. per ton. The friction of carriages is 6 lb. per ton. This gives an excess of 8 lb. per ton for the friction of the engine. But from this must be deducted the resistance of the air, a most important item in considering high velocities. The resistance of air on the carriages is much greater than on the engine in proportion to the weight of each. We should be quite safe in supposing that at velocities ranging from 30 to 50 miles an hour, the resistance from this cause is 3 or 4 lb. greater per ton on the carriages than on the engine. So that on the whole we may safely conclude that when the engine and train are disconnected at a high velocity, the steam being cut off at the same time, the excess of resistance on the engine is certainly not more than 5 lb. per ton.

Now we shall have no difficulty whatever in showing that the pressure which the carriages will exert on the engine under these circumstances is no greater than that which could be easily exerted by a boy 12 or 14 years old. By the very simplest mathematics it may be demonstrated that the pressure is equal to 5 times the *product* of the number of tons which the train and engine weigh respectively, divided by the *sum* of those numbers.* For instance if we suppose the weight of the train 40, and of the engine 10 tons, the product of those two numbers (400) being divided by their sum (50) gives 8, which multiplied by 5 gives 40 lb for the pressure on the engine. Again, take the weight of the train at 60 tons, and of the engine at 12 tons, 12×60 is 720 and $12 + 60$ is 72: dividing 720 by 72, and then multiplying by 5 as before, we get 50 lb. for the pressure on the engine.

It must be carefully noted that the pressure here calculated represents the *whole* effect of the train on the engine. There is nothing like impact or collision because the velocities of both engine and carriages are initially the same, and are *gradually* retarded.

Now it would be perfectly ludicrous to imagine that a pressure of 40 or 50 lb. would injure an engine or force it off the line. Taking the weight which a man can usually raise at 200 lb. (no very high estimate) we have for the pressure in question one-fifth to one-fourth of the average of human strength. Even if we take Mr. Bidder's own account and assume the excess of resistance to the engine over that to the train at 7 to 12 lb. per ton, the case is made very little better, for even then the pressure is not nearly so great as that which could be exerted by one man.

---

* Let M be the number of tons which the train weighs, F the resistance per ton to it, P the mutual pressure between the train and engine: then measuring the accelerating force from the time of disconnecting the two, in the direction of motion, we have

$$M\frac{d^2 x}{dt^2} = -MF - P$$

for the motion of the carriages. For the motion of the engine we have, putting M' for the number of tons, and F' for resistance per ton,

$$M'\frac{d^2 x}{dt^2} = -M'F' + P$$

P here changing its sign. Equating the values of the differential (which we may clearly do since the carriages and engine are supposed to continue moving at the same velocity) we get the pressure P equal to

$$\frac{MM'}{M+M'}(F'-F).$$

So that if we leave mere generalities and come to actual calculation, the whole theory seems fallacious enough. What is the pressure in the case in question compared with that which the carriages and engines exert on each other when the engine has to be reversed to move carriages backward? And this occurs daily and hourly without any very disastrous consequences.

A much more serious source of accidents on the Norfolk Railway appears to us to be the manner in which the tranverse sleepers are laid. Being made from unsquared timber sawn in half lengthways, their form is hemi-cylindrical. Now these half cylinders are not (we understand) laid with their flat sides downwards, as in many other railways where they are of course firmly supported by the soil: but in the Norfolk Railway the sleepers are laid with the flat sides uppermost. The hold which the *rounded* sides have on the soil is comparatively small, and it is obvious that a pressure on one side of the upper side of the sleeper might easily cause it to slip round. If for instance, a stone resting on the edge of the sleeper were pressed upon it by the passing of the train, it would certainly tend to shift the position of the sleeper, and therefore of the rails.

Mr. Robert Stephenson's Report.

The following report upon the causes of this deplorable occurrence has been presented by Mr. Robert Stephenson to the directors:—

To the Directors of the Norfolk Railway.

Gentlemen,—Absence from London on urgent business has prevented me complying earlier with your request that I should report to you my observations on the statements made in the evidence given at the inquest on the late accident upon the Norfolk Railway.

I returned to town last night, and now proceed to lay before you such remarks as have suggested themselves. In the outset I may state, that I concur generally with the engineering evidence given by Mr. Bidder and Mr. Marshall. I shall therefore confine my observations to the evidence of General Pasley, but before I direct your attention to the individual statements, I must observe, that I have experienced considerable difficulty in dealing with them, in consequence of their being merely expressions of opinion, without adducing arguments or specific facts to support them. If the General had, after giving an opinion, stated the particular reasons or result of calculations which led him to such conclusions, then their validity might have been tested. In the present instance such a course is doubly necessary, because the subject, from the tone assumed, is made not merely a scientific one, but one involving professional character. I shall, however, confine my remarks to the former.

General Pasley commences by stating that the description of engine was one of "extraordinary length, of such a length as was never used on the narrow or any other gauge."

From this statement everybody would conclude that this class of engine was not in very general use; that little or no experience had been obtained of its peculiarities; that it was an experimental engine, possessing several obvious defects.

Against this assumption I only think it necessary to state the fact that upwards of 150 engines of this description have been in daily use in this country and on the continent for the last two or three years; that the long boiler has, by every experienced and impartial locomotive manager with whom I have communicated, been received as a decided improvement; so much so, that since this class of engine was first introduced, the boilers of old engines have been, in several cases within my own knowledge, very considerably lengthened; thus offering the most incontestable proof that the old construction of engine is admitted to be deficient in length of boiler. You will bear in mind that I am now speaking of the boiler simply; the other parts of the construction of the engine upon which General Pasley offers an opinion I shall come to afterwards. I need hardly say, that during the working of such a number of engines over such a length of time, it is impossible to conceive the avoidance of accident. If this construction of engine involved danger to the extent stated by General Pasley: but, as if to meet this argument, the General in his evidence qualifies his opinion of danger by saying, "that such an engine as the one in question can go at 30 or 35 miles an hour, and I think I have gone 45 miles upon them."

I can only state my own experience leads me to a different conclusion, and that I have frequently been upon this description of engine when the speed far exceeded those above referred to without the slightest accident occurring.

Oscillation in the body of the engine at high velocities I regard as inevitable, no matter what the construction may be; but this oscillation arises from causes which cannot have come within the Inspector-General's sphere of observation. It is only the practical man whose opinion on such points can be depended upon; it is not the occasional riding upon an engine that can enable any one to decide between the construction of one class and another, or to decide that dangerous oscillation is caused by an overhanging firebox or a long boiler. In a word, to decide a point of this kind it is absolutely essential to examine the condition of the engine as well as its construction; for instance, the steadiness of all six-wheeled engines essentially depends upon three conditions,—

1. The distribution of the weight upon the three axles.
2. The lateral play in the bearings.
3. The distance between the extreme axles, that is, the extreme length of bearing upon the rails.

Of these the last only is permanent; the two first are constantly subject to change. An engine which is perfectly safe and comparatively steady to-day may become unsteady, and even dangerous at high speeds, in a short time by an alteration either in the springs or by the lateral wearing of the bearings. Now, I have reason to know that the White Horse of Kent, the only engine which General Pasley quotes as having oscillated excessively, although he has tried several others, was not in the best working condition at the time he made the experiment; no opinion with reference to its motion could therefore with propriety be drawn without taking into account the condition in which the bearings were at the time, together with the disposition of weight upon the wheels.

All engines when allowed to get play upon the bearings become unsteady at high velocities, and oscillation from this source is aggravated if more than a due proportion of weight be thrown upon the middle pair of wheels.

I believe nearly all the accidents which have occurred by engines leaving the rails are mainly attributable to want of attention to this condition.

In bad weather, when the rails are slippery, the temptation to the engineman to increase the weight upon the driving wheels is very great, and I have frequently known it carried to an improper extent. How far this may have operated in the Norfolk Railway accident cannot now be ascertained, but, referring to that which took place during the progress of the experiments on the Great North of England Railway, under the Gauge Commission, I have ascertained that this improper distribution of weight was one of the chief causes of the engine leaving the rails. On a piece of absolutely perfect road this cause would in all probability not have produced the result, but in cases of this kind the ultimate result seldom, very seldom indeed, flows from one cause; it is the concurrence of two or more circumstances operating in the same direction.

If accidents on railways arose from any peculiarities of construction in the engine, we ought to have them every day. If the overhanging firebox so much objected to by General Pasley were dangerous, it would be absolutely impossible to work the London and Birmingham one day without a series of accidents. The engines upon that line have fireboxes projecting beyond the bearing axle fully 4 feet 6 inches, being 5 inches more than the corresponding projection of the Norfolk engine. The London and Birmingham line has been worked now nearly eight years with an unparalleled traffic with engines having overhanging fireboxes, without any accident which can fairly be attributed to such a peculiarity of construction.

I originally objected to this projection of the firebox beyond the axle; but, after an experiment continued uninterruptedly for a series of years, with an enormous traffic, it would be absurd to reject such practical evidence and to hold to such an opinion.

It was this opinion that led me to the construction of the new long-boiler engine, and the abandonment of the objection I originally entertained and acted upon. When I considered, moreover, that the London and Birmingham engines had, in addition to the overhanging firebox, a remarkably short bearing upon the rail, and, consequently, admitting of the overhanging weight operating with increased effect, the testimony appeared to me conclusive.

The London and Birmingham engines in the commencement had a bearing upon the rail of only 5½ feet (they have since been extended), whereas the Norfolk engines have a bearing of 10½ feet. On this point I need not confine my reference to the engines upon the London and Birmingham, because they are not peculiar to that line; they are to be found on many others.

Whatever may be the effect of such evidence upon the minds of others, I must confess that to me it appears perfectly conclusive that the overhanging box exercised no influence such as General Pasley imagines.

In confirmation of this, I may state that yesterday, with a passenger train of 40 tons, with a boisterous side wind, I came from Darlington to York on the A engine, which has an overhanging box and long boiler, accompanied by Mr. T. E. Harrison, Mr. Fletcher, and Mr. Joseph Stephenson, for the express purpose of trying the oscillation of the engine. For several miles the speed exceeded 58 miles an hour, and in some we passed the consecutive quarter mile posts in 15 seconds, being 60 miles an hour. In addition to the overhanging firebox, we were all standing on the footplate with the engineman, excepting Mr. Joseph Stephenson; consequently, the circumstances were peculiarly calculated to excite oscillation, if the tendency existed to any appreciable extent. I am, however, enabled to declare most positively, that this engine was not only entirely free from any dangerous oscillation, but as steady as any engine I ever rode upon. Here I will leave the question of overhanging firebox and proceed to notice the next peculiarity of the Norfolk engine specially noticed by General Pasley—viz., "The wheels being huddled together."

In looking at this part of the subject, I am relieved from any discussion as to matters of opinion; it is simply one of dimension, which admits happily of no dispute. I therefore give you the dimension of Slaughter's engine, which the General returned to town upon, and declared safe and steady, and those of the Norfolk engine, which he condemns:—

	Ft.	In.
Slaughter's engine, distance between extreme axles ..	11	0
Norfolk engine, distance between extreme axles ..	10	6

I leave the General to say whether this difference of six inches justifies the epithet, "huddled together," as applied by him to the wheels of the Norfolk engine.

The General, in another part of his evidence, says, "These engines (alluding to Slaughter's), although they are of a long boiler construction, have no overhanging weight like Mr. Stephenson's." This, like the last, is merely a question of dimension, the fact being that at the chimney end Slaughter's engine overhangs precisely to the same extent as the Norfolk engine—viz., 4 feet 9 inches; at the firebox end in Slaughter's engine the axle is placed underneath the middle of the firebox, whereas in the others it is placed immediately in front of it, without, however, giving the engine more than 6 inches additional base upon the railway, and this in a distance of 11 feet; yet this shade of difference, according to the General, makes the one engine safe and steady, and the other dangerous, and apt to "roll like a vessel at sea," and this without reference to the fact that the centre of gravity of the Norfolk engine is fully a foot lower than Slaughter's. Were it necessary to adduce any further evidence it would only be necessary to recall to mind the base of the London and Birmingham engines, where, with an overhanging firebox, the base of the rail does not exceed 7 feet.

I do not think that comment on such a conclusion is necessary: if a shade of difference of this kind be really adequate to produce such consequences as are here stated by the Inspector-General, the sooner the construction of every class of locomotive engine is revised the better.

General Pasley states in another part of his evidence, that "the narrow gauge not offering so great a diameter of boiler as the broad, Mr. Stephenson, to remove the obstacle, constructed the long boiler engines, to equal them in power, and they have failed in the purpose for which they were intended." And again, "that owing to the fore part of the boilers being so far from the firebox, the tubes being so much distant, the engines do not afford the power that was expected from them."

This paragraph I have no hesitation in declaring to be entirely erroneous. In the first place, the motive for lengthening the boiler had no reference to gauge at all, because it is equally applicable to all gauges; the object was to save fuel, by preventing the escape of a large quantity of waste heat up the chimney; in this it has been perfectly successful, which has been established by every experiment tried with this object. Even with the longest tube yet introduced in locomotive engines, the temperature at the chimney end has been found sufficient to melt lead, which is upwards of 200 degrees above the temperature of the water in the boiler. The opinion of General Pasley on this point is equally at variance with the most extensive experience with stationary engine boilers, which are much longer, with much less velocity of draught.

It must be obvious to every one that every addition to the economy of fuel obtained by an enlarged evaporatory capacity is necessarily attended with a corresponding increase of power, and therefore, as before observed, although my original object in lengthening the boiler was with the view of economical results, it has been attended with a large increase of power. I beg therefore to remove the impression produced by General Pasley's evidence, by emphatically declaring that the long boiler arrangement suggested itself to my mind, indeed was in actual operation, years before the question of gauges was agitated. I forbear here going into the question of gauge, which has been so pointedly introduced by General Pasley both in his evidence and in his letter in *The Times*, because it is both foreign to the subject, and can lead to no result whilst it is under the consideration of the commission appointed for that purpose.

In conclusion, I am willing to believe, nay, I am sincerely convinced, that General Pasley, in giving his evidence, was actuated by no other motive than a wish to arrive at the truth, but in the present instance I must be excused for regarding him as having ventured to give opinions upon a difficult subject, and one with which neither his education nor experience can have made him thoroughly acquainted. In venturing thus to express myself, I am far from wishing to imply the least disrespectful feeling to General Pasley; on the contrary, my experience in the mode in which he has filled the difficult office of Inspector-General has led me to respect him, and at all times to aid him by giving him opinions on practical subjects whenever an opportunity presented itself; but in the present case I am so personally involved by his evidence, and feel so strongly convinced that his views are entirely erroneous, and calculated to injure railway interests, that to express my opinion with any reservation would be injustice to many railway companies whose confidence I enjoy.

I am, Gentlemen, your obedient servant,
Robert Stephenson.

24, Great George-street, Westminster, Jan. 21.

FALL OF A VIADUCT ON THE ROUEN AND HAVRE RAILWAY.

(*Extract from a Private Letter.*)

It being possible that the news of the falling of the whole of the viaduct of Barentin, on the line of the projected railroad between Rouen and Havre, and within three leagues of the former place, may not yet have reached you, I therefore hasten to send you all the particulars that I have collected.

This event took place on Saturday last, the 10th January, and has made a deep impression on the feeling and fears of the population of Havre, who looked forward with much anxiety to the speedy and safe accomplishment of an undertaking in which their commercial and general interests are so importantly involved. Now that the accident has happened, opinions, which were formerly kept in subjection, are expressed without reserve, and it would appear that doubts have long been entertained of the solidity of the works, of the amount of care observed, and of the quality of the materials used in the construction of this railroad. One shudders at the idea of the dreadful consequences which might have ensued had the road been in full operation at the time of the accident. The fall of this enormous work, raised to the height of 32 yards French, (about 105 English feet) above the soil, naturally gives rise to the most serious apprehensions for the eventual fate of two others, those of Malanney and Mirville, which the same conditions expose to a like result.

Public confidence in the general stability of the works upon this railroad has, by this dreadful event, received a blow, the effects of which can only be removed by the test of time and a long series of successful operations. Happily, no lives have been lost, nor much property in the immediate vicinity destroyed by the fall of the viaduct. A flourmill, situate upon the river St. Austreberthe, was entirely knocked down, and it was not till within an hour afterwards that the inhabitants of Barentin could make their way across the masses which eucumbered the road to the rescue of the sole inmate, who miraculously escaped with a slight wound only of the finger. The machinery and fragments of the mill were scattered about in every direction.

The *Journal des Debats* publishes the following letter on the subject of the late catastrophe which occurred on the Rouen and Havre Railroad:—"I have the honour to address you the following note, with a request that you will insert it in your next number. The directors of the Rouen and Havre Railroad Company hasten to publish the first information transmitted to them on the state of the viaduct of Berentin by Mr. Locke, the principal engineer of the company. The directors have since had a conference with the principal engineer, at which the announcement made in the journals of last evening was fully confirmed—viz., that the cost of the rebuilding of the viaduct of Barentin will be at the expense of the contractors, and that the reconstruction of the viaduct will not retard for more than two months the opening of the line. The plan of the reconstruction was this day arranged by the board of directors, and will be presented to-morrow to the Minister of Public Works. The damage caused to the proprietors in the neighbourhood of the viaduct is of no serious importance, and can give rise but to a slight indemnity, already partly arranged.—E. Delacour, Secretary to the Company."

THE JANUS STEAM SHIP.

(Wecopy the following article, addressed to the Editor, from the *Times*.)

Sir—The frequent articles inserted in your universally circulated paper relative to the Janus, indicate that the success or failure of the engines, boilers, and lines of construction are subjects of public interest.

Being thus confirmed in my opinion, I enclose to you the last report made on the original revolving engine erected by the late Admiralty in Portsmouth Dockyard, the performance of which engines gave to the present board the confidence they have manifested in promoting the attainment of an object highly interesting to the naval service.

Those only who attempt to introduce an important novelty can estimate the effects of jealousy and prejudice. I confide, however, in your liberality to aid in their removal, and beg that you will inquire whether any reciprocating engine has ever performed duty equivalent to 13 consecutive double voyages from England to America (as the Portsmouth engine has done), almost without repair?

I am, Sir, your obedient servant,
Dundonald.

Portsmouth, Jan. 8.

Report of the Earl of Dundonald's Rotatory Engine erected in Her Majesty's Dockyard at Portsmouth.

On the 22d of December, 1845, two years and nine months of constant performance of the rotatory engine expires, during all which time it has been working in the most effectual and satisfactory manner, no derangement of consequence having ever taken place.

It is presumed that these two years and nine months of constant and laborious operation (requiring no more than slight attention by the workmen) have gone far to establish that quality which, until now, had not been sufficiently developed,—namely, durability, and consequent continuity of operation.

The principal repair this engine has required was taken in hand about nine months ago. This was so trifling that six men could have accomplished it in one day, but having been much pressed with work at the time, one man only could be spared, which consequently protracted its completion for one week.

Thus after four years and nine months constant working as a prime mover, two years and nine months of which have been so successfully performed, nothing more can be wanting even by the most sceptical to establish its merits as a powerful, economical, and durable engine, equal in point of efficiency to any reciprocating engine in Her Majesty's service.

Should additional evidence be sought to establish further claims as a rival in steam mechanism, it is to be found in the simple fact, that this first essay on the Earl of Dundonald's principle, although at first altered and mutilated to bring it to perfection, is nevertheless at the present time perfectly free from those indications of weakness and declining energy which any other engine, under similar circumstances, might probably evince, as is proved by its exhibiting a vacuum at all times equal to 28 inches of mercury.

Another fact which gives great confidence in the utility and applicability of this principle is its freedom from liability to internal derangement, and consequently the service in which it is engaged is scarcely ever inconvenienced by stoppages.

The engine has not been opened for examination since July last.

R. Taplin, Engineer and Machinist.

Her Majesty's Dockyard, Portsmouth, Dec. 31, 1845.

ARTIFICIAL ULTRAMARINE.

Till within the last twelve or fifteen years the only source of this beautiful pigment was the rare mineral, *lapis lazuli*. The price of the finest ultramarine was then as high as five guineas the ounce. Since the mode of making it artificially has been discovered, however, its price has fallen to a few shillings the ounce. Artificial ultramarine is now manufactured to a very considerable extent on the continent, but, as far as I can learn, none has as yet been made in Great Britain. The chief French manufactories of ultramarine are situated in Paris; and the two largest ones in Germany are those of Meissen in Saxony, and of Nuremberg in Franconia. Three kinds of ultramarine occur in commerce, the blue, the green, and the yellow. The two first only are true ultramarines, that is sulphur compounds; the yellow is merely chromate of baryta. Both native and artificial ultramarine have been examined very carefully by several eminent chemists, who, however, have been unable to throw much light upon their true nature. Chemists have undoubtedly ascertained that ultramarine always consists of silica, alumina, soda, sulphur, and a little oxide of iron, but no two specimens, either of the native or artificial ultramarine, contain these ingredients in at all similar proportions. . . The last chemist who has examined ultramarine is Dr. Elsner, who has published a very elaborate paper upon it in the 23rd number of Erdmann's Journal for 1841. The first part of Dr. Elsner's paper is historical, and contains an account of the accidental discovery of artificial ultramarine by Tassart and Kulhman in 1814, and of the labours of subsequent chemists. He then gives a detailed account of his own experiments. . . Dr. Elsner's paper does not, however, furnish any details by which ultramarine could be manufactured successfully on the great scale. Thus, for example, in regard to the necessary degree of heat, perhaps the most important circumstance in the process, he gives no directions whatever. We know, however, from other sources, that it should be a low red heat, as at much higher temperatures both native and artificial ultramarine soon become colourless. Dr. Elsner, indeed, does not affirm that he was able to procure ultramarine in quantity of a uniformly good colour. In fact, the process of Robiquet, published nearly ten years ago, is the best which scientific chemists possess, though undoubtedly the manufacturers have greatly improved upon it. Robiquet's process consists in heating to low redness a mixture of one part porcelain clay, one and a half sulphur, and one and a half parts anhydrous carbonate of soda, either in an earthenware retort or covered crucible, so long as vapours are given off. When opened, the crucible usually contains a spongy mass of a deep blue colour, containing more or less ultramarine mixed with the excess of sulphur employed, and some unaltered clay and soda. The soluble matter is removed by washing, and the ultramarine separated from the other impurities by levigation. It is to be regretted, however, that the results of Robiquet's process are by no means uniform; one time it yields a good deal of ultramarine of excellent quality, and perhaps, at the very next repetition of the process in circumstances apparently similar, very little ultramarine is obtained, and that of an inferior quality. The fabrication of ultramarine is a subject which well deserves the attention of English chemical manufacturers, as it could be carried on with peculiar advantage in this country. The chief expense of the process is the fuel required, which can be purchased in Great Britain for less than half the money it would cost either in France or Germany.—*Proceedings of the Glasgow Philosophical Society.*

The Nelson Monument.—The completion of this work has at length been determined on by the Woods and Forests, and to this effect a communication has been made to the artists to whom the commissions have been confided, by the Earl of Lincoln. The subjects proposed for the four bassi relievi are the victories of Cape St. Vincent, Copenhagen, the Nile, and Trafalgar; and the sculptors appointed to execute these works are Mr. Watson, Mr. Woodington, Mr. Carew, and Mr. Turnouth. The four lions will be executed by Mr. Lough. The relieved works will be in bronze—the lions in stone or granite.—"Examiner."

PROCEEDINGS OF SCIENTIFIC SOCIETIES.

ROYAL SCOTTISH SOCIETY OF ARTS.

Monday Jan. 12. Sir Geo. S. Mackenzie, Bart., of Coul, F.R.S.E., President, in the Chair.

The following communications were made:

1. "*A Development of the operation of the Harmonic Ratios in a progressive series of Scalene Triangles, and of their effect upon the Rectangles which these Triangles produce, by the union of their hypothenuses; with Remarks upon the utility of such a series in an Æsthetical point of view.* By D. R. Hay, Esq.—Mr. Hay, in reading this paper on the harmonic ratios, exhibited by drawings, made in presence of the meeting, their operation, by a natural process, in producing a series of scalene triangles having all the harmonic properties in relation to *form*, that the natural diatonic scale of music has to *sound*. He showed that the beauty of proportion and symmetry depends upon the operation of the numbers 2, 3, and 5, and that these numbers operate in the formation of geometrical figures by the division of the circle into 360 degrees; asserting that no other mode of division would produce the same results, because that number is in a peculiar manner (which he also exhibited to the meeting) a multiple of those three harmonic numbers. He also showed that, by the combinations of the scalene triangles resulting from his process, a series of rectangles was produced, and proved that these rectangles had peculiar harmonic qualities, that belonged to no other figures of the same species. He stated that such a scale was a desideratum in architecture, and that its adoption would be attended with incalculable advantage in that as well as in every other art in which form was treated in the abstract. He also mentioned that his scale of harmonic forms was applicable to curvelineal as well as rectilineal figures, and that he was engaged in a work in which this should be proved.

2. *Description and Drawings of a Circular Saw for general purposes, but more particularly for Agriculturists.* By Capt. G. D. Paterson.—This saw, it was stated, is adapted both for cross-cutting and all other kinds of work, but more particularly for running cuts through battens, deals, &c., and can travel through timber of any length. In cross-cutting, the workmen can cause the saw to advance or retreat by means of a handle. For long work the saw is driven backwards and forwards by machinery. Captain Paterson adopted the plan of making the saw travel instead of the wood, not only because by that means greater precision is obtained than by moving the wood to the saw (which indeed, in cross-cutting large trees is almost impracticable), but also in order to avoid the risk of crippling the saw, which he had often known to occur from careless or inexperienced workmen twisting the wood in the act of cutting. The saw is driven by belts.

3. *Description and Drawings of a Railway Indicator.* By William Anderson, mail-guard.—The machine, as it has been in action for three months past on the Dundee and Arbroath Railway, was exhibited. The indicator shows, at any moment, the number of miles the train has travelled from the station at which it started, as well as the number to travel to the end of the journey. It also enables the engineer or any other person in the train to ascertain at night or in dense fogs, within a few feet of the particular spot on the line upon which the train is travelling. It also tells the rate of speed, and the different stations and localities which the train passes; and also the hour and the length of time it takes to run every mile. It was stated that it would be an effectual check to careless or reckless driving, and would be also a complete check upon book-keepers, conductors, and every other servant connected with the train, as at the end of the journey it has only to be examined in order to show the time when the train started—when it reached every one of the different stations—and the precise speed at which it had travelled during any part of the journey; and were its indications copied into a book, this would form a complete and lasting register of the whole working on the line.

A tail Signal Light, to be attached to the upright spindle of the indicator, was also described, viz. a revolving red and white light, which would show at night the speed of a train in advance of another at a distance of four or five miles, and thus enable the driver of the following train to keep at a proper distance from the one in advance.

4. *An antique cabinet Lock and Key of curious and ingenious workmanship*, was exhibited by Adam Gib Ellis, Esq., W.S., F.R.S.S.A.

5. *A Model of* Mr. W. G. Gover's *Removeable Window Sashes for the more easy and safe means of Cleaning Windows entirely within the apartment.*—The advantages of the invention are stated to be, that the iron corner-pieces strengthen the sashes, and render them removeable, and capable of being taken inside the apartment to be cleaned. They also cause the sash to slide more freely and silently in the frame; and when closed, the window is perfectly firm, and free from any rattling or vibration. They can be applied either to new or old windows at a cost of 10*s.* per window.

ARCHÆOLOGICAL INSTITUTE.

January 9.—Sir Richard Westmacott in the Chair.

The increasing number and interest of the communications submitted to the Institute has induced the Committee to devote two meetings in each month solely to the exhibition of antiquities, and to archæological discussion.

The first of these conversazioni was held at the apartments of the Institute (12, Haymarket), on Friday last at four o'clock, as had been announced in the printed circulars of the Committee and the recently published number of the *Archæological Journal*.

On opening the proceedings, Sir R. Westmacott observed that, before entering into an examination of the objects submitted to them, he thought it right to state, that it was far from the intention of the committee of the Institute, in holding these meetings, to interfere in any degree with the proceedings of the Society of Antiquaries. He conceived that there was a marked distinction in the province of the two societies. It was competent to the Society of Antiquaries to undertake far more important objects;—its range of research was wider, its resources were more ample. The Institute was necessarily subsidiary—designed to act in a pioneer capacity, and to supply by its extended correspondence those materials not otherwise accessible, on which the more important labours of the Society of Antiquaries must ultimately be based. The constitution of the Institute was so framed as to embrace all classes interested in the study of Archæology,—not those only whose support was valuable from their position and influence, but also those precluded by their limited means from joining the Society of Antiquaries, and deriving full benefit from its valuable publications. By this more comprehensive enrolment, the Institute hoped to secure the co-operation of those who were the official conservators of our great ecclesiastical edifices, and those also whose professional education involved the study of Archæology; and of the national sympathy thus created the Society of Antiquaries would, he felt sure, reap the benefit. He confidently anticipated that, by the annual meeting, a very great stimulus would be given to the study of Archæology, and that in each successive visit a new and interesting locality would be explored and illustrated, and many precious objects, which lie concealed in private collections, would be brought to light. By the smaller meetings, such as the committee held this day, they hoped to give the opportunity for much friendly intercourse and valuable discussion. He rejoiced to see, on the present occasion, such a variety of interesting objects and communications as those laid before them,—a most gratifying assurance of the manner in which these meetings would be supported by the members of the Institute; and he could only regret that the limited space of their apartments did not allow them to accommodate, on the present occasion, a larger assembly.

Sir Richard then called the attention of the meeting to some beautiful Italian sculptures in ivory, which had passed into his possession from the collection of Flaxman. He observed, that they probably represented, in a series of groups, the incidents of some legend or mediæval romance. They appear to have been executed in the earlier part of the fourteenth century, and afford a remarkable example of a peculiar style of design, considered by foreign antiquaries to be Venetian, and of which several specimens may be seen in the Musée Charles X. at the Louvre, and several private cabinets at Paris and other parts of the continent. He also submitted for inspection a head sculptured in stone, of the 13th century, from Hereford Cathedral, remarkable for the fine character of the features and general expression.

The Marquess of Northampton exhibited a bronze Etruscan vase, of unusual form, found at Bomazza, and a mirror ornamented on the reverse with an engraved group of the Judgment of Paris, and a number of beads formed of vitreous pastes, discovered near Rome, much resembling the beads found in British barrows.

Several interesting primeval weapons of flint and bronze, discovered in Glamorganshire, belonging to the museum of the Royal Institution of South Wales, were communicated for exhibition, by permission, through Mr. G. G. Francis, local secretary to the Institute. A valuable illustration of these remains was contributed by Mr. J. Winter Jones, consisting of an unique assemblage of lance and arrow heads of silex, discovered in Canada, which, as Mr. Birch remarked, closely resemble in form and adaptation the weapons of the primeval tribes of Great Britain and Northern Europe.

Mr. Dilke exhibited a portrait on glass of late Roman times, purchased at Strawberry Hill, representing a female bust, and that of a boy wearing the bulla. This portrait is remarkable, not only from a variety of details of classical costume, rarely to be met with, but also as an example of ancient design, showing a great knowledge of form and chiaroscuro. The head-dress of the female resembles that of the Empress Julia Momœa, and the portrait is probably not later than the time of Gordianus Africanus. The mode in which the work is executed is also curious: it is apparently formed by scraping way parts of a black pigment, so as to show a gold ground below, the surface of the picture being protected by a glass plate cemented over it. Another beautiful portrait of the same kind was exhibited by Mr. Burgon; and other examples of this species of glass have been noticed by Buonarotti, in his work on ancient glass.

Mr. Talbot exhibited a warrant for the payment of 55 sols tournois to Ristandore, trumpeter of the Comte d'Angoulême, for bringing the "good and joyful news of the death of Talbot and the defeat of the English before Castillon," in the year 1453. Mr. Talbot also exhibited some Roman silver Imperial coins from Vespasian to Severus, found near the Giants' Causeway in Ireland, and a Chinese porcelain phial said to have been found in a tomb at Thebes.—Mr. Birch stated that all these phials were probably very much later than their alleged date; first, from their being inscribed with a character not earlier than the first century B. C.; secondly, from the fact that in the Chinese annals the first mention of porcelain does not occur till the seventh century A. D., and then it is spoken of as a rarity; thirdly, that the merchants were in the habit at the present day of bringing these vases to Cairo on the return of the caravans from Mecca.

Mr. C. Villiers Bayly exhibited a slab of wood, probably part of a coffer, ornamented, and with groups in relief and pounced work, supposed to represent a subject from some romance; the costume of the figures was Italian, of the latter part of the fifteenth century.

Mr. Poynter exhibited some stamped leathern hangings of beautiful design, from Bradwell House, Bucks; they presented a good example of the decorations which supplied the place of hangings of Arras, towards the close of the seventeenth century.

Two drawings, on a very large scale, of early Christian, inscribed and sculptured crosses at Nevin and Carew, in Pembrokeshire, were exhibited by Mr. Westwood. Mr. Westwood stated, that these were the two finest specimens of this class of monument that he had been able to discover, and that their date was probably the eleventh century.—The representation of a remarkable sculptured monument, at Auldbar, near Brechin, was exhibited at the same time, and several features of resemblance in design were noticed. This curious early Christian memorial had been communicated to the Institute by Mr. Chalmers, of Auldbar.

Several communications were read to the meeting, among which was a letter from Sir Philip Egerton, stating some singular facts connected with the Roman occupation of Cheshire, as detailed by Mr. Hostage, of Northwich. Letters were also read from the Rev. Hugh Jones, D.D., and the Rev. H. Longueville Jones, announcing their intention of commencing excavations on the site of Segontium, near Caernarvon, where it was anticipated that interesting discoveries would be made. Dr. Jones stated that the walls of Caernarvon Castle had recently been repaired in a most satisfactory manner, but that some portions of the town walls, the property of Mr. Asheton Smith and Lord Newborough, were in a very decayed state.

DECORATIVE ART SOCIETY.

A continuation of the paper "On Chromatic Decorations in England," was read by Mr. E. Cooper. He commenced by noticing the progressive regard for coloured decorations exhibited during the Norman and Gothic epochs; alluding to the simple and chaste effect produced by the polished Purbeck marble shaft at Ely, and the Temple Church, the rich grandeur of the earlier stained glass windows at York and elsewhere; with the attendant painted decorations on ceilings and walls, and the pavements of encaustic tiles. He attempted to elucidate the principles which predominate in the better examples, by explaining the general application of the three primary colours, and the more usual construction of the designs. He then noticed the stained glass windows at King's College, Cambridge, where the whole of the subject and detail are designed with a feeling of Renaissance (it is supposed by Giulio Romano); he said, from personal observation, that nearly all the coloured glass is what is technically termed pot-metal, so that where it is not so, as probably in the finest colours, it is enamelled glass; and he observed that drawing and shading were placed upon these, as is evident from the disappearance, in many cases, leaving the pot metal only. A *disconsonance* was alluded to, arising from the colours of back-ground and fore-ground in pictorial subjects being of the same intensity; and a method of producing light and distance by removing more or less from the thickness of the enamel was suggested as applicable to windows, and a specimen was exhibited. Mr. Cooper then commented on the agreeable effect of stained glass windows when the walls are of a simple or uniform colour, but urged careful consideration when the walls are decorated with pictures. He observed that the altar-piece at King's College is entirely neutralized in effect by the overwhelming coloured rays of light entering in every direction upon it; the earlier examples of Gothic windows were said to allow the transmission of a greater proportion of pure light. He maintained that the ancient coloured glass had no superiority over that now produceable, and that the prevalent opinion of inferiority had arisen from the greater use of *painted*, instead of *pot-metal or enamelled glass*. After some remarks on encaustic tiles (specimens from Reading Abbey), and the peculiarities of Gothic drawing, colouring, and sculpture, Mr. Cooper described some examples of transition, or mixed Gothic and Italian character in the ceilings of the Chapel Royal, St. James's, and the chapel of Bishop West, in Ely Cathedral; also the fine specimens of baronial decorations lately restored at Hampton Court. He then took occasion to censure the manner in which some of the coloured decorations in the spandrils below the windows of the aisles in Westminster Abbey have been destroyed or concealed by misplaced and absurd mythological monumental tablets; and he noticed some fine and well known examples of "high tombs," richly ornamented with marble, colour, and gilding. The decorations of the Elizabethan period were noticed, and a specimen of embossed, silvered and coloured leather hangings from the Manor House, Billingshurst, was exhibited. The introduction of Italian architecture, by Charles, led to the consideration of the ceiling of the Banquetting House, Whitehall, painted by Rubens, also of the works by Thornhill, Verrio, Languerre, and Charles de la Fosse at Greenwich Hospital, St. Paul's, Chatsworth, and Montague House (late British Museum). At present, he remarked, there appears to be a struggle for supremacy between the Gothic and Italian styles; and, in his criticisms on some recent decorations, Mr. Cooper expressed an opinion that the imitations have been unsuccessfully applied, instancing those in the Temple Church as partaking too freely of yellow ochreous tints, the Royal Exchange as being too *petite* and paltry for their purpose, the Conservative Club as presenting a bewildering profusion of trifling ornaments devoid of any important character

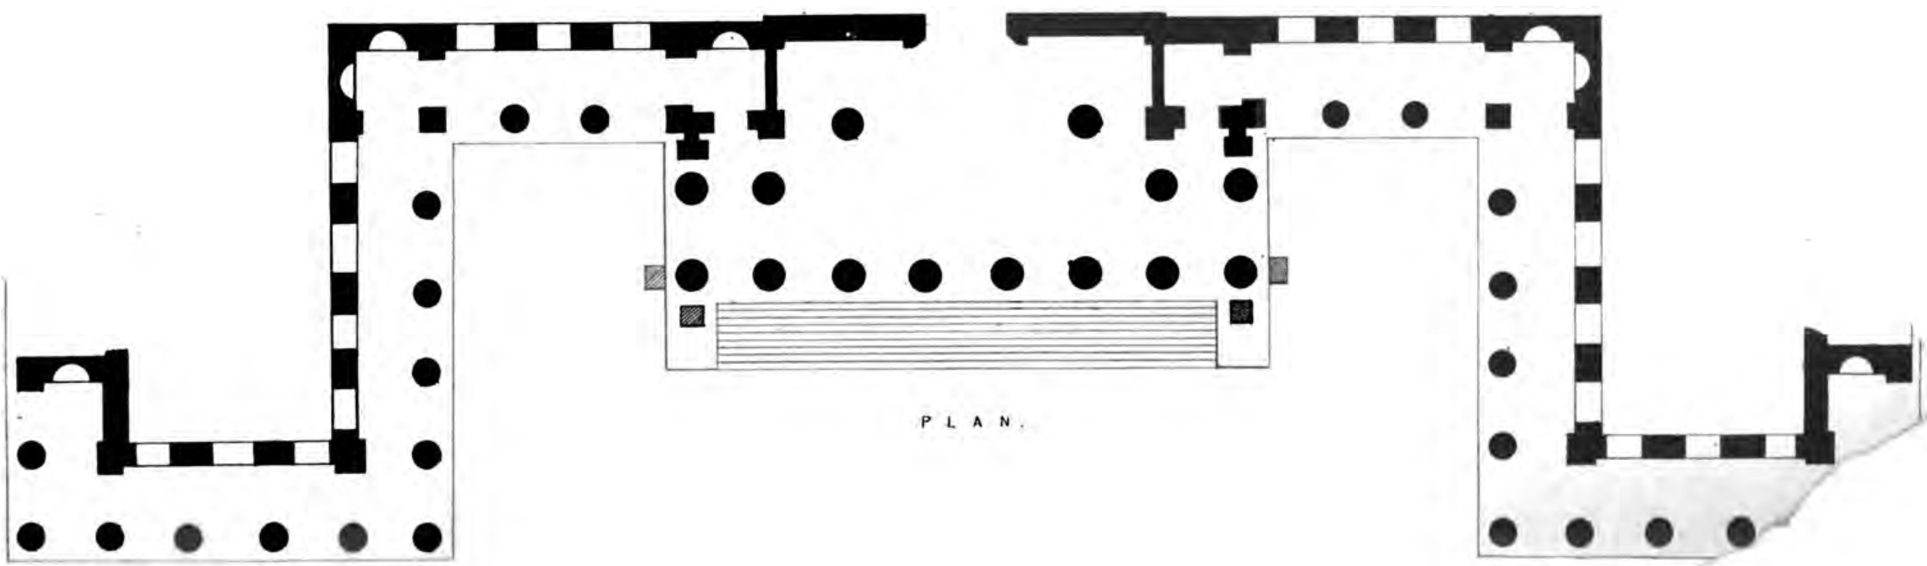
ELEVATION.



PLAN.

or design, and materially diminishing any grand effect that the architect might have contemplated. After some remarks explanatory of his views on domestic decorations of the present day, Mr. Cooper submitted a question as to the applicability of *Gothic decorations to modern purposes*, with more especial reference to the New Palace of Westminster; he admitted that decorations should be in accordance with the style, and subservient to the architectural character of the edifice; but, he asked, must we therefore follow the earlier Gothic mannerisms? Copy the attempts of an age of comparative barbarism in Art? Or, are we to adopt all the improvements and knowledge of form of the present day? He contended that the Gothic did not admit of pictorial decoration in proper keeping, and that the modern school of painting presented too many inconsistencies. He concluded by asserting that the Italian style of the fifteenth and sixteenth centuries, as found in the designs of Palladio, Scamosi, Sansovino, and others, admitted of the utmost degree of refinement, both in sculpture and painting, and afforded profitable materials for study for such a purpose.

INSTITUTION OF CIVIL ENGINEERS.

Extracts from the Annual Report.—Session 1846.

Premiums.

Telford Medals, in silver, have been awarded to Philip Chilwell De la Garde, for his "Memoir of the Canal of Exeter, from 1563 to 1724," and to George Edwards, M. Inst. C.E., for his paper "On Blasting Marl Rocks under water in the River Severn."—Premiums of Books, suitably bound and inscribed, have been awarded, to John George Bodmer, M. Inst. C.E., for his paper "On the advantages of working Engines with High-pressure Steam expansively, and at high velocities, &c.;" to Benjamin Lewis Vulliamy, Assoc. Inst. C.E., for his paper "On Railway Clocks;" and to John Baldry Redman, Grad. Inst. C.E., for his "Description and Drawings of the new Cast Iron Pier at Gravesend."

Obituary.

The deceases are few; they are Robert Thomas Atkinson, Member, and Lieutenant Edward Nicholas Kendall, R.N., and John Llewellyn, Associates.

Mr. Atkinson was the nephew of the late Mr. Buddle, and after being brought up by him, assisted him for some years in his large mining and engineering undertakings in the North. Not long before his death he took the management of the Seaton Delaval mines, where he is stated to have displayed great talent and judgment in difficult positions. His communication to the Institution in the session of 1842, "On sinking and coffering pits in the North of England," will be recollected by the members and increase the regret which must be felt for his loss.

Lieutenant Kendall, whose grandfather, Admiral Hicks, and father, Captain Kendall, were both distinguished naval officers; received his education and became first boy, at the Royal Naval College, Portsmouth. He entered His Majesty's service as a Midshipman in 1814, on board the Mutine. He served with credit in several other ships, and from his scientific acquirements was chiefly employed on the surveying service; upon the trigonometrical survey in Orkney, Shetland, the coast of Ireland, and in the North Sea. On the fitting out of the Polar expedition, under Captain (now Sir Edward) Parry, he volunteered his services, and acted as Master's Mate on board the 'Fury,' Captain Lyon. He was subsequently selected by Captain (now Sir John) Franklin, as one of his companions for the land Arctic expedition, and returned with the proud distinction of being attached to the only one of the Polar expeditions that had completely effected its objects. The charts, drawn up by Lieutenant Kendall, from the astronomical observations made by Sir John Franklin and himself, remain as evidence of his talent and industry. He was then appointed, at the recommendation of the Royal Society, to the 'Chanticleer,' for the purpose of assisting the late Captain Henry Foster in a series of experiments on the pendulum, and various other branches of scientific research in the Equatorial and South Polar regions. He then conducted the survey of the Western Coast of Africa in the 'Hecla,' the officers of which vessel had nearly all fallen victims to the climate. He was then employed by the Secretary of State for the Colonial Department, in a secret and confidential survey of the boundary line of the British and American states, in New Brunswick, and executed his task in the most satisfactory manner. On his return he compiled a complete map of the province of New Brunswick, from his own astronomical and other observations. He then turned his attention to the subject of Steam Navigation, and after superintending for a Joint Stock Company, the building and fitting out of the 'India' steam ship, which was destined for opening a direct communication with the East Indies, viâ the Cape, he was appointed to a post under the Royal Mail Steam Packet Company, which he only held for a short time, and then became the agent at Southampton, for the Peninsular and Oriental Company; and the Directors and all who knew him in that capacity, bear testimony to his zeal, talents, and high integrity. While holding that position, he was attacked with sudden illness, and expired on the 12th of February, 1845, in the prime of life and usefulness, being only in his 45th year. He made several useful communications to the Institution, and attended its meetings as frequently as was compatible with the nature of his engagements.

SOCIETY OF ARTS, LONDON.

The second ordinary meeting for illustration took place on Jan. 21, at the Society's House, Adelphi. Edward Speer, Esq., in the Chair.

The following communications were made—

1. *On the theory of Photographic Action, illustrating the connection between the Photographic agent and Electricity.* By J. Nott, Esq.—The substance of this highly important and original paper, which led to an interesting discussion, and was to be resumed at the next meeting, was as follows. "Since the discovery of Photography there is, perhaps, no branch of electrical physics more interesting than that which comprehends the phenomena of phosphorescence. For though light be the apparent agent in the production of the photographic picture, yet the accompanying circumstances can only be satisfactorily explained by a reference to electrical principles. Light is a term merely relative to us, but light itself has no absolute existence no more than sound; then how unphilosophic are the terms, latent light and light in darkness, which we sometimes hear, as if that which is merely an effect, could be regarded as a cause, or a physical force, at the same time that we know it is not possible to demonstrate the existence of any other physical force in nature than electricity.

"Light is, therefore, only an attendant circumstance in the production of the photographic picture, and this seems clearly proved by the fact of one body impressing its image upon another in the dark, when the bodies are approximated in electrical phraseology is called the striking distance.

"As light then cannot be regarded as the photographic agent, electricity, which in all probability is the principle of light, would seem to be, and the effects produced when phosphorence is developed through juxta-posed transparent media, of different densities or electrical affinities, bears a striking an analogy to those which are produced upon a sensitive surface, when exposed to the action of light reflected from bodies in different degrees of intensity as to render it more than probable, that what is understood by the term photography, is a simple case of phosphorescence by insulation. For we find that some parts of the sensitive surface, then exhibit what may be called an elective affinity for certain substances, while others do not. The results can only be the effects of simultaneous attractions and repulsions, the manifestation of which is inconceviable independent of the presence of electricity.

"The question then arises, if the photographic picture be the result of electrical action, why may not the colour as well as the contour of bodies be taken down, seeing that colour is not a property matter, but as a property of light. All bodies are seen only by reflected light, and their colours vary in tint according to the position of the spectator with respect to the plane of reflection. For instance, in the normal of the plane of reflection, the colour of bodies is most distinct, and at every deviation from this point, the local tint changes, and in many cases, is totally extinguished when the eye of the spectator reaches the angle of total reflection. Thus then, where the reflected light is the strongest, the colour of bodies is least perceptible, and *vice versâ*.

These considerations induced me to try what comparative effect would be produced upon a sensitive surface, by light reflected at various angles of incidence from the plane of the picture.

"The effects which were thus produced were quite analogous to those which are observed in nature, the local tints of the bodies represented varying with every change that was made in the angle of reflection in which the picture was taken down, and the direct ray invariably gave less picturesque results than when a parallel glass was used. In some specimens taken with the parallel glass when they were looked at directly, all the appearance of a radiating reflection were presented, and when looked at obliquely, all those of a speculary reflection, as if the sun were actually shining within the photographic picture itself.

These results gave promise that some remarkable effects would be produced by polarized light, I therefore had a small sundial made, the style of which was formed by a bit of very fine silver-wire, and from the centre of the dial a bit of the same wire was erected perpendicularly, so that the hour angle and the sun's azimuth were given at the same instant.

By means of this instrument Mr. Nott observes, he was able to determine with a good deal of accuracy, the position of the sun, with respect to the plane of the picture that he wished to take a photographic representation of. The glass of the camera was also made adjustable to the polarizing angle by an attached graduated quadrant.

When, by these means the light was polarized into the camera, by a double reflection from the plane of the picture, and from the parallel glass it was found that the objects in deep shadow and those in sun-light were taken down simultaneously and with equal precision, and that without the slightest trace of solarization, exhibiting a sun-light view of the greatest truth and beauty, in which the transparency of the shadows and the effect of the distance produced by an exquisite gradation of tint, such as art could scarcely hope to imitate. This result of polarized light seems doubly interesting since the recent and beautiful discovery of Faraday, where a ray of extinguished polarized light is reillumed by electricity.

How far this discovery may enable us to determine the nature of the active agent concerned in the production of the photographic picture, we will not at the present moment presume to decide.

2. *On the new Patent Oil Integument, or skin of Paint*, by H. Page, by which great facility is afforded for interior or exterior decoration. The author, after pointing out the various inconveniences which the public experience in having the painting, graining, and oil decorations done on

the premises, proceeded to show some of the advantages which he obtains by substituting a prepared skin of paint for the ordinary common painting. These advantages are very apparent in the decoration of ceilings, or in the execution of any kind of flat ornamental work, whether it be imitations of woods, marbles, lettering in gold or colours, on walls or wood-work, as it is only necessary that the dimensions of the parts to be ornamented should be previously taken, and the work can be completed at the artists' shop or study. He next proceeded to describe the process of manufacture, remarking, that the skins at present made are 12 feet by 3 feet, that being found the most convenient size, but they can be made of any dimensions. A sheet of elephant, or any stout paper, rather larger than the skin required, is taken, and the surface on one side only is prepared with a mixture of gum arabic, treacle, and water, upon which when dry a coat of paint made with boiled oil and white lead in the ordinary way is put upon it; when that is dry, the operation is repeated till the skin is of the required thickness, but two coats are found to be sufficient for general use. To separate the skin from the paper it is laid on a clean board, with the painted side downward; the paper is then wetted at the back with clean water, and after it has stood a few minutes, the paint may be removed without any difficulty or the least fear of its tearing. The same paper may be painted on thirty or forty times, but must always be prepared as described above. The paint where removed is carefully wiped with a sponge and then dried with a wash leather to remove any portion of the preparation which adheres to it. The skin is then folded and put away till such time as it may be required for use. The mode of fixing the skin is to rub down the surface to which it is to be attached, and, when thoroughly clean, it is gone over with boiled oil and gold size; a smear is sufficient. The skin is then laid on with a soft cloth, as in the ordinary paper-hanging. Several beautiful specimens were exhibited.

INSTITUTE OF BRITISH ARCHITECTS.

January 12.—H. E. KENDALL, Esq., V.P., in the Chair.

A paper was read by John Britton, Esq., *descriptive of Roslyn Chapel, near Edinburgh*. This edifice was commenced in 1446, and his widow and successors continued the works, which had been left unfinished at the death of the founder, in 1479. Mr. Britton observed, that his attention had been directed by Mr. David Roberts to the aisle at the east end, which is wider than the other; and it would appear that the plan had been changed after the stone-work for the vaulting was prepared, and in order to make it available, the architect had resorted to the expedient of carrying the arches upon large projecting corbels,—a remarkable feature in the construction, which it would be difficult otherwise to explain.—Mr. Burn observed, that the picturesque tradition (so well handled by Sir Walter Scott) of the interment of the Sinclairs, shrouded in the armour and uncoffined, in a vault beneath the chapel, is destitute of foundation. There is a crypt, not under, but beyond the chapel, to the eastward, which Mr. Burn believes, on a careful examination never to have been used as a sepulchre; and there is only one other small vault, where some of the family have been deposited in oaken coffins.—Mr. Fowler observed, that the nave of the building was vaulted on the uncommon, though not singular principle of a solid roof, the extrados of the arch forming the external covering. The vaulting of the east end aisle is remarkable for its excessive flatness, and appears to have been retained in its place by iron ties grooved into the stones—a singularity in the construction of the Middle Ages.

Mr. Donaldson read a letter from Mr. Knowles, from Athens, describing some late discoveries made in further disencumbering the Acropolis of its rubbish. One result has been to ascertain, that the interior of the Parthenon was supported by columns of the Doric order, 3 ft. 7½ in. in diameter, of which the fluted contours remain traced on the pavement. Mr. Donaldson made some remarks on the model of the Parthenon by Mr. Lucas, exhibited at the British Museum, in which the lower range of interior columns is represented as of the Ionic order, and promised some further remarks on this subject at a future opportunity.

STEAM ENGINE.—At the *Academie des Sciences*, Paris, Dec. 20, M. A. Segnier read a notice of a new steam engine, the invention of Messrs. Isoard and Mercier. After describing the construction of this engine, M. Segnier says:—"It differs from all that has hitherto been invented, not only in its construction, but also by the special manner in which the steam is employed. Instead of being conveyed from the generator to the motive apparatus, and undergoing on the way, or at the moment when its action is required, all the losses due to the diminution of volume by the causes of the cooling process, the steam is maintained at a very elevated temperature in the generating tube, and the relations of the heated surfaces and of hot water injected are calculated in such a way that the heat does not escape by the orifice until it has acquired an increase of temperature which permits it to act at once as steam and as dilated gas.

A VIEW TAKEN OF A REVIEWER;

In a Letter to the Editor of the Civil Engineer and Architect's Journal.

[We are compelled by an unfortunate misprint at p. 13 of this journal, and from an anxiety to avoid all appearance of injustice, to give insertion to the following letter. It is rather of a philological than architectural character, and this, together with a full appreciation of the writer's merits as an architectural critic, renders it wholly unnecessary for the Reviewer to enter upon a detailed reply. We have taken the liberty of omitting one or two passages in which the writer's feelings have betrayed him into personality. The misprint of the word "façade" was marked on the proof-sheets, but the correction was neglected by the compositor.]

SIR—To crave as a particular favour, or favour at all, what I can demand as an act of justice, would be no particular compliment to yourself personally. It would imply that I thought so meanly of you as to suppose that you would not feel yourself sufficiently bound by your own sense of honour and honesty to afford me, as mere matter of course, the opportunity of exposing in your own Journal the not only very unfair but actually falsifying remarks which the "Review of the Companion to the Almanac" has rendered it the vehicle of. I need not adopt the submissive tone of a petitioner, nor do you require to be tickled by dainty phrases into doing what your own feelings must prompt you to at once, or if not your feelings, mere regard to your own interest and to the character of your publication.

Your very clever Reviewer has blundered in the oddest manner throughout, and has committed both himself and your Journal. If not a downright blunder, it was surely a piece of great indiscretion on the part of the "Civil Engineer" to assail, or suffer to be assailed all at once, in its own columns, and that, with rancorous spite, and undisguised hostility, that very portion of the Companion which the Journal itself has hitherto especially and almost exclusively noticed, and has recommended to its own readers, as containing much interesting architectural description, remark and information. I do not say that because the Companion had all along been spoken of favourably—at least civily by the "Civil Engineer," the latter ought for mere consistency's sake, to have continued to speak of the Companion in the same tone as formerly. In the course of time, publications of the kind are apt to alter—and after greatly for the worse. They quite lose their original spirit and character, and merely live on upon the reputation which they have acquired during their season of vigour. Such unfortunate change may have come over the "Companion:" its architectural writer may be in the condition of the poor archbishop of Grenada, and your Reviewer has kindly undertaken to be its honest, and disagreeable *truth*-telling Gil Blas. A change has of late come over even your own Journal, although it has not numbered quite so many years as the Companion, consequently has not become superannuated. That change, however, is of course one decidedly for the better. Still, it has in some respects been rather a too sudden and startling one. Most of your readers must have been not a little astonished by the "Review" in question. If the Companion—by which is to be understood the architectural part of it—has altogether degenerated, and is no longer of any interest and value, it might have been coolly dismissed or have been passed over without any notice at all.

Between not speaking favourably of a publication, and speaking of it abusively, there is a wide difference,—a wide difference between not praising, and coarsely reviling. Wide as it is, your "Reviewer" has displayed his agility by leaping over it at a single bound. In performing which notable feat he has, unluckily, jumped plump into a quagmire. Let us hope, Mr. Editor, that he has not dragged your Journal into it at the same time.—In his hurry to fire his *blunderbuss* at the Companion, he overloaded it so incautiously that it has recoiled, and laid him sprawling.

Intended to be severe, his remarks show chiefly impotent savageness; and if he does not actually foam at the mouth, he has discharged a great deal of nonsensical froth from his pen. As to severity, I can be severe myself; perhaps, Mr. Editor, you think me so now; it would, therefore, as ill become me to exclaim against that "*qualification*,"—or what looks like it—in your Reviewer's observations, as it has done him to protest so lustily against every—even the most innocent species of artifice, sham and deception, at the very time that he was imposing upon the readers of your Journal his own distortions and manglings of words and meanings, as remarks actually made in the Companion.

Such being the case, I might very well pass them over as too contemptible for notice. Undoubtedly, I might do so—most others, perhaps would do, because that same "too contemptible for notice," is a very cheap and convenient mode of showing one's philosophy. I also should perhaps have adopted it, had not the Reviewer among his other fabrications, hammered out and sharpened weapons to be turned against himself. There are in the world those who can very heroically submit to bear any amount of contempt so long as it is not expressed publicly. It is not the mere contempt itself, but the publicity of it, which at all touches them. Besides all which, however contemptible the matter may be in itself, the opportunity of turning a Reviewer completely inside out is by far too tempting. It is not every day that a similar one presents itself, and perhaps it is better so than otherwise.

As I have already said the Reviewer's perversions and misrepresentations are so gross as instantly to expose themselves, yet very few readers indeed take the trouble of comparing a Reviewer's remarks and quotations with the book itself that happens to be under notice. And your Reviewer must not only be of such opinion, but must have felt pretty well assured in his own mind either that no readers at all ever do so, or that the "Companion" was of all books in the world the most unlikely to fall in the way of the readers of the Civil Engineer, else he would hardly have ventured upon assertions calculated to induce people to turn at once to the Companion, for the purpose of ascertaining whether the remarks on Public Improvements were as nonsensical as he has represented them.

The Reviewer commences his attack on that chapter in the Companion with what is rather an unlucky slip for a gentleman who pretends to take others to task, for carelessness of expression, and inaccuracies of language, giving it as his opinion—and a Reviewer's opinion can be nothing less than a *plumper*—that the new range of buildings near the Royal Exchange, called "Freeman's Place," is praised for the "*qualification*"! which it least of all possesses. Here, then, we find "qualification" confounded with "quality," and though what the writer means to say is obvious enough, he has no right to expect that his own meanings will be indulgently made out for him, when he himself studies to misinterpret the at least equally plain meanings of other writers. Perhaps he thought that "qualification" being the longer one, was the finer sounding word of the two, and gave it the preference accordingly. Still, however awkwardly expressed, the censure itself may be just; and it is certainly no slight censure upon one who pretends to speak of architecture, to say that he praises buildings for qualities which they do not at all possess;—not but that such malaprop praise has been dealt in very largely by architectural critics.

The particular merit claimed for the building above mentioned is, that it is a fine and well-proportioned architectural mass, as will hardly be disputed by those who have seen it. Therefore, in order to make evident with what painstaking ingenuity the Reviewer has proved it to be wholly undeserving of the character given it, it is necessary first to give the remarks in the "Companion" at length, and then consider what sort of fair construction the Reviewer has put upon them.

"Freeman's Place, is in a manner so connected with the Royal Exchange" (mentioned just before in the book) "to which it may be considered a sort of architectural satellite, that we proceed to notice it at once before we come to other general improvements and alterations of the kind, more especially as it distinguishes itself from all the rest by having more the air of a single large edifice, than a mere piece of street architecture. This range of building, which immediately faces the east front of the Royal Exchange, and forms the opposite side of a wide paved avenue between the two buildings, that is reserved for foot passengers only, is in a style of noble simplicity that says much for the good taste and judgment of its architects, Messrs. E. I'Anson and Son. Equally free from the usual common-place of pretensious decoration—apt to run into the meretricious, and from baldness and insipidity—apt also to be mixed up with the former, it is at once sober and dignified—with neither too much nor too little of embellishment, but consistent throughout, and all of a piece. Not only is it a fine mass as far as mere size goes, but the importance so derived, is well kept up and preserved by the character of the "fenestration," which is such as not to cut up the mass itself into littleness, as is too generally the case, owing to windows being put too closely together, which inevitably occasions an ordinary dwelling-house to prevail, in spite of every attempt to mask it by ornament; whereas this façade"—let this be particularly attended to—"is exceedingly well proportioned both as to the quantity of window opening as compared with the entire surface, and well-proportioned also in regard to mass (about 160 feet by 60 high) wherefore the eye takes in the whole of it as a distinct architectural object."

More need not be quoted, there being already enough for the purpose, and also to show the kind of writing and architectural comment in the Companion, which, if none of the best, are quite as good as what we generally get from architectural journals. Now, after reading the above, would any person in his senses suppose that by "fenestration" is to be understood merely the ground-floor windows, which, speaking architecturally and artistically, answer much better to the name of glazed arcades than of windows? The design would have been precisely the same had the ground-floor arches been entirely open, as for instance, in what is called Covent Garden Piazza. And did the Reviewer understand any thing of architecture beyond a few crude notions about it, he must know that fenestration and arcading require very different proportions in regard to the ratio between *solids* and *voids*. So desperately determined, however, is he to abuse the Companion, and "to show the ridiculous and ignorant absurdity of the criticism," that he obstinately shuts his eyes to what is meant by the term "fenestration"—for of the windows and the general composition of the façade he takes no notice—but invidiously confines himself exclusively to the ground-floor, the very part which is *not* pointed out for notice in the Companion, applying to that alone what is evidently intended to be understood as characteristic of the general mass. So, in order to give some plausibility to his own distorted representation of the matter, and to make it appear that the author of "the ridiculous and ignorant criticism" alluded expressly and exclusively to the glazed openings of the ground-floor, he converts the words "this FAÇADE," into "this ARCADE!!" * * *

Perhaps he will now attempt to say that the alteration was a mere misprint: if so, it was a most pat and convenient one at the time, and he accordingly took care not to alter *that* when correcting the proof. Yet the *mistake* is so unluckily lucky and convenient, that without it the quotation would *not have answered his purpose at all*, but would rather have told against him! He has in consequence cut off, having exerted his ingenuity, somewhat after the manner of the fellow in one of Hogarth's Election Pictures, who astride on a sign post, is sawing it through most vigorously, the result of which achievement will be, that he must certainly come to the ground.

'To make assurance doubly sure,' the Reviewer takes some pains to convince us of the marvellous fact, that when Conservatories are built to correspond with the architecture of the mansion they happen to be connected with—whether designed as arcades or otherwise—the spaces between the glazings are quite as wide as the piers of the ground-floor in Freeman's Place. What a notable piece of information! how wonderful that an arcade forming the ground floor of a street building should resemble any other arcade, more especially one used as a conservatory! Fortunate was it for the Royal Exchange that the Reviewer did not turn round upon that, and discover the aggregate surface of the windows, compared with that of the masonry, to be as great or greater than it is in many conservatories, for the reason that "the ground-floor of the building exhibits one continued series of arched window-openings, separated only by piers."

Of course he himself has seen the building—or if not, there is a partial elevation of it in the Companion to inform him what is its design, and what are its proportions. Besides seeing it, he gives us to see that he examined it very carefully—so very carefully indeed, as to see nothing at all in it except the single part which it served his purpose to look at,—which he took a "rough admeasurement of," and concerning which he had written some very rough remarks. The only thing in which he shows any smoothness is the gentle protestation—flung out as a sop to the architects themselves—that he does "not intend the slightest censure of the actual arrangement of the windows." How vastly candid and generous! how soothing and flattering it must be to them to be assured that their building is passable enough, only it does not at all answer to the character given of it in the Companion, as being a noble and well-proportioned astylar façade not cut up into littleness by too great a number of windows. How far such really is or is not the case will be rendered tolerably evident by stating, that in a frontage of 160 feet or thereabouts, there are only thirteen windows over the *terazzo* or ground-floor, which being treated as an arcade has, of course very much wider openings than the rest of the façade. The general façade is assuredly quite as solid in its proportions as those of the Reform and other palatial club-houses,—at least as regards the fenestration of the several floors, for it must be admitted, that there is not quite so much space between one floor and another as could be desired. Still, upon the whole, the Freeman's Place façade is marked by the quality—or as the Reviewer has it, by the qualification of *breadth*—by which, I ought for his benefit to explain, is not to be understood *width*.

The next subject of commentary, observes the Reviewer, is Trafalgar Square; whereupon he proceeds to comment upon the commentary in the Companion, after his own ingenious and ingenuous fashion. The *Civil Engineer* pronounced, some time ago, the two fountains in Trafalgar Square to be not only far from beautiful, but positively ugly, and not only ugly but of "intense ugliness!" which the Companion opines to be rather 'too severe,' assigning as reason for such opinion, that "the insignificance of their (the fountains) appearance is at least an equal defect." Which observation has not been thrown away on the Reviewer, for he seizes hold of it in two ways, first to broach a novel and very peculiar notion entirely his own, and next to expose the writer's false and absurd logic. According to the Reviewer, *Insignificance* of appearance and *Ugliness*,—hitherto considered two distinct and very separable, although not always separated qualities, are so incorporated together as to constitute one and the same; so that whatever is ugly must be also insignificant, whatever is insignificant, ugly; whence it should follow that what deserves either one or the other epithet in the superlative degree is superlative with regard to both attributes at the same time, and "intense ugliness" is equivalent to *intense* insignificance. Hence—if such very curious argument be worth anything,—a pigmy must be a far uglier monster to encounter than ugliest Polyphemus, or what is the same thing a hideous monster of a giant more insignificant than a pigmy. After this, it will be absurd to talk of things being "too insignificant and contemptible for notice." Nevertheless, there are some difficulties attending the doctrine and its application. 'Insignificance' has till now passed for being rather a relative than a positive quality: the same thing may be either insignificant or the contrary according to place and circumstances. What would be admired as a very elegant and tasteful ornament upon the mantelpiece of a lady's boudoir, might make but a very *insignificant* appearance in a stately and spacious saloon, yet would it therefore become at all ugly in itself?—hardly. To such awkward conclusion, however, those must arrive who go along with the Reviewer, the curiousness of whose ideas on that point of theory has seduced me into something like digression. The notion which he has briefly thrown out is by far too good to be thrown away; wherefore it is to be hoped that he will evolve, expound, and elaborate it, taking it as the germ of a new "Philosophy of Æsthetics," which, if it should not edify will at least astonish the public.

Besides the mistake of supposing there is any distinction at all between ugliness and insignificance, the Companion has committed the egregious error of assigning one defect, not as additional cause for censure, but in mitigation of very strong censure on account of some other imputed defect. Yet there is surely nothing illogical in that, unless logic consists more in verbal forms than ideas. The Reviewer excepted, every one is aware that opposite defects neutralize each other more or less; consequently what is so far from being noticeable as to be insignificant, cannot be especially remarkable or offensive for its ugliness. Neither does the remark in the Companion admit that Mr. Barry's fountains deserve to be called ugly at all. It is rather levelled against the outrageously vituperative criticism which brands them with that epithet in the hyper-superlative degree as if they exhibited the very 'præterpluperfect' of hideousness. When it was first bestowed on them, the expression "intense ugliness" seemed to be uttered very inconsiderately, but as it has been brought into notice again without any admission of its impropriety, or with the least attempt to soften it down, we must perforce conclude that it was penned deliberately at the time, and that its author still maintains it most resolutely.

That critic's vocabulary must be exceedingly limited indeed, who can find no terms for the numerous intermediate gradations between beauty and positive ugliness and the extreme of hideousness. The Reviewer seems to have only black and white upon his palette, and to daub every thing he notices with one of those two colours, as best suits his purpose at the moment.

In point of design the Trafalgar Square fountains are not remarkable for any particular beauty, neither are they so for the opposite reason. What is most to be complained of is that they are not upon a sufficiently noble scale. A single fountain equal in capacity to both the present ones would have formed a noble decoration—a far more imposing object in the centre of the square. But I forget—the Reviewer has an *intense* horror of every thing that is *imposing* or partakes of imposition. Let us, however, see what sort of imposition he can, nevertheless, stoop to himself,—what sort of sense, or nonsense he has made out of what is said in the Companion respecting the general appearance of Trafalgar Square. And here it is necessary to quote from the book.

"A more striking architectural fault as regards the enclosure or Square itself is, that the two side boundary walls, east and west, are made to slope according to the fall of the ground from north to south, although the enclosure itself is on a uniform level plane. Within the enclosure this produces a singularly disagreeable effect, for the tops of walls are not made to rise and fall like hedges according to the inequalities of the ground."

Undoubtedly, this is not so well expressed as it might have been; still the meaning is sufficiently obvious, viz. that an unpleasing effect is occasioned by the tops of those walls being made to slope, instead of being carried horizontally, and parallel to the flat pavement of the area. Yet the Reviewer has made it appear that it is complained of by the Companion, that "the tops of *the* walls are not made to rise and fall like hedges." How came that remarkably significant "*The*" to be conjured into the text?—or did it jump in entirely by accident, and just into the very place where it so admirably suited the purpose of the honest and conscientious Reviewer? Can that, too, be a mere mistake? If so, the mishaps which have occurred in printing the Reviewer's comments, are not so much mistakes and mishaps as actual miracles. Still, prodigiously lucky and convenient as they may have been just at the time, they prove anything but agreeable in their consequences, when they are pointed out. They occasion not only ugly, but "intensely ugly" suspicions; and those suspicions are rather confirmed than at all lessened when it is perceived how studiously the Reviewer labours to fasten upon the Companion more silliness than it really contains. Where did he find in the book itself such a Balaam expression as that of "making Trafalgar-square agreeable?—and, if it be not in the book, but one of his own concocting, wherefore should "agreeable" be printed with inverted commas, as if it was the very word there made use of, and the one constituting the silliness of the phrase employed. It is also in some degree made to appear that, while it speaks of Trafalgar-square as an "ill-arranged spot," the Companion calls it "one of the noblest sites in Europe," those words being also printed between inverted commas, as if a quotation from the book; which, not being the fact, the Reviewer ought to have guarded against misconception by saying, "*what has been called by some*, '(most people) one of the noblest sites in Europe.'"

It is, however, absurdity in me to talk of his guarding against misconception, when misconception and misconstruction, and misrepresentations are what he has evidently laboured at in all that he has said of the section headed "Public Improvements" in the Companion to the Almanac.

In like manner as he has reiterated his crushing condemnation of the Trafalgar-square fountains, he has again attacked—for there can be very little doubt that the former attack proceeded from himself—the new building at Lincoln's Inn, on account of deal being used for the ceilings of some of the rooms, which he not only derides, but absolutely vilifies as mere sham and deception, notwithstanding that it is the real wood which shows itself, without pretending to be any other material than what it actually is. In asserting that the members of the Inn themselves vote the ceilings in question to be Brummagem, he may be right, for if he *assists* at the "Hall dinners," he of course can best tell whether they do or not—and his veracity is of course also unimpeachable. Still, few will agree with him that the sneering exclamation "Brummagem" is at all the criticism of "gentlemen and men of educated taste." On the contrary, it is a very Brummagem sort of criticism, to which those only have recourse who have neither reasons nor arguments wherewith to support the opinions they pretend to hold.

Singularly enough too, just after seeming to allow that it is the clumsiness of the deception which renders imitative materials despicable, he is shocked at the Companion for its commending the columns in the Colosseum because they imitate white marble "most deceptively." Admirable consistency, truly! Are we then to suppose that, in his opinion, the imitation would have been all the more praiseworthy had it been less successful and less deceptive?—that the paltriness of deception is in proportion to the exactness and truthfulness of the imitation.

At any rate he has started a fresh and fertile topic for discussion—one which I must here pass over, contenting myself with keeping it in reserve for some other occasion, only remarking that the Reviewer seems to consider Design as altogether secondary to Material; wherein he shows himself to be a much more matter-of-fact kind of person than he has done as regards sticking to matter-of-fact quotation. According to his notions, Pompeii, with its stucco columns, Venice, with its so called "marble palaces," and Vicenza, with its Palladian façades of brick coated over with intonaco, ought to be scouted as exhibiting the mere Brummagem architecture. The Travellers' Club House, Pall Mall, is but of mock material; and there is plenty of Brummagem, viz. sham marble, or scagliola, not only in the other club-houses, but in Buckingham Palace and Sutherland House. Nay, there is even mock masonry—wood-work ceilings painted to imitate stone vaulting, in some parts of both York Minster and Ely Cathedral, surely, therefore, the deal ceilings at Lincoln's Inn are not such very dishonest things after all—perhaps honest enough to satisfy most people, if not one who is as straightlaced in his notions of honesty as the Reviewer has shown himself to be. * *

To your own Readers, Mr. Editor, I leave now to judge if I am the ridiculous ignoramus which your publication has represented me; and whether I am capable of writing tolerably correct and intelligible English. This letter contains some pretty plain English, and also some sufficiently intelligible and significant hints, which you ought to thank me for not having made plainer.

I remain, Sir,

Yours, &c. &c.

THE WRITER IN THE COMPANION TO THE ALMANAC.

CHRIST CHURCH, PLYMOUTH.

SIR—In reference to your observations on the fault of a "show front," the "other sides" of my church being "merely plain masonry," it is only necessary to inform you that the sides of the building *unite* with the buildings on either hand: that the Eastern end is entirely concealed, with no more than a space for light of ten feet deep; and, in short, that the front alone is visible; or that it alone *will* be visible when the intended school is built against the Southern side. The church is already built in on the *north* side. Of course, nothing *can* be worse than the *making* of an insulated building with a "show front."

Yours truly,

G. WIGHTWICK.

[Among the difficulties which architects meet with from the injudicious wishes of those who employ them, not the least is that of erecting buildings on sites wholly unsuited for them. A church of which the sides "unite with the buildings on either hand," must have three great defects: 1st. It has a show front which greatly diminishes its architectural value. 2nd. The difficulties of procuring light must be obviated by some unchurchlike arrangement: 3rd. The adjacent houses produce inharmonious combinations and secularize the character of the church.]—ED.

ICKWORTH.

SIR—In a memoir which I have just been reading of Mario Asprucci, an Italian architect who died in 1804,—and who, I may observe, is omitted not only in Nagler's Kunstler-Lexicon, but in the enormously copious Biographical Dictionary of the Society for the Diffusion of Useful Knowledge,—it is stated that he designed for "Milord Ervei," a splendid palace which that nobleman afterwards began to erect in England. By "Milord Ervei"—that "gran mecenate delle belle arti," is of course meant the eccentric Hervey, Earl of Bristol and Bishop of Derry, but is it Ickworth that is the edifice alluded to? In the "Beauties of England and Wales," that mansion is said to have been begun from the designs of two *Portuguese* architects, named *Carvalho*,—which has always struck me as an improbability. Supposing, however, the latter account to be correct, what is the other "palazzo" which "Milord Ervei" erected or began to erect in England? Or is that a mistake on the part of the Italian writer, who perhaps confounded Ireland with England, in the former of which countries there is or was somewhere in the county of Derry—the name of the place, I do not now recollect—another stately country-seat, built by the "Bishop;" and which like Ickworth was remarkable for the singularity of its plan, the body of the house, being in both instances, an ellipsis.

Whether the mansion in question be really Ickworth or not, the designs for it were engraved and published, that circumstance being alleged as sufficient reason for merely mentioning that specimen of Asprucci's abilities, "che tutti, perché inciso, *bastamente conoscono*"—it being what is so well known to every one by means of those engravings. Be they ever so well known in Italy, no copies of such work or engravings seem to have reached this country,—at least not for sale; nevertheless I take refuge in the *possibility* of their having been seen by some one among your readers and correspondents, who in such case will *probably* communicate what he knows respecting them. If no one else, the present Marquis of Bristol, no doubt, can, and no doubt also, would afford me the information which at present I endeavour to elicit through your Journal. I dare say it would be the very first and last time of his Lordship's being ever troubled with so *eccentric* an application—one paying him the compliment of my taking such very strange interest in his mansion at Ickworth.

Strange as in the opinion of most persons such course would be, in my own opinion it is infinitely more strange that so remarkable a piece of architecture as that mansion is, should have altogether missed the celebrity which many structures far less deserving of it have obtained. Most of the houses shown in "Vitruviussis" "Views of Seats," and similar collections, are scarcely worth showing at all—as studies, or as architecture mere nullities—things not worth the powder and shot of engraving them; whereas Ickworth is unique if only on account of the lavish display of sculpture in *relievo* on its exterior. Yet do those who can tell to a hair's-breadth every admeasurment of the Parthenon, know not of even the existence of Ickworth.

I remain, your's, &c.,

ECCENTRIC.

If additional information be required respecting any patent, it may be obtained at the office of this Journal.

PURIFYING OF GAS.

HENRY PHILLIPS, of Clist Honiton, Devon, Chemist, for "*Improvements in purifying Gas.*"—Granted April 15; Enrolled Oct. 15, 1845.

In the purifying of gas by lime two means are resorted to, called the wet and the dry lime processes; in some works one only of the two processes is used; in other works both processes are used consecutively, and the lime employed for each process (where both are used) is fresh lime. The object of the present invention consists in using for the wet lime process the lime which has been previously employed for the dry lime process, by which a considerable saving of lime will result. The gas is first passed through the wet lime purifiers, and then through the dry lime purifiers; new or fresh lime in the ordinary manner is employed for the dry lime process, and afterwards this lime is used for the wet process, to be immediately mixed with water, in a vat, vessel, or other receiver, to prevent it from becoming hard—which lime, by means of additional portions of water, is brought to the proper consistency for the wet lime process in the same manner as if using fresh lime for such purpose; and such mixture of lime is applied in the ordinary apparatus used for the wet lime process.

PROPELLING RAILWAY CARRIAGES.

ELIJAH GALLOWAY, of the Strand, for "*Improvements in propelling railway carriages.*"—Granted April 10; Enrolled Oct. 10, 1845. (*With Engraving, Plate* III.)

This invention is for certain improvements in rope traction, the object being to propel the train of carriages at a speed greater than that of the travelling or propelling rope, and is effected by means of an apparatus termed a "drag," attached by any convenient means to the first carriage forming the train. The following is a description of the apparatus, reference being had to the drawings of which fig. 1 is an elevation; fig. 2 a plan; and fig. 3, an end view. Similar letters denote corresponding parts in each figure; *a a*, is a rectangular or oblong frame supported on travelling wheels *b b*, which run upon auxiliary rails placed within those upon which the train of carriages move, the whole apparatus being so constructed as to pass underneath the carriages forming the train, or in other words that the train shall pass over the drag. *c c'* are two shafts supported at each end in suitable bearings at *d d*; upon each of the shafts *c c'* there are pullies *e f*, of different diameters; *g g*, *h h*, are two ropes extending the whole length of the line, the one marked with the letters *g g* being a travelling rope, the other marked with the letters *h h*, being a fixed rope, the ends thereof being attached to a fixed point at the termini of each station. The ropes *g* and *h* pass round the pullies *e e'*, and *f f'* in the following manner, namely, the rope *g g'*, which is the travelling rope passes under the pulley *e'*, over the pulley *e*, and round the driving pullies or drums connected with the engine at each station. It will therefore be evident that if motion be given to the rope *g g'*, such motion will be imparted to the pullies *e e'*, *f f'*, the carriage or drag *a a*, at the same time remaining stationary. We will now suppose the stationary rope *h h* to pass under the pulley *f'*, and partially round the pulley *f*, and to be fixed at each end. By this arrangement it will be apparent that if motion be given to the pullies *e e'*, *f f'* by the travelling rope *g g*, such motion would be transmitted to the rope *h h*, which would (if it were loose) travel at a greater velocity than the rope *g*, in consequence of the difference in the diameters of the two pullies *e* and *f*. But in consequence of the rope *h h* being a fixed rope, it necessarily follows that such motion will be given to the drag, which will travel upon the auxiliary rails at a speed double or treble the speed of the propelling rope, depending upon the difference in diameter of the pullies *e* and *f*. By this contrivance the stationary engines will only be required to work at one-third or one-half the speed (depending on the different diameters of the pullies,) in order to obtain the same velocity as trains worked on the lines constructed on the present principle.

Mr. G. proposes at each station to detach the drag from the train of carriages which are taken up and propelled by another drag to the next station; the train of carriages in arriving at the station passes over the drag; for this purpose the carriages must either be constructed so that the drag can pass under them or a recess must be made at each station for the drag to run into, so as to lower it sufficiently for the axles of the carriages to pass over. The pullies *e e'* and *f f'* are capable of being disconnected by means of a clutch-box, so that the train can be stopped at any part of the line without stopping the stationary engines.

RAILWAY CARRIAGE BUFFERS.

THOMAS WALKER, of Euston Square, mechanic, and GEORGE MILLS, of Dover, coal merchant, for "*improvements in springs and elastic power a applicable to railway carriages and other vehicles, and to other articles an purposes in which springs or elastic power is now used.*"—Granted July 3 1845; Enrolled Jan. 3, 1846.

This invention for springs and elastic power consists in the application of steel springs or other elastic substance in combination with atmospheric air to buffers of railway carriages. Fig. 1 shows a longitudinal section of a buffer constructed according to this invention, in which *a a* is a cylinder of cast iron, *b b* are the buffer-rods which pass through holes formed in the end of the cylinder; *c c* are pistons made to fit tight within the cylinder, which is divided into two compartments by means of a diaphragm *e*; *f f* are holes in the piston, which are provided with valves opening inwards; *g g* are spiral steel springs, one end of which presses against the diaphragm *e*, and the other against the piston, so as to force the same outwards; the object of the valve is to admit air between the piston, and diaphragm during its motion outwards, which air is prevented returning or escaping from such place by means of the valve at *f*; the object of this arrangement being that should a force be applied to the buffer, such force is not only counteracted by the spiral spring, but also by the air contained within the cylinder, forming the buffer, which becomes forcibly compressed, and thereby acts as a resisting power to the opposing force.

Another modification of this buffer is shown at fig. 2, in which the inventors employ elastic bags of India-rubber placed within cylinders, and filled with atmospheric air which is supplied through openings at *g g*.

Another part of this invention consists in a peculiar mode of obtaining motive power, for which purpose the inventors have shown in the drawing a sectional elevation of an engine to be worked by the vapour of ammonia, which is contained in a boiler placed in a water bath heated to 212°. The vapour or motive power obtained from the ammonia passes through the eduction and induction pipes of a cylinder constructed in the ordinary manner, with the exception that the patentees employ India-rubber bags (similar to those described), within the cylinders above and below the piston, the object of which is to prevent the vapour escaping through the stuffing box or between the piston and sides of the cylinder.

IMPROVED ARTIFICIAL MANURE.

JAMES MUSPRATT, Esq., of Liverpool, gentleman, for "*Improvements in the manufacture of manure.*"—Granted April 15; Enrolled Oct. 15, 1845. (A communication from Prof. Liebig.)

It has been ascertained, that the growing of any crop on land, and removing and consuming it wholly from the land where it was grown, takes away certain mineral compounds; and it has been suggested by Professor Liebig, that in cultivating land and applying manure thereto, that the manure should be such as to restore to the land the matters and the quantities thereof, which the particular plants have abstracted from the soil during their growth. It has been observed in the chemical examination of marls and vegetable ashes, that the alkaline carbonates and the carbonate of lime can form compounds, the solubility of which depends on the quantity of carbonate of lime contained in the particular compound. It has further been found, that the said alkaline carbonates can form a like compound with phosphate of lime, in which the carbonate of potash or soda is partly changed into phosphate of potash or soda. Now the object of this invention is to prepare manure in such manner as to restore to the land the mineral elements taken away by the crop which has been grown on and removed from the land, and in such manner, that the character of the alkaline matters used may be changed, and the same rendered less soluble, so that the otherwise soluble alkaline parts of the manure may not be washed away from the other ingredients by the rain falling on the land, and thus separating the same therefrom. And it is the combining carbonate of soda or carbonate of potash, or both with carbonate of lime, and also the combining carbonate of potash and soda with phosphate of lime, in such manner as to diminish the solubility of the alkaline salts to be used as ingredients for manure (suitable for restoring to land the mineral matters taken away by the crop which may have been grown on and removed from the land to be manured), which constitutes the novelty of the invention.

Although the manures made in carrying out this invention will have various matters combined with the alkaline carbonates, no claim of invention is made thereto separately, and such materials will be varied according to the matters which the land to be manured requires to have returned to it, in addition to the mineral substances above mentioned. The quantity of carbonate or phosphate of lime, used with carbonate of soda or potash, may be varied according to the degree of solubility desired to be obtained, depending on the locality where the manure is to be used, in order to render the preparation less soluble, in localities where the average quantity of rain falling in the year is great; but as in practice, it would be difficult to prepare manures to suit each particular locality with exactness, the average preparation as will suit most localities will be given. In making manure according to the invention, carbonate of soda or of potash, or both are to be fused in a reverberatory furnace, such as is used in the manufacture of soda-ash, with carbonate or phosphate of lime (and with such fused compounds are mixed other ingredients as hereafter mentioned,) so as to produce manures; and such composition, when cold, being ground into powder by edge stones or other convenient machinery, the same is to be applied to land as manure. And in order to apply such manure with precision, the analysis and weight of the previous crop ought to be known with exactness, so as to return to the land the mineral elements in the weight and proportion in which they have been removed by the crop.

Two compounds are first prepared, one or other of which is the basis of all manures, which will be described as the first and second preparations. The first preparation is formed by fusing together two or two and a half parts of carbonate of lime with one part of potash of commerce (containing on an average sixty carbonate of potash, ten sulphate of potash, and ten chloride of potassium or common salt in the hundred parts), or with one part of carbonate of soda and potash, mixed in equal parts. The second preparation is formed by fusing together one part of phosphate of lime, one part potash of commerce, and one part of soda ash. Both preparations are ground to powder; other salts or ingredients in the state of powder are added to these preparations and mixed together, or those not of a volatile consistency may be added when the preparations are in a state of fusion, so that the manure may represent as nearly as possible the composition of the ashes of the preceding crop. This is assuming that the land is in a high state of cultivation, but if it be desired to grow a particular crop on land not in a high state of cultivation, then the manure would be applied in the first instance suitable for the coming crop, and then in subsequent cases, the manure prepared according to the invention would, as herein described, be applied to restore to the land what has been taken therefrom by the preceding crop.

Preparation of manure for land which has had a wheat crop grown on and removed therefrom.—Take of the first preparation six parts by weight, and of the second preparation one part, and mix with them two parts of gypsum —one part of calcined bones—silicate of potash, (containing six parts of silica)—and one part of phosphate of magnesia and ammonia. This manure is also applicable to be used after growing barley, oats, and plants of a similar character.

Preparation of manure for land which has had a crop of beans grown thereon, and removed therefrom.—Take fourteen parts by weight of the first preparation, two parts of the second preparation, and mix them with one part of common salt, (chloride of sodium,)—a quantity of silicate of potash, (containing two parts of silica,)—two parts of gypsum, and one part of phosphate of magnesia and ammonia. This manure is also applicable for land on which peas or other plants of a similar character have been grown and removed.

Preparation of manure for land on which turnips have been grown and removed therefrom.—Take twelve parts by weight of the first preparation, one part of the second preparation, one part of gypsum, and one part of phosphate of magnesia and ammonia. This manure is also applicable for land where potatoes or similar plants have been grown and removed.

The claim is for preparing and applying in the manufacture of manure, carbonate of potash and carbonate of soda with carbonate and phosphate of lime, in such manner as to render the alkaline salts in manufactured manure less soluble, and therefore less liable to be washed away by rain before they are assimilated by the growing plants.

STEAM ENGINES.

Richard Haworth, *of Bury, in the county of Lancaster, engineer, for certain improvements in steam-engines.*—[Granted February 10; Enrolled August 10, 1845.]—*Reported in Newton's London Journal.*—(*With engravings, Plate III.*)

The principal feature of novelty in the invention is as follows:—The entire working engine has both the common reciprocating rectilinear motion, and also a circular motion round the centre of the driving-shaft; the steam cylinder being fixed at one end of a lever, whilst the crank revolves loosely in a step or bearing at the other end of the same lever. The boss or centre of this lever is keyed fast upon the main driving-shaft, and is intended to communicate the motion of the engine to the same. This motion is transmitted in the following manner:—Upon one end of the crank-shaft a spur-wheel is keyed fast; the radius of its pitch line being equal to half the distance of the centres of the crank-shaft from the main driving-shaft of the steam-engine. This wheel gears into another of the same diameter, which is fixed, and remains perfectly stationary; the main driving-shaft revolving loosely through its centre: consequently, the wheel upon the crank-shaft has a double motion to perform,—one being a rotary movement round its own axis, communicated from the piston by means of the connecting-rod, as in ordinary steam-engines,—the other being a planetary motion round the main driving-shaft, occasioned by the spur-wheel upon the crank-shaft revolving, while the other wheel (through the centre of which the main driving-shaft passes) remains perfectly stationary. The wheels being both of the same diameter, the "planet-wheel" will complete its orbit round the main driving-shaft and "sun-wheel" in exactly the same space of time as the crank takes to make one revolution round its own centre. The object of these improvements is to gain both power and speed, which is accomplished by the motion being communicated to the driving shaft by a much longer leverage than usual; the increase of power being in proportion to the difference between the length of the crank and the length of the lever, in the end of which it revolves: the speed is gained by the shortness of the crank, as the piston has a smaller distance to travel at every stroke of the engine.

In Plate III, fig. 1, is a plan or horizontal view of the improved steam-engine, to be worked by high-pressure steam; and fig. 2 is a partial section, shewing more clearly the contrivance for the entrance and exit of the steam to and from the cylinder; *a*, foundation walls which support the main shaft *b*; *c*, fly-wheel; *d*, steam-cylinder; *e*, connecting-rod; *f*, crank; and *g*, the crank-shaft. This crank-shaft *g*, instead of revolving in fixed bearings, as in ordinary steam-engines, revolves in bearings at one end of the levers *h*, *h'*; the centre or boss of the lever *h*, is keyed fast upon the main-shaft *b*; the steam cylinder *d*, being attached, by bolts and lugs, to the other end of the levers *h*, *h'*. The steam is admitted into the cylinder, for the purpose of actuating the piston, in the following manner:—It will be seen, by referring to fig. 2, that the end *b'*, of the shaft is made hollow, having a midfeather *i*, through the centre, to divide the entrance-pipe *k*, from the exit-pipe *l*, and revolves in a hollow steam-chest or chamber *m*, being packed steam-tight by means of stuffing boxes. Steam is introduced into this chamber by the feed-pipe *n*, and passes through the opening *o*, into the entrance-pipe *k*, and thence through the slide-valve (which is of the ordinary construction) to the steam cylinder. The action of the piston communicates rotary motion by means of the connecting-rod *e*, and the crank *f*, to the crank-shaft *g*; upon one end of this crank-shaft *g*, the planet-wheel *p*, is keyed, gearing into a sun-wheel *q*, of the same diameter; this wheel *q*, has no motion whatever, but merely serves as a rack, around which the planet-wheel *p*, travels. Through the boss of the wheel, *q*, the end *b*, of the main driving-shaft passes, revolving loosely. Thus it will be evident, that, in consequence of the wheel *q*, remaining perfectly stationary, the rotation of the crank-shaft *g*, will cause the planet-wheel *p*, to travel round the sun-wheel or circular rack *q*, in the same space of time in which it revolves upon its own axis, thus causing the engine to revolve, while going through its reciprocating action; the main-shaft *b*, *b'*, being the fulcrum, and revolving with it, in consequence of the bosses of the levers *h*, *h'*, being keyed fast upon that shaft. In this improved arrangement of the steam-engine, in order to work the slide-valve, the excentric *r*, is stationary, and is connected to the valve by a series of links and levers *s*, *s*, *s*; the rotation of the engine communicating the requisite motion to the valve, the same as the revolution of the excentric *r* would do if the engine were fixed or stationary. Fig. 3 is a face view and section of a cam, to be used in connection with this arrangement, in place of the excentric, if it is desired to work the engine expansively; this cam being calculated to cut off the steam at half stroke.

The patentee remarks, that he has represented his invention as applied to a high-pressure "stationary" steam engine; but he considers the improved "planetary engine" equally adapted to condensing engines, and whether employed for marine or other purposes.

MANUFACTURE OF GAS.

James Murdoch, of Staple-inn, Middlesex, mechanical draughtsman, for "*certain improvements in the manufacture of gas, and in the apparatus employed therein.*—(Being a communication.)—Granted February 20th; Enrolled August 20th, 1845; with engravings. Plate III.

This invention consists in certain improvements in the manufacture of gas for illumination, which are effected by means of an apparatus shown in the engraving. fig. 1, is a transverse section, and fig. 2, a longitudinal section thereof. *a*, is for the coal. The neck *a'*, of the retort is connected by a horizontal tube with a vertical retort *b*, at the back of the apparatus; and this retort *b*, is connected by another horizontal tube *c*, parallel to the first, with the neck *d*, from whence a pipe *e*, extends to the cooling apparatus *f*: the two horizontal tubes are termed purifying retorts; and each contains a spiral piece of iron. The retort *b*, is nearly filled with coke or charcoal, and is usep for decomposing water, supplied through the syphon-pipe *g*, which descends nearly to the bottom of the retort, as indicated by the dotted lines in fig 2. The lid of the cooling apparatus *f*, has, on its under side, a long spiral channel, interrupted by stops, so as to cause the gas, admitted into the apparatus by the pipe *e*, to pass over a large surface of water, and occasionally through it, previous to its escape through the pipe *h*, to the gasometer. *i*, is a syphon-pipe, for carrying off the surplus water of the cooling apparatus. *l*, *l*, are fire-bricks to protect the retort *a*, from the direct action of the flame; and *m*, *m*, are openings, conducting the

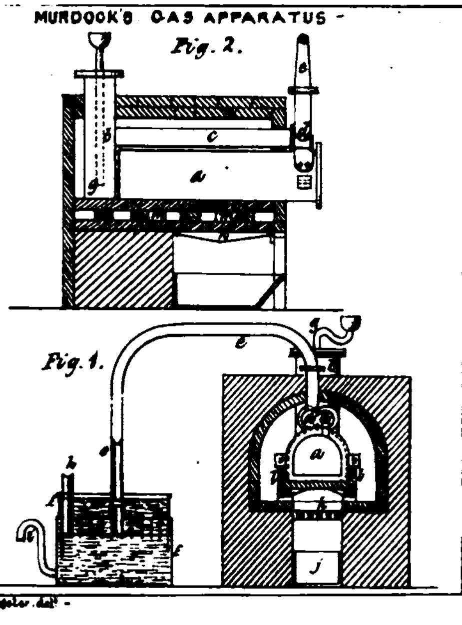
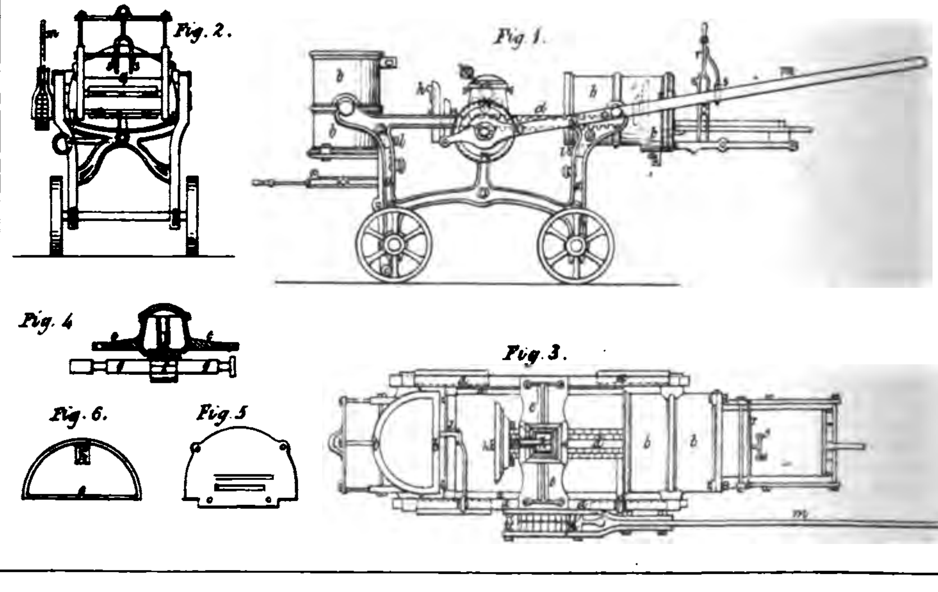
MURDOCK'S GAS APPARATUS



WELLER'S BRICK MACHINE



C. Bagley del.

flames to each side of the retorts, and heating them by reflection from the roof *n*, of the furnace, composed of fire-brick. *j*, is a vessel containing water, to protect the fire-bars *k*, from the destructive action of the fire, and by the steam arising therefrom to increase the combustion of the fuel.

The mode of working with this apparatus is as follows:—The covers of the purifying retorts are first secured and carefully luted; the retort *b*, is nearly filled with coke or charcoal, and its cover secured and luted; a fire is then lighted in the furnace, to bring the retort *a*, and purifying retorts to a cherry-red heat, and the water retort *b*, to a bright red heat; and when this heat is attained, the retort *a*, is charged with coal, and water is admitted, in small quantities, into the retort *b*. The action of the heat upon the coal disengages gas mixed with tar, which passes into the first purifying retort, and the sulphuretted hydrogen contained therein is decomposed by the coil of incandescent iron; at the same time the tar undergoing a second distillation is converted into gas, and mixes with that coming direct from the coal. The gas, which is now more dense from its combination with the carbon contained in the tar, proceeds along the purifying retort, until it arrives at the retort *b*, where it mixes with the hydrogen resulting from the decomposition of the water by the incandescent coke or charcoal, and passes into the second purifying retort, *c*, carrying with it the carburetted vapours and volatile oils which may have escaped decomposition, but which, in their course along the retort *c*, become decomposed by the heated coil of iron, and give out their carbon to the hydrogen. By this means the hydrogen becomes carburetted without impoverishing the other gas. The gas then proceeds through the pipe *e*, to the cooling apparatus *f*, and thence through the pipe *h*, to the gasometer. Instead of coal, resins, schistus, oils, fats, and similar substances, may be distilled in this apparatus; and, provided the purifying retorts, with the coils of iron, are retained, the gas may be distilled and purified at one operation, without the employment of a water retort.

MANUFACTURE OF TILES.

Richard Weller, of Capel, near Dorking, Brick and Tile manufacturer, for "*Improvements in the manufacture of drain and other tiles and pipes.*"—Granted March 27, 1845; Enrolled Sept. 27, 1845.—(*With an Engraving.*)—*Reported in the Repertory.*

We gave a brief description of this invention last Dec., which for want of drawings was not properly understood, we now give another description, with reference to the drawings, which will make the invention intelligible. The invention consists of improvements in arranging and constructing machinery for facilitating the making of drain, and other tiles and pipes.

Description of the Drawing.—Fig. 1, is a side view of a machine, constructed and arranged according to this invention. Fig. 2, is an end view; and, Fig. 3, is a plan of the machine; and the other figures of the drawing show details; and in all the figures, the same letters are used to indicate the same parts of the machinery. *a*, *a*, is the framing of the machine, the nature of which will readily be traced on examining the various figures of the drawings. The machine is mounted on four wheels, to facilitate the transport thereof from place to place. *b*, *b*, are two vessels, within which work pistons, for expressing the clay through dies or moulding orifices at the outer ends of the vessels, *b*, *b*, and the machinery is so arranged, that when one of the vessels *b*, is having the clay expressed therefrom through the moulding orifice or die, affixed thereto, the other vessel, *b*, is brought into a position for allowing the same to be filled with clay. The vessels, *b*, are of a cylindrical form at their upper parts, and flat at the under parts, which will be found to be a very convenient form, particularly when making half cylinders, or bent tiles of large diameter, compared with the diameter of the vessels, *b*; and, although it is believed that it is better to have somewhat more than half a cylinder as shown, yet the shape may be varied, so long as the sectional figure of the vessels *b*, be composed of a curve and a straight or horizontal line. The vessels *b*, *b*, are mounted on necks or trunnions, so that they may move in bearings, in such manner as to assume at one time a horizontal, and at another, a vertical position, by which, when either of the vessels *b*, has been emptied by its piston or plunger, it may be turned in a position to be again filled. *c*, *c*, are the two pistons or plungers, which respectively work in the two vessels *b*, *b*. These pistons are fixed to the two ends of the bar, *d*, which is supported, and slides in a suitable bearing in the bridge, *e*. On the under surface of the bar, *d*, is formed or affixed a toothed rack, which is worked by means of the pinion, *f*, on the axis, *g*, such axis receiving motion, by means af a lever hereafter described. In each of the pistons is an opening, over which is placed a flap or valve, *h*, which allows of the air passing between the piston and the clay, when the piston is drawn back, and thus is the drawing back of the piston facilitated. On the upper surface of the bar, *d*, are formed four rows of ratchet teeth, two rows being formed so as to receive the catches or stops, *i*, which will retain the band from going back in one direction, the other two rows of teeth being formed or cut in an opposite direction, so as to receive the two catches or stops, *j*, to retain the bar, *d*, from moving back when working in the other direction; and the object of thus stopping the bar, *d*, is, that the piston which is in work, may not be driven back by the air which may have been compressed between the piston and the clay, when the lever, *m*, is put back, in order to make another stroke. The two sets of catches or stops, *i*, *j*, are connected together as shown, so that, by moving the lever, *k*, those stops or catches which have been in action are moved out of action, and those which are out of action, are brought into action. By this arrangement the bar will be held from returning, in whichever way it may be working; and when the piston at the end of the bar, *d*, has been forced up to the end of its stroke, the lever, *k*, is reversed, which will change the positions of the catches or stops, *i* and *j*, and then the bar, *d*, may be reversed in its direction of movement, which will, by the other piston, force out the clay from the other vessel, *b*, and allow the vessel, *b*, which has just been emptied, to be moved in its axis or trunnions, so as to assume a vertical position, in order again to be filled with clay. *l*, *l*, are catches which retain the vessels, *b*, in the horizontal or in the vertical position. It may be remarked, that although the vessels, *b*, *b*, are preferred when mounted on axes to be of the form shown and described, yet this part of my invention is equally applicable to vessels of a cylindrical or other shape, from which clay is forced by pistons or plungers, through moulding orifices, or dies, to make tiles or pipes; for such vessels may, with equal advantage, be mounted on axes or trunnions. The moulding orifices are formed in the said covers of the vessels, *b*, and are as heretofore, suitable for making tiles of different forms or pipes, and are well understood, and therefore do not require to be described in this specification. The bar, *d*, is moved to and fro by means of the lever, *m*, which gives motion to the axis, *f*, first in one direction, then in the other, in the following manner:—*n*, is a ratchet-wheel fixed on the axis, *f*: this ratchet wheel has two sets of teeth cut in opposite directions, and the lever, *m*, (the nature of which is clearly shown in the drawing,) has the drivers *o*, *p*, so that when the lever-handle, *m*, is on one side the axis, it will, on being raised and lowered, cause the wheel, *n*, and consequently the axis, *f*, to move round, which action will be continued till the piston (in action) has completed its stroke, when the small lever, *k*, is to be moved over, which will reverse the stops or catches, when the lever, *m*, may be moved over to the other side of the axis, *f*, when the working of the lever, *m*, up and down, will cause the axis, *f*, to be moved in the opposite direction, and by the other piston, it will force out the clay from the other vessel, *b*, allowing time for the empty vessel, *b*, to be filled again with clay. The tiles, as they are forced out, are received on suitable "horses" as heretofore; and they are cut off by means of the wires, *q*, carried by the sliding frame, *r*; and when the tiles are to be punched with holes, such as flat tiles for roofing purposes, a suitable punch is applied, *s*, to the frame, *r*, so that in causing the frame to descend, a tile will be cut off, and punched at the same time.

MISCELLANEA.

An interesting experiment took place at Portsmouth on the 13th Jan off the Excellent, Captain Chads, on the most speedy and efficacious mode of destroying a boom, which might impede the progress of boat squadrons in narrow rivers, as in the case of the recent attack on the pirates of Borneo by the squadron under Rear-Admiral Sir Thomas Cochrane. The first experiment took place on the 9th, but was on a smaller scale than the present, consequently was not so convincing or successful in its results. On the present occasion two line-of-battle ships' lower masts were taken from the old mast pond and moored at a short distance from the Excellent. Six turns of small chain lashing secured the two spars in the centre; the ends of the spars were secured by two half hitches of chain, and two parts of the chain cable ran along the spars, and were secured in the same manner round the opposite extreme. The spars being thus secured, as if at the entrance of a river or creek, to prevent intrusion, the operations now commenced to dislodge them:—A breaker, containing 56lb. of gunpowder, was brought to the spot; at one end were eight inches of port-fire passed into it, over which was secured a copper tube made perfectly water tight, and two threads of quick match being attached to the upper end of the port-fire, and the opposite extreme brought through to the mouth of the tube above the water, they were ignited, and the breaker being thereupon hauled and secured immediately under the spars, a sufficiency of time (eight minutes) was provided for the boat to get clear of the mass before the port-fire reached the powder, which it did in the time above mentioned, when a tremendous explosion took place. On examining the spars and their fastenings afterwards, the following was the result:—14 feet out of the centre of both spars were shivered into atoms, with one of the chain lashings blown up with the timbers. The same experiment was afterwards repeated upon the shorter end of the obstruction, under the parts of the chain cable, the result of which was that the whole of the spars was blown to pieces. These experiments were highly successful and satisfactory. On the following morning a further experiment was made upon the two long ends of the same spars, with the chain cable wound round them, and a hemp (13-inch) cable hove "taut" in the intervals, the rest of the arrangements being the same as yesterday, except the quantity of powder, 112lb. being used to-day. The result was the total demolition of both spars, the chain cable was thrown to the bottom, and the hempen one blown away. Thus the success of the experiments is most unqualified and important. They were performed at the desire of Lord Ellenborough, who had expressed to Captain Chads, in a letter, his opinion upon the importance of naval officers becoming acquainted with the safest and most speedy method of removing such obstructions as those offered to the China squadron on the late occasion of the conflict with the pirates in the Malvado river. Captain Chads personally superintended the operations of the respective experiments, and which were executed by Lieutenant Robert Jenner, gunnery lieutenant to the Excellent, in a manner highly creditable to the talents and ingenuity of that officer.

Difference of Time.—In the streets of Brussels there may now be seen in the windows of the clockmakers' shops large mahogany clocks with the following inscription, "Railway time." It appears that it is owing to the care of the directors that these clocks have been exposed, in order to facilitate the arrival of travellers at the different times of departure.—"*L'Observateur.*"

An American Manufacturing City.—The ten manufacturing companies of *Lowell* consume annually 12,000 tons of coal, 3,070 cards of wood, 72,549 gallons of sperm, and 19,000 of other oil. Of the whole population of Lowell, 6,320 females, and 2,915 males, together 9,235, are employed as operatives, either in the mills or connected with other mechanical employments. There are 33 mills and about 550 houses belonging to the corporations. The capital invested in manufacturing and mechanical enterprises is 12,000,000 dollars. There are made in Lowell every week 1,459,150 yards of cloth, or 75,868,000 yards per year. The cotton worked up every year is 61,100 bales. The printed calicoes made annually amount to 14,000,000 yards, the payment annually amounts to more than 1,500,000 dollars, and the annual profit of this immense business has been estimated at the same amount, or at about 12½ per cent.—"Globe."

The Amphion Frigate.—This frigate of 36 guns was launched at Woolwich on the 14th January. The building commenced on the 5th of April, 1830; she has since been lengthened 16 feet by the bow, and fitted in the stern for a screw-propeller as an auxiliary, every other part and fitting being the same as a proper sailing frigate. She appears to be a sightly vessel, and sits well upon the water. Her figure head is a bust of the late gallant Captain Sir William Hoste, Bart., and her stern is of a neat square form externally, but round internally, for fighting her guns. To all appearance she will be a fast sailer, and a good ship of war. The following are her dimensions:—

	Feet.	In.
Length of the lower deck	177	0
.. .. keel for tonnage	152	5¼
Breadth extreme	48	2
.. For tonnage..	42	8
.. moulded	42	0
Depth in hold	13	4½
Burden in tons, old measure, ...	1473 66-94ths.	
.. .. new	978 141-3500ths.	

The Amphion is fitted with engines of 300-horse power by Messrs. Miller, Ravenhill and Co., and will be the first constructed for the steam navy of this country with the whole of her machinery considerably under the water line, and consequently not liable to be deranged by shot. The screw will be 15 feet in diameter, on Ericson's principle, attached to engines on the direct action principle, with four-feet stroke, performing 48 revolutions per minute. The boilers will also be under the water line, and the vessel is expected to be a superior ship of war by the aid of these appliances.

Valuable Discovery.—A French mechanic formed the idea that by subjecting iron-dross to the slow cooling process which is known to produce a total change in the nature of glass, a new and useful species of stone might be obtained; and as iron dross, such as the large furnaces yield, is a wholly useless substance, the announced successful result of his persevering attempts cannot but be matter of great interest, more especially at the present time, when the smelting furnaces of England are in a hitherto unknown state of activity. The object which the Frenchman sought to accomplish was, to impart to iron-dross the compactness and hardness of granite, and, at the same time, to save the cost and labour which the hewing of the real stone requires. To this end he contrived to let the iron refuse, while in a fluid state, run into iron forms, which were previously brought to a red heat by being placed so as to receive the superfluous flame which issues from the mouth of the furnace; and in order to ensure the slow cooling, these forms are provided with double slides, between which sand is introduced, which is well known to be a bad conductor of heat; the whole is then brought again to a glow heat, and in like manner again cooled off. By this procedure, it is asserted, the ingenious discoverer has succeeded in forming paving-stones, flags, large building-blocks, and even pipes, of any given form, of a degree of hardness and polish equal, if not superior to the best hewn natural granite, and at the most trifling conceivable cost.

The Manufacture of Steel in Spain.—The following particulars, respecting the fabrication of cast-steel and Damascus steel, at the forges of Toledo, in Spain, may perhaps be deemed interesting. It has been found that ovens do not produce a sufficient heat to melt the steel, consequently they have been obliged to construct forges, and the metal is placed in crucibles of earthenware, that withstand the greatest fire. The first process is by mixing the oxydes and filings of iron in a crucible, which is placed in the forge, heated by charcoal and continued with coke. The crucible is kept about half an hour in the fire, so as to become a clear red heat, after which it is exposed to the air to cool. Then comes a second fusion, by taking 100 parts of this crystallised matter, and mixing it with 100 parts of iron filings, which, after being exposed to the fire for one hour and a half, a very pure metal is obtained for forging. The forging of the melted metal must be done with great caution, and at a degree of heat far below bright red. When it has acquired the temper necessary, it is reduced to one quarter its size by the means of heavy hammers, and formed into bars; after which it is filed at each end, so as to ascertain if it is of good and pure quality, and the variegated stripes can be given at pleasure. It is re-heated, and tempered at dark red heat, and rubbed with wax, which evaporates. It is afterwards polished with pummice stone, and, to ascertain that it is free from grease, it is emerged in pure water, which adheres to its surface; it is then dipped in acidulated water, and covered, after being well dried, with oil for a day. The fabrication of Damascus steel is by placing three lines of cast-steel one upon the other, and heating them together, so as to form but one blade. The composition is 6lb. of soft iron, 150 grammes of wolfram, and 144 ditto of carbonate of manganese, which makes 2lb. of fine Damascus steel; pulverised nickel is also used, but it must be pure and free from arsenic—the best nickel is that received from Germany. In giving the steel the different colours, it is cleaned of all grease, and emerged in distilled water, mixed with oxalic acid, which causes the various veins in the steel to appear. The working of steel, is one of the greatest branches of Spanish commerce in the iron mining districts which abound in wood and coal.

LIST OF NEW PATENTS.

GRANTED IN ENGLAND FROM DECEMBER 22, 1845, TO JANUARY 27, 1846

Six Months allowed for Enrolment, unless otherwise expressed.

Henry Pershouse, of Birmingham, manufacturer, for "a certain improvement or certain improvements in apparatus used in connection with writing, and also in attaching postage stamps and labels."—Sealed December 22.

John Pain, of Greenwich, in the county of Kent, engineer, William Hartree, of Greenwich, lace-maker, engineer, and John Matthew, the younger, of the same place, engineer, for "certain Improvements in steam engines and machinery for propelling vessels which improvements are also applicable for other purposes."—December 23.

William Cole, of Coventry, warehouseman, for "certain Improvements in looms."—December 23.

John Dearman Dunnicliffe, of Nottingham, lace manufacturer, and William Bull Dexter, of the same place, lacker, for "Improvements in the manufacture of warp fabrics."—December 24.

Daniel Towers Shears, of Bank Side, Southwark, for "Improvements in the treatment of zinc ore for the purpose of producing zinc ingots, which improvements are applicable to the reduction of other ores and metal." (A communication.)—December 24.

Charles William Siemens, of Finsbury Square, in the county of Middlesex, engineer, for "Improvements in steam engines, and improvements in regulating the power and velocity of machines for communicating power."—December 24.

Wilton George Turner, of Gateshead, in the county of Durham, doctor in philosophy, for "an Improved mode of treating guano for the purpose of obtaining chemical compounds therefrom."—December 24.

John Russell, of the City of Edinburgh, accountant, for "a manufacture of glass tiles."—December 30, 1845.

Thomas Swinborne, of Lincoln's-inn, Esq., for "Improvements in railways and in the means of propelling and carrying thereon."—January 3, 1846.

Arthur Eldred Walker, of Bouverie-street, London, engraver, for certain ["Improvements in machinery for sewing."—January 6.

Conrad Haverkam Greenhow, of North Shields, gentleman, for "Improvements in the construction of railways and railway carriages."—January 6.

Henry Watson, of Newcastle-upon-Tyne, brass-founder, for "Improvements in withdrawing air and vapours from furnaces, or other apparatus, and in condensing and employing such vapours."—January 6.

Joseph Romnald Boxek, of Cheapside, mechanic, for "Improvements in the construction and application of railroad carriage-wheels."—January 6.

William Smith Brown, the younger, of Broad-street, Ratcliffe-cross, sail-maker, for "Improvements in the manufacture of square and quadrilateral sails, for ships and other vessels."—January 6.

Joseph Douglas, of Cross Cheaping, Coventry, furnishing ironmonger, for "improvements in the patterns used for casting and in casting metals."—January 9.

Charles Chinnock, of Cook's-grounds, Chelsea, for "Improvements in the construction and methods of extending and compressing articles of furniture and domestic use, also applicable to cutlery, workmen's tools, windows, blinds, shutters, and similar useful purposes."—January 12.

Charles Hancock, of Grosvenor-place, gentleman, for "certain Improvements in the manufacture of gutta percha, and its application alone, and in combination with other substances."—January 12.

Henry Schloss, of Finsbury-square, gentleman, for an "Improved instrument, or instruments for producing ignition."—January 12.

John Seaward, of the Canal Iron-works, engineer, for "Improvements in the steam-engine, and in machinery for propelling."—January 12.

George Tillett, of Snow-hill, Ironmonger, for "Improvements in stoves and fireplaces."—January 13.

Jean Marie Durnerin, of Paris, Doctor of Medicine, for "Improvements in treating fatty matters."—January 13.

Thomas Moorcroft Benbow, of Birmingham, surgeon, for "Improvements in fastenings for surgical and other bandages, and for articles of dress."—January 13.

Robert Bewick Longridge, of the Bedlington Iron-works, near Morpeth, Northumberland, for an "Improved locomotive engine."—January 13.

Joseph Maudslay, of the firm of Maudslay and Field, of Lambeth, engineers, for "Improvements in propelling and propelling machinery."—January 13.

Edmund Leahy, of Cork, Ireland, Civil Engineer, for "Improvements in locomotive carriages, intended to be employed on ordinary roads."—January 15.

William Benson, of Allerwash House, Haydon-bridge, Northumberland, gentleman, for certain "Improvements in machines for the manufacture of tiles and other plastic substances."—January 15.

William Clark of Nottingham, and William Vickers the younger, of the same place, lace manufacturers, for "Improvements in manufacturing lace and other fabrics by lace machinery."—January 17.

Arthur Wellington Price, of Manchester-street, Gray's-inn-road, gentleman, for "Improvements in the construction of anchors."—January 17.

Peter Taylor, of Hollingwood, near Manchester, machinist, for "certain Improvements in machinery for propelling vessels, carriages, and machinery, parts of which improvements are applicable to drawing and propelling fluids, also improvements in the construction of vessels.—January 20.

Gerard Andrew Arney, of Mare-street, Hackney, gentleman, for "Improvements in the preparation of gelatine, and improvements in fining or clarifying liquids.—January 20.

John Braithwaite, of Bedford-Square, Civil Engineer, for "Improvements in heating, lighting, and ventilating.—January 20.

William Vincent Wennington, of Goscote Iron works, Stafford, esquire, for certain "Improvements in, or improved methods of cutting plate and sheet iron.—January 20.

Richard Archibald Brooman, of Fleet-street, London, gentleman, for certain "Improvements in railway and common road carriages. (A communication.)—January 20.

William Malins, of Mansion House-place, London, and West Bromwich, Stafford Iron Master, for certain "Improvements in the construction of buildings.—January 20 (A communication.)

William Newton, of Chancery-lane, Middlesex, Civil Engineer, for certain "Improvements in manufacturing piled fabrics.—January 20. (A communication.)

John Nott, of the city of Cork, gentleman, for certain "Improvements in the means of communicating intelligence from one place to another.—January 20.

William Henry Burke, of Tottenham, gentleman, for certain "Improvements in the manufacture of fabrics which may, if required, be made air and waterproof; a part of the materials employed herein, when combined with other matters, being intended to produce coverings for vessels of capacity.—January 20.

Andrew Kurtz, of St. Helen's, Lancaster, manufacturing chemist, for certain improvements in the construction of furnaces, and apparatus connected therewith, for evaporating or concentrating sulphuric acid."—January 20.

John Spenceley, of Whitstable, in the county of Kent, Master Blockmaker, for "Improvements in the construction of ships and other vessels, and also improvements in apparatus to be attached to ships and other vessels."—January 20.

John Walker, of Manchester, silk manufacturer, for certain "Improvements in weaving or manufacturing piled or napped cloths or fabrics, and also improvements in machinery or apparatus for cutting the pile or nap of the same."—January 20.

Charles Wheeler, of Speenhamland, Berkshire, machinist, for "certain improvements in the construction and working of railways."—January 22.

Joseph Cooper, of Great Chart-street, Hoxton, chemist, for "an improved mode of separating certain of the fluid, and soluble parts of certain vegetable substances from the solid parts thereof."—January 22.

Frederick William Campin, of Fleet-street, in the City of London, gentleman, for "certain improvements in obtaining and applying motive power."—January 22.

Daniel Ross, of South-street, Southwark, hat manufacturer, for "Improvements in the manufacture of hats."—January 27.

CORRESPONDENTS.

The appearance of Mr. Bashforth's letter prevents us from inserting a very ingenious paper on atmospheric traction, received in the earlier part of the month.

ERRATA.

In speaking of the plate of the engines of the Great Britain, in our last number, p. 9, we were made to say that the engraving was "not sufficiently explanatory," the word "not" should have been omitted.

In the notice of the Model of the Parthenon, in the present number, p. 44, col. 2, the first note belongs to Mr. Lucas's book; the second is editorial; the word "cella" is misprinted "cellar."

IDEA FOR THE FACADE OF THE BRITISH MUSEUM.

(With an Engraving, Plate IV.)

Little less than marvellous is it—certainly unaccountable, that so important a structure as the British Museum—the most public of all our public edifices, because that to which the public have freest access, should be regarded by the public and the public press with so much apathy and indifference. Or if it is not to be attributed to sheer indifference, the sullen silence which has succeeded to the bitter remonstrances made against the design for the Façade at the time the works for it were first commenced, argues despair. and the unhappy conviction that all the remonstrances in the world would have no effect upon those whom it has behoved to consider very seriously what they are about, and to reconsider the design adopted for the Façade, ere it be altogether too late. Poor as it would be, it would still be some sort of satisfaction to be informed what it is that has recommended the design in question, what are the particular merits and beauties discerned in it, and claimed for it. Instead of which, all that has been said about the intended Façade has been strongly AGAINST it, without the slightest attempt having been made to reconcile us to it, by gainsaying any one of the objections which have been urged in condemnation of it. If they can fairly be set aside, the neglecting to do so looks much more like scornful disregard of public opinion, than like generous forbearance. However matters of the kind may have been managed formerly, at the present day, we have some right to expect to be tolerably well satisfied beforehand that a work of such magnitude and importance, will be found perfectly satisfactory when completed.

To bid us wait—to suspend our judgment until we shall have the entire Façade before us, is merely idle evasion, for the Model might all along have been exhibited for general inspection in the Museum itself, instead of being kept there under lock and key, jealously secluded from all eyes but those of a privileged few,—eyes likely to be far more partial and indulgent, than at all critical. Does such very cautious *vigilance* bespeak comfortable confidence—well-grounded assurance that the model justifies what was on one occasion said of the design?—but said, be it remarked, very long ago, when the name of its architect stood very much higher in general estimation than it does at present; and that, not because he himself has fallen off from what he once was—on the contrary, he remains just the same as he always was *ab initio*,—but because others have far outstripped him, and because several structures have in the interim arisen both in this and other countries, in comparison with which the British Museum will show exceedingly poor,—rescued from insignificance only by its mere magnitude as a building, and on that very account all the more distressingly unsatisfactory, because the occasion both demanded, and afforded opportunity for something infinitely superior. For that to be merely passable, which ought to be a *first-rate* piece of architecture of its kind, and to display all the very best qualities of the style adopted for it, amounts to nothing less than failure. We are annoyed by the disagreeable contrast which impresses itself upon us, between the what *is* and the what *might have been, and ought to have been.*

In the case of the British Museum, those who will have to answer for the disappointment which the building will create, will have left themselves very little excuse for their error. They will in a manner have made themselves doubly responsible by waiving off all interference whatever in the shape of opinion, remonstrance, or the expression of wish that the building should prove at least not inferior to other contemporary ones, in the same or a similar style. Interference of that kind being totally disregarded, all the less scrupulous need we be about speaking out quite freely, being well assured that our remarks will not in the slighest degree disturb or perplex either the architect himself, or those who sanction his treatment of the British Museum façade.

There is no necessity for waiting longer when the whole already exhibits itself very clearly to an architectural eye, the entire mass being shaped out, and as much of it completed as very distinctly shows the precise quality of the architecture, and the degree of finish and effect. There is nothing at all doubtful,—nothing left for conjecture: we cannot flatter ourselves with the possibility of being mistaken in regard to any of the architect's intentions, or with the hope of being taken very agreeably by surprise by aught that yet remains to be done. Even yet, indeed, there remains an opportunity for redeeming the Façade by introducing into it a magnificent feature that should be superior to every thing which we now have of the same kind. We are not therefore exactly too late, though certainly not at all premature in submitting an idea of our own; though its being in sufficient time to allow of its being adopted, makes, we are fully aware, no difference whatever. By some, perhaps, it would be considered better timed, were it to be kept back until the possibility of adopting it, had altogether passed away. We of course lay ourselves open to the charge of presumption in pretending to *correct* the architect's design, more especially as it is one in regard to which the Horatian precept of *Nonum prematur in annum* has been observed in more than its fullest extent. Let us be deemed ever so presumptuous, we will not show ourselves sneaking also, by gently protesting that we feel exceedingly doubtful whether our variation would be any improvement after all,—that we here produce it most hesitatingly, and reluctantly,—with many other pretty perjuries of the kind, which if Jupiter does not laugh at them, all sensible readers will at once see through. All that we have to observe apologetically is that the accompanying Elevation (see Engraving) purports to be not such a design as we could have wished to see adopted, but merely an alteration of the existing one, adapted to the Façade as already shaped out, so as not at all to disturb the structure itself, or in any way interfere with what is actually done, except in so slight a degree as to be of no moment.

Nothing more would be required than to enlarge the plan of the centre portico, making it of a different order and upon a larger scale than the colonnades along the rest of the façade, whereas now that portico will be merely in continuation of them, and not otherwise distinguished in the general mass than by the addition of a pediment—very insufficient to give a decided expression of loftiness to the centre of the composition. For the colonnades alone, as subordinate to the main feature, the present Ionic order may be upon a sufficient scale, but it will not produce a portico upon a scale at all more majestic than some which we already possess—not comparable in that respect—or indeed, any other—with that of the Royal Exchange. Projecting only a single intercolumn in advance of the lateral colonnades, it will not display itself at all advantageously, neither will it be of sufficient depth within to be attended with much architectural effect on that account, or properly to answer the purpose of a *Vorhalle*, or open colonnaded vestibule containing the entrance to the building, because it will be in a manner choked up with a second row of columns within corresponding with those in front, and dividing it into two spaces not at all wider than the other colonnades. Great advocates as we are for the use of internal columns in porticos, we are far from approving of the arrangement of them in the portico that is to be, of the British Museum. A certain degree of richness will, no doubt, be so produced, but, it may be apprehended, it will cause the rest of the colonnading to look meagre and scanty, by comparison, especially at the external angles,—where we could wish to have seen square pillars, if only in order to break the monotony arising from such a number of columns as there will be, and nothing else. The whole façade will consist of nothing more than columniation put up in front of a fenestrated structure. Take away the former, and so far from losing any thing essential to it, the rest would remain as good as ever, without there being aught to show that there had been columns, or that the structure was framed with reference to their becoming constituent parts of it. Were they taken away, there would be no hiatusses on the design; it would be only rendered astylar, with a single range of windows, not very dissimilar from the Hall of Commerce in Threadneedle Street, except that it would be somewhat less ornate. Over-decoration will certainly not be the failing of the façade of the British Museum: the absence of sculpture and all other artistic embellishment may obtain for it the reputation of simplicity from those who have no have no other idea of simplicity than that of nudity and bareness; yet the inscription of "British Museum" will be necessary to apprise strangers that within such structure may be found some of the most precious remains of ancient art and sculpture, and the model of the Parthenon, to boot. Even the order itself is nowise distinguished: it is a fair average example of Grecian Ionic, and nothing more, and except that the shafts of the columns are fluted, it is quite plain. It is in fact the same example as that employed for the Post-office, without any attempt at difference of character and expression. Its merit therefore is merely of a mechanical kind, for it has not cost the architect the exertion of a single fresh idea. What will serve for a Post-Office, will serve, it seems, equally well for a Museum; although there had need be something more than usually striking in the order to make amends for the tameness and monotony of the general design.

In our altered version of the Elevation, the Ionic order becomes a secondary one, and as such contributes to contrast with and set off the Corinthian octastyle, which though considerably loftier (being somewhat higher than the portico of the Royal Exchange) would not in its turn have the effect of diminishing the other columns by comparison, the latter being on quite as large a scale as we are accustomed to. By exceeding that scale, and rising up higher than the Ionic colonnades, the central portico would confer dignity on the whole façade. That such combination of two different orders is not in strict accordance with Grecian precedent, is what we need not be told; yet it seems to us that, instead of requiring excuse, such deviation from the letter of Greek architectural law, would rather tend to excuse those violations of it which there will now be, by proclaiming at once that the building does not affect to be severely Grecian.

The Plan accompanying the Elevation, shows the Corinthian octastyle to be brought forward two intercolumns in advance of the adjoining colonnades; owing to which it would be rendered unusually spacious, and would constitute a rather striking piece of architecture internally; while another advantage would be that the portico would display itself more prominently in an oblique view of the façade. In the external elevation of our Corinthian Portico, there is nothing either amounting to design, the sketch merely indicating the order and showing that the frieze of the entablature, and the pediment would be enriched with sculpture. But perhaps some little degree of novelty may be claimed for the mode in which the portico is connected with the lateral colonnades, which latter are entered through open doorways or portals, answering to the extreme intercolumns of the octastyle. Thus treated the portico would be better enclosed than if open at its ends, into the colonnades, and a greater variety of effect upon the whole would be produced. One other thing that may deserve to be pointed out as partaking of novelty, is the position of the two statues against each of the extreme columns of the octastyle, in which situation such figures would, we conceive, tell very forcibly, and throw a good deal of play into the architecture.

We are aware that such a portico as we have imagined could not be applied to the building in its present state: it would be necessary to carry up the back wall of the portico higher, and also to raise the centre of the roof to the pitch of the loftier pediment. What then? there would be nothing of very awful or unheard of extravagance in doing that; far better that, than to erect what may some time hence be doomed to be taken down again to make room for something more dignified. If Sir John Soane built the exterior of his Law Courts twice over;—if the wings that were first put to Buckingham Palace were no sooner up than they were taken down again, the mere consideration of a little more expense and a little more delay, ought not to deter from effecting even at the eleventh hour an alteration greatly for the better in the façade of the British Museum. That we ourselves consider it would be one greatly for the better is evident; and most persons we fancy, will be of the same opinion; still others may think very differently, in which case they are heartly welcome to be as free in their strictures upon us as we have been in speaking of the design which is now being carried into execution.

DECEPTIVE ARCHITECTURAL MATERIALS.

II.

We published last month a long letter subscribed "The Writer in the Companion to the Almanac," controverting certain criticisms which have appeared in former numbers of this Journal. It is not worth while to prolong an uninteresting and unprofitable controversy by replying categorically to the letter; at the same time, there are views suggested by it on one subject—that of deceptive materials—which are certainly worth examining. It is a matter of very general interest to architects and those who employ them, that the general question as to the propriety of using deceptive materials, and also the specific questions as to what particular materials are to be considered deceptive, should be clearly and definitively answered.

But a mere unsupported *dictum* will not be a sufficient answer. On subjects like these the reader claims the right of reasoning and examining for himself, and will not be satisfied with simple statements of opinion, however authoritatively pronounced. It will be necessary therefore to observe some sort of method in considering the question, and as we have already assigned in the former paper with the same title as the present one, the abstract reasons for condemning architectural deceptions, we now purpose to examine the specific applications of the general rule.

It may then be first remarked that every rule of art which is of the nature of a restriction must be applied more strictly to works of the highest order than to those of a trivial or unpretending character. So that, in condemning architectural deceptions, the condemnation must be considered to fall far more heavily when it affects important public edifices, churches, collegiate buildings, &c., than when it refers to ordinary domestic architecture. There would, for instance, be no dispute as to the impropriety of making the great doors of a cathedral of some common wood painted in imitation of oak, but it would be mere affectation to object to the use of "grained" deal in an ordinary dwelling room. Neither, we presume, would there be found at the present day many defenders for an architect who constructed an elaborate roof like that of Henry the Seventh's Chapel, of some cement or stucco resembling stone; but it would be absurd to conclude that there was any impropriety in using plaster ceilings in private houses. Neither, again, would it be possible to deny that a chimney piece of wood painted and varnished to resemble marble would appear contemptible in a noble banquetting hall; but it is quite possible to conceive instances where wood painted like marble might be introduced without any grievous offence to good taste.

The more immediate occasion of the present paper arises from the remarks which have been made in defence of the use of *varnished deal*, and as this material has of late been very frequently used in buildings of the highest pretensions, it becomes a matter of great interest to the architect to ascertain under what circumstances its use is justifiable. It is clear that no reason exists for making it an exception to the remarks just made respecting the cases where imitative materials may be allowed, and those remarks are of the more importance with respect to varnished deal, because there are methods of using this substance by which it altogether avoids the risk of being ranked among deceptive materials. In many of the old mansions and seats of the nobility the wood-work is of the Norway pine timber, varnished; and this wood from its superior hardness and closeness of texture compared with common deal, admits of considerable delicacy and minuteness in carving. The grain of the wood also is free from that coarseness which renders deal generally inapplicable for ornamental purposes. The colour of the Norway pine wood when varnished somewhat resembles that of pear wood, and produces a very agreeable effect; the varnish also improves the appearance of the wood by developing its texture and "bringing up" the grain, which often exhibits considerable delicacy.

This point however is particularly to be noticed—that where the Norway pine wood has been used with good effect, there has *never been any attempt to produce deception by artificially disguising the natural colour of the wood.* This remark is most important, because, otherwise, all attempts to *improve* the natural appearance of architectural materials might be considered synonymous with architectural deception. It is very necessary for the consistency of our argument, that this distinction should be clearly made; for otherwise it might lead to most absurd inferences. An unthinking person might, for instance, condemn the polishing of marble on the mere ground that marble when polished presents an appearance altogether different to that which it has in its natural state. But the essential distinction between the improvement of natural materials and architectural deceptions is—that by the latter, a poor and cheap material is made to look like some other well known material, which is more rare and costly. Marble, by being polished, cannot be said to be made to resemble anything more costly than itself; neither can varnished Norway pine *when unstained* be supposed to be a spurious and deceptive substitute for a more expensive wood.

If, however, some cheap common wood, such as the ordinary pine be stained of a dark colour, altogether different from its natural hue, and if moreover, as in the case of the timber roofs at Lincoln's Inn, the stained wood is placed at such a height that the eye cannot detect the poverty of the material by its shapeless knots and coarse grain, it seems impossible for any one but a mere disputer about words to deny that in such a case varnished deal must fairly be reckoned in the list of deceptive materials.

It does not appear any answer to our objection to say that in this case the wood is not *painted.* Of what consequence can it be whether the deception be produced by painting the wood or by staining it? The object of the discussion is to ascertain the *fact* of the existence of deception—not the *mode* of producing the deception. So long as it remains undisputed that a common material is made to look like another, better and more expensive than itself, it really seems wholly immaterial to dispute about the specific means by which the deceptive resemblance is effected. The notice of ceiling at Lincoln's Inn, copied into our pages from the *Athenæum*, stated that the wood was first *stained* and then varnished, and that the colour of the wood was entirely changed; these facts are perfectly sufficient for our argument.

It may appear perhaps that we are prolix and unnecessarily minute on a point of comparatively little importance. This however is not the case. The particular kind of deception which we now notice seems growing into fashion, and believing, as we do, that a great—if not *the very greatest*—barrier to the improvement of modern architecture, is the tendency which has unhappily crept in of using all kinds of tricks and artifices and make-beliefs, we do not think that we can be mispending the time of our reader by endeavouring to set forth clear and explicit notions on the subject. By accurately explaining the nature of one architectural deception, we, by implication, determine the nature of all; and it may be added that it is the want of clear notions on this subject, and not the subject itself, which has occasioned those exaggerated inferences by which attempts have been made to throw ridicule on the important rule of architectural criticism now under consideration.

It is not very easy to see from what cause have arisen the loud remonstrances which have been urged against us in justification of architectural deceptions. Were our condemnation of them an altogether new and unheard-of rule, it might be anticipated that objections would be raised against the doctrine, not on account of any inherent defects in it, but simply for its novelty. But we do not claim the merit of novelty. The doctrine asserted by us has been assented to by almost every thinking writer on architectural subjects; it was rigidly observed by all the ancient architects, both Classic and Christian; and we may observe that in works published at the present day, which contain architectural criticisms, the same principle is universally recognized. We quoted not long ago some remarks from the pages of *The Builder*, respecting the church built of terra-cotta, near Manchester, the tendency of the extract being to show that such a building ought to be condemned, not because of accidental failures in the workmanship, but *per se* as an attempt of the worst kind at architectural deception. To this testimony we might add that of the *Athenæum*, and it would be impossible to read a single number, scarcely a single page of the *Ecclesiologist*, without meeting with numerous censures of the employment of imitative materials.

We repeat boldly that there is scarcely a more fatal obstacle to the advancement of architecture than the system now too prevalent of building showily, instead of well. There is no doubt that those builders who have been trained in the "Cheap Gothic" school will feel much offended to find their mouldings and mullions of patent cement, their walls of stucco panelled to resemble masonry, and their showy-looking ceilings of stained deal condemned for ostentatious vulgarity, but their disappointment does not awaken our pity. From the days of Esop, the jackdaw has been condemned for excessively bad taste in arraying himself in the plumage of the peacock.

It is far better taste to use homely materials honestly and without concealment, than to trick them out with a vulgar unreal magnificence. There is an honest and substantial appearance in good dark brickwork, which is far preferable to the splendour of the best mock-masonry ever constructed. Of the former material some of the noblest and most stately edifices have been built—fine old mansions, ancient gateways, halls and towers; the latter is the type of suburban cockney architecture, it gladdens the eyes of retired tradesmen, and assorts well with those notions of the beautiful which are learned at the counter or in the counting-house. It is perfectly congenial to the taste of the ruralising stock-broker, who prefers that his *rus in urbe* with its patch of garden and smart summer-house should look *spruce* and *trim*, just like the new proprietary chapel-of-ease over the way; who sees no beauty in the old village church with its great sullen tower and dingy frowning buttresses, and pronounces the neighbouring baronial hall (which is coeval) a dull, dark, solemn place, which he would not live in for the world, for fear of growing melancholy and—romantic.

Now though we have no expectation or desire of converting such a critic, the readers to whom we now address ourselves claim that respect by education and profession, that it cannot be a matter of indifference whether they consent to, or dissent from, the views here laid down. We can have no fear that men, who are necessarily compelled to examine for themselves the principles of pure taste, will condemn the honest *real* architecture of the Grecian temples, and our own glorious cathedrals; the only ground of apprehension is that our rules may not be expressed with sufficient clearness to prevent exaggerated and inconsistent inferences. The true criterion as to the deceptive use of materials is—not that the natural appearance of the materials is *improved*—but that an attempt is made to cheat the eye, to impose the belief that what is in reality homely and common is some well known substance of a more costly description. The criterion is altogether independent of the particular method by which the deception is produced, and it is also irrespective of the *degree of successfulness* of the deception. It is no palliation, but rather an aggravation of the evil, when the imitation is close and minute, because in this case the amount of deception is only increased. If a nobleman were to appear at a great public solemnity with false jewels in his insignia, he would certainly be making a display in the worst possible taste, and the vulgarity of his ostentation would not be diminished, if his paste diamonds were so well made that they passed for real.

It is well worthy of remark that the art of imitation has always been most successfully practised in countries and at epochs distinguished by the debasement of the fine arts. A painter who could paint a joint of meat, or a knife with all the minuteness of reality, might certainly claim the credit of being a good mechanical imitator, but could scarcely take his rank among the disciples of "high art." Imitation is the faculty of the Ape, and is most observable among nations least elevated by moral and intellectual energy. Wonderful stories are told of the minuteness with which the Chinese and Japanese imitate natural objects, but none of the lofty beauty of their sculpture, painting, and architecture. The mimetic faculty is seldom predominant in men of original genius, and is never displayed in their greatest works; the substitution of the fictitious for the real, the minute for the beautiful, has uniformly been found to presage the neglect and speedy degradation of the Fine Arts.

ST. MICHAEL'S CHURCH, PIMLICO.

Notwithstanding the rapid advancement of church-architecture during the last few years, it must be confessed to be still in a state of transition from the barbarism of the last age, and to have as yet but imperfectly regained its original purity. A characteristic defect of modern Pointed architecture appears to us to be the want of that boldness and massiveness which distinguished the architecture of the fourteenth century. There is in modern art a general tendency to what may be called, for the want of a better term, *prettyism*. This affectation of smoothness and delicate ornament is especially observable in sculpture and architecture, and in neither of those arts have we the energy and boldness of the old artists. We seem altogether afraid of exercising that kind of courage which produced the strong simple lines, the bold salient angles, the sudden alternations of lights and shadows which distinguish Westminster Abbey or King's College Chapel. And it is the more to be regretted that these simple means of rendering architecture effective should be altogether missed in modern buildings, because they seem to be the very means which should be most valuable at a time when architects are constantly complaining of the parsimony by which their efforts are restricted. Speaking economically, it must be clear that bold simple ornaments must be cheaper than those of more delicate workmanship, and the architect can complain of no one but himself if for want of the former his works appear ineffective.

The new church of St. Michael's, Chester Square, built from the designs of Mr. Cundy, possesses in a great measure that necessary play of light and shadow without which the first and distant view of a church can never be satisfactory. The plan of the building is cruciform, there is a bold tower surmounted by a lofty spire, the roofs are of high pitch, and the combination of the various parts produces a very picturesque specimen of the style adopted—the Decorated. The entrance is not at the west, but beneath the tower which stands on the north side near the north-west angle, and is strengthened by buttresses divided into three stages, and panelled. The buttresses are surmounted by pinnacles with crockets and finials; between these rises the spire which is surmounted by a vane at the height of 160 feet from the ground. The roofs of the church are slated and have floriated crosses at the gables. The whole of the exterior is faced with Kentish ragstone, with Bath-stone dressings oiled to resist the effect of moisture.

The entrance to the church is beneath the tower, of which the lower part is entirely open, and forms an arched portico. Similar examples exist at West Walton, Norfolk; at Dedham, Essex, and in one of the churches at Cambridge. Within the church there is accommodation for 1200 persons, 750 in pews and 450 in free seats. The roof is of open wood-work, and is supported by piers between the nave and aisles. The font which is at the west end, has a cover of carved wood, and the pulpit and reading desk are low, and stand on either side of the "communion recess," which is paved with encaustic tiles. The commandments are written in panels beneath rich canopies, and on the south side are *sedilia*. If these are to be *used* there can be no objection to them in an architectural point of view, if how ever they be useless and are merely for show, the architect would have certainly done well to have omitted them.

Where there is much to praise it is very painful to have to find fault; truth and consistency however compel us to state that there are many things in the interior arrangement of the church which cannot be praised. There are galleries intersecting the piers and blocking up the side windows; the shafts attached to the piers have poor bases which are hoisted on a species of stilts to the level of the pew-seats. But above all there is an appearance of *unreality*, objectionable in all kinds of architecture, but perfectly indefensible in that kind which ought to be the very highest and most truthful—church architecture. The walls of the church and of the staircases are coated with plaster on which black lines are drawn to imitate, or rather, mimic the courses of real masonry. Some of the window mouldings are "run" in cement, and are the more deceptive because the mullions and corbels are of stone. The same remark applies to the shafts attached to the piers, which are partly of stone and partly imitations; the piers themselves are all of plaster decorated with the black lines aforesaid. The pews are of stained deal. Of the value of this material we have pronounced a sufficiently explicit opinion in another part of our present number. It may be added that here the coarse shapeless knots of the wood and the harsh lines of the grain have a very disagreeable effect. The glazed and shining appearance of varnish is, to our taste at least, very objectionable. This however is merely an individual opinion,—but it is a matter of certainty that the effect is very unchurchlike.

We regret also to find the appearance of sham windows—indentations or shallow recesses in the plaster of the walls, with imitation hood-mouldings in cement. In the exterior of the church there is also apparently an untruthfulness about the western side which is treated as if it were the *back* of the church, (a church ought to have no back or inferior side,) for on this side we find nothing but plain blank walls of masonry without ornament, and with a surface entirely unbroken, except by one or two very small windows in the upper part. This defect is certainly not necessitated by the site of the church, which is quite isolated. The western side is not quite so conspicuous as the other sides, still it is far from being actually concealed. There are indeed houses on the north side, but at such a distance as to leave plenty of room for viewing the building in that direction.

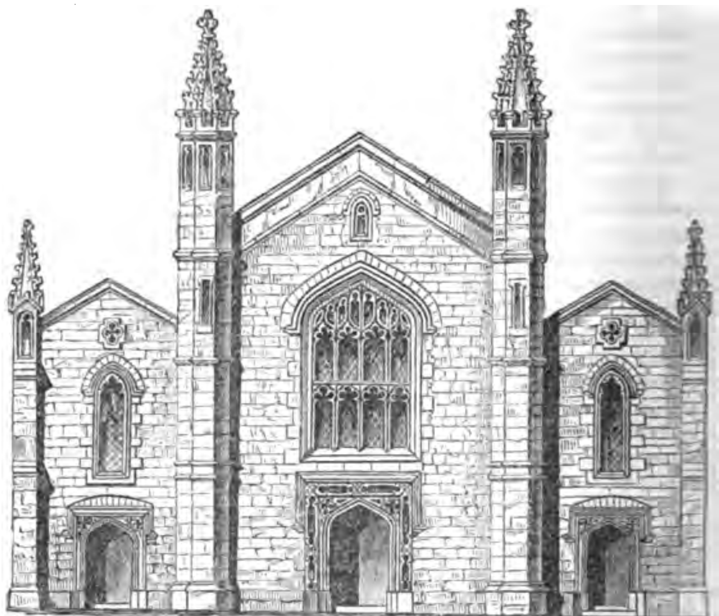
It is very tedious to have to repeat the same obvious truths over and over again. But till the lesson is perfectly learned and practically exemplified we must not cease to set forth the truthfulness and honest sincerity which the old builders scrupulously observed in their works. To express a species of excessive vulgarity by a vulgar phrase, there is in modern church-building a tendency to *show-off*, which is utterly repugnant to the principles of good taste. And not only is this ostentation and affectation of fictitious magnificence contrary to reason, but it is against precedent also. The old architects uniformly used real materials and were never guilty of leaving one side of a church poor and unembellished that they might lavish richer ornaments on the conspicuous parts. Until our own times the art of make-belief decoration has been monopolised by milliners and scene-painters.

We must not be understood to express these sentiments in an unfriendly spirit. The architect of St. Michael's Church cannot be censured for the existence of a widely-spread error which is doing the greatest possible injury to architecture, and which we boldly affirm *must* be corrected before the constructive arts can regain their original excellence. At the same time we must express regret that in the present case the architect should have fallen in with a bad custom, and we sincerely hope to see many excellent works of his, as bold and effective in design as St. Michael's church, but free from its faults in detail.

There is one good arrangement with respect to the comfort of the future congregation of the new church which must not be passed over. The church is warmed by hot-air pipes, which are contained in channels in the floors covered by grating. There is nothing like concealment here; the pipes honestly reveal their purpose—they are not *concealed*, but they are put where they do not obtrude on the sight, and are simply rendered inconspicuous. We have no doubt that the titled congregation who will frequent St. Michael's, will prefer this arrangement to the delightful inventions of the Cambridge Camden Society.

The first stone of the church was laid on the 20th of May 1844, by the present Marquis of Westminster, who subscribed 5000*l.* towards the building, and gave the fee simple of the site. The remainder of the cost must be raised by subscription before the church can be consecrated. There is at present a deficiency of 5,200*l.*, which includes the cost of an organ, bell and clock, and of inclosing the church-yard.

CHRIST CHURCH, PLYMOUTH.



The accompanying illustration represents the elevation of a Chapel-of-ease recently erected in the parish of St. Andrew, Plymouth, from the designs of Mr. Wightwick, to whose courtesy we are indebted for the sketch from which our view is copied. Mr. Wightwick has also favoured us with some brief but very pertinent observations on the strictures which appeared in the January and February numbers of this Journal, respecting the manner in which light was obtained in the new building. He says,

"I do not exactly see that a church united with other buildings is necessarily so beyond all successful treatment as you suppose. Is it *quite* fair to call the only front that shows "a show front?" Is there any thing "unchurchlike" in the "arrangement" by which I obtain light? viz., by a clerestory? 3rdly. The adjacent buildings harmonise with the church in style; the one being a residence of a simple Tudor character; and the other a School-building literally belonging to the church. Furthermore the building is but a Chapel-of-Ease."

With respect to the use of the word "unchurchlike," we would observe that it was meant to refer, not to the admission of light by clerestory windows, but to the non-admission of it by aisle windows. It must be obvious that when a church is lighted by clerestory windows alone, either the amount of light obtained must be insufficient, or else these windows must be so enlarged as to become very prominent features of the architecture, or at all events, to lose that subordinate relation which they bear in ancient churches.

The omission of aisle windows has also this disadvantage, that the whole of the north and south walls are broken and unbarred; and this again is contrary to precedent, for in ancient examples large surfaces of "dead" wall are uniformly avoided. Another disadvantage arising from the same cause is that the quantity of light obtained in the centre aisle must far exceed that in the north and south aisles. In Christ Church the lateral aisles contain galleries extending from the walls to the piers of the nave;* and it is certainly against usage that a lateral aisle of a church should as in this case be divided into two stories or compartments, each of which constitutes a spacious windowless recess.

Light obtained from upper windows alone produces an effect very different to that to which we are accustomed in Pointed Architecture. The lights and shadows are, so to speak, reversed. This may seem at first sight an unimportant remark, and one rather of an artistic than architectural nature, but if the reader will compare a building lighted by vertical

* We had formerly understood that these galleries did not intersect the piers.

lights in the roof (such as the National Gallery, the Elgin Room of the British Museum, &c.) with a chamber in which there is a series of side windows, he will see that the effects produced are totally different, and as the beauty of Christian Architecture depends most materially on the disposition of light and shadow, this consideration is by no means to be neglected. We never should expect to meet with an ordinary *skylight* in an ancient church; in that case, it is *immediately* obvious that the effect would be contrary to the spirit of Pointed Architecture. It needs, however, but little reflection to be satisfied that there is a similar objection to the exclusive employment of clerestory windows. By the arrangement of windows similar to that in the National Gallery the light is so generally diffused that it nowhere casts strong sharply defined shadows; this arrangement is therefore very advantageous in a Museum of Art, but the effect produced is essentially secular, and very different to that "religious light" which is so beautiful a characteristic of the Mediæval churches.

It is however by no means necessary that a church should be built in a perfectly isolated situation. Our noblest cathedrals have attached to them accessory buildings (Cloisters, Chapter-houses, &c.) of corresponding date and architecture. Much injury has indeed been done by the injudicious temerity of modern "restorers" in their zeal to isolate ancient churches. We may here perhaps refer to M. Didron's vehement denunciation of the Vandalism which has recently destroyed the Chapter-house at Troyes, and which contemplates a similar destruction at Rouen under the pretext of revealing the beauties of the Cathedral itself. But though it be perfectly allowable, and frequently desirable that a church should have dependent buildings attached to it, there seems no warrant whatever for so placing those buildings as to prevent the admission of light to the church by aisle windows.

Of course these remarks must be considered perfectly general in their tendency; it would be absurd to censure the architecture of the new chapel at Plymouth because the architect has not performed physical impossibilities. On the contrary, there is every reason to suppose that his expedient is the very best which the circumstances of the case admitted. At the same time it is one which can never be defended, except on the ground of absolute necessity, and we certainly should never feel disposed to approve of the omission of aisle windows, unless the question lay between building the church without them—or not building it at all.

AMALGAMATION AND LEASING OF RAILWAYS.

In continuation of the papers on this subject, that appeared in the Journal for October and December 1845, my only apology is the difficulty of getting this description of information after until the period at which it appeared in the public papers, and although these papers may not claim the merit of original thought, yet their computation at the period of the Railway Fever of 1845, the one previous and the other after the dreaded month of November, may in itself be some merit. In the last paper speaking in reference to the new infusion of lines of the session of 1845, and the position of the remnant of the new lines that has not formed any alliance with the old companies, an alliance was indicated as probable, and which has since taken place, as will be found in the after part of this paper.

The remnant of lines not yet allied to, the old companies is reduced to the Kendal and Windermere, Cockermouth and Workington, Newport and Pontypool, Weir Valley, Richmond (Surrey) and Leeds and Thirsk and these may be further reduced as the latter line, and the Great North of England have come to an understanding so as not to compete, and the Weir Valley may be said to have the same interest as the Stockton and Darlington. As regards Scotland, the following are the groups into which the railway interest have naturally divided this country entirely from the East Coast; we have the North British, Edinburgh and Hawick, Edinburgh and Dalkieth, and meeting with the West Coast Interest at Peebles, which may be considered as a fixed point. The Western write to be obtained from Carlisle, is by the Caledonian Line, 137 miles long, which is united with the Clydesdale Junction, Pollock and Govan, Glasgow and Garnkirk, and Caledonian and Dumbartonshire Junction, and West of the meridian of Glasgow, and North of Carlisle, is the group proposed to be called the Great South Western of Scotland, composed of the Glasgow and Greenock; Glasgow, Kilmarnock and Ardrossan, and Glasgow, Paisley, Kilmarnock and Ayr, and Glasgow, Banhead and Neilston Direct, and taking the parallel of Edinburgh and Glasgow, we have the Edinburgh and Glasgow, and Lanarkshire Lines, viz: Ballochney, Slamannan and Monkland and Kirkintillock, also the Glasgow Junction, Scottish Midland, and Scottish Central, and Coupar Angus, and Glammis; and East of Edinburgh, and North of the Firth, we have the Kingdom of Fife group, the Edinburgh Northern, and Edinburgh, Leith and Granton, and from Perth Northward, we have the Dundee and Perth, and Dundee and Newtyle, and its continuation by the Dundee and Arbroath, Arbroath, Forfar and Aberdeen.

The following are the groups of alliances in England. South of London, and to the East, we have the South Eastern to the West, the South Western, and intermediate the group of Lines compressed in the London and Brighton.

The district seems fairly assigned to each, and the three companies are on friendly terms, and disposed to become consolidated; indeed, two years ago, the South Eastern offered 100,000*l.* per annum, for the Brighton, which would have been just equal to the present dividend.

North of London, and to the East, is the group composed of the Eastern Counties, Northern and Eastern, with proposed Extension to York, and the Norfolk, East Anglian, and Eastern Union, and its Extension.

North of London, on the East Coast, is the Midland, from Bristol to Berwick.

North of London, on the West, the Great London and Liverpool extension, to Carlisle.

London to the West, the first group Line is the Great Western, which with the London and Birmingham occupies the whole of Wales, the one South, the other North.

The Second Cross Line is from Liverpool to Hull by the Manchester and Leeds.

The Third Cross Line is from Manchester, by the Sheffield and Manchester, Hull and Barnsley Junction, and Sheffield and Lincolnshire.

The Fourth is from Shields on the East to Maryport on the West Coast, by the North Coast and Carlisle.

The above general view may be confirmed in detail by a reference to the former papers, and the amalgamation there indicated, and since taken place, is the East Anglian.

The Board of Trade having ceased to report on new schemes, I record their period of influence. The total notices together were eleven, the first appeared 31st Dec. 1844, and then in January, 14, 17, 24. Four in Feb. 4, 7, 18, 28. Three in March; and nineteen reports were published, accompanied with twenty-one maps of districts into which they had divided the country, and the name of the different districts and date of reports are as follows.

First, Feb. 13. Kentish and South Eastern.

Second, Feb. 24, Manchester and Leeds, and Newcastle and Berwick.

Third, Feb. 28. District of Berks, Hants, Wilts, Dorset and Somerset, —District, London, Worcester and Wolverhampton—District, Birmingham and Shrewsbury.

Fourth, March 4. Norfolk and Suffolk, Cornwall and Devonshire.

Fifth, March 13. Trent Valley, North and North West of Ireland, approaches to the Metropolis and Scotland.

Sixth, March 20. London and York, West of Dublin, South of Ireland, South Wales.

Seventh, March 31. Colchester and Harwich, Portsmouth, North of Leeds and West Riding.

Eighth, April 16, 1845, Lancashire.

The influence of these reports will be felt in the present session. The Chairman of the Great Western at the Meeting, Feb. 12, 1846, says, "There could be no doubt that under the report of the Board of Trade, the traffic of Exeter and Yeovil was to be provided for by the Great Western." The Chairman of the South Western at the Meeting, January 21, says, the Great Western would not treat for a friendly alliance until the Board of Trade reported in January 1845; the Board of Trade made their report, and was appointed mutual arbitrator and sole referee betwen the two companies, which, however, the G. W. R. now decline, and the Board of Trade declined to interfere, and the Chairman further says, "An opposition was eventually made to that board, which could not be foreseen. Lord Howick commenced it in connexion with the atmospheric, and others followed by which the Board was overthrown." From the above there can be no doubt the quarrel between these two powerful Companies will be much perplexed, by the record of the Board of Trade Report. Nevertheless we have the experience of the last session, that the Committees of Parliament are jealous of this interference, and are prepared to act independently as they sanctioned the following lines contrary to the report of the Board.

Leeds Dewsbury and Manchester, Exeter and Crediton, Lynn and Dereham, Londonderry and Coleraine, Londonderry and Enniskillen, Irish Great Western, (Dublin to Mullingar,) Leeds and Thirsk, Shrewsbury, Oswestry and Chester, Ely and Huntingdon. The abandonment of a portion of the Great North of England and Eastern Counties Line, seems to have had great influence with the Board.

I have been curious to know what lines, for which Acts of Parliament had been obtained, havebeen abandoned, they are as follows: 1811; Berwick and Kelso; 1812, Penrhynn; 1814, Mambilad; 1816, Peak Forest; 1825, West Lothian; 1826, Dulais, Manchester, Oldham, Limerick and Waterford; 1831, Rutherglen and Wellshot, Lanarkshire, Sheffield and Manchester; 1832 Exeter and Crediton; 1836, London Grand Junction, Thames Haven, Launceston and Victoria; Deptford Pier. In looking over the above it will be seen at a glance that many of the projects are carried out by Companies incorporated since.

I will now proceed to give a general summary of the acts of each Session, and those which were refused the sanction of Parliament, although from want of data I cannot separate those refused into the two heads of New and independent Lines, and those promoted by Old Companies, or being amendments of former Acts. The first Act was passed in 1801, and; in 1802, two; 1803, one; 4, one; 8, one; 9, two; 10, one; 11, three; 12, two; 14, one; 15, one; 16, one; 17, one; 18, one; 19, one; 21, one; 23, one; 24, two; 25, five; 26, six; 27, six; 28, eleven; 29, nine; 30, eight; 31, nine; 32, eight; 33, eleven; 34, fourteen; 35, eighteen; 36, thirty-five; 37, forty-two; 38, sixteen; 39, twenty-six; 40, twenty-four; 41, nineteen; 42, twenty-two; 43, twenty-four; 44, forty-eight; 45, one hundred and twenty; and 1846, seven hundred and twenty-one applications. And commencing with the same period, there are distinct titles of new Companies, and old ones with a distinct application exclusive of amended Acts, 1801, one; 2, two; 3, one; 4, one; 8, one; 9, three; 10, one; 11, two; 12, one; 15, one; 17, one; 18, one; 19, one; 21, two; 24, two; 25, seven, 26, seven; 27, one; 28, five; 29, six; 30, five; 31, three; 32, four; 33, five; 34, five; 35, nine; 36, twenty-four; 37, thirteen; 38, two; 39, three; 41, one; 42, four; 44, sixteen; 1845, sixty-two; being upwards of 200 Railways with distinct titles, no Act is dated in 1805, 6, 7, or 1813, 14, or 1815, or 1820, 22, 23, or 1840, and 1843. Commencing with 1801, the number of Railway Bills, that was passed in each session, that I can find account of is the following: in 1826, two; 1826, one; 1830, five; 1832, four; 1833, five; 1834, four; 1836, twenty-four; 1837, forty; 1839, nine; 1840, seven; 1841, six; 1842, five; 1843, ten; 1844, twenty-three; 1845, one hundred and five.

I will now proceed to give an account of the alliances formed since the preceeding paper, viz:

Dundee and Newtyle, leased in perpetuity to the Dundee and Perth, at an annual rent of 1,400*l*, or 1¼ per cent.

Edinburgh, Leith and Granton, amalgamated at par with the Edinburgh and Northern, on a capital of 310,000*l*, the preference shares are guaranteed 4 per cent, by the united companies, and 1 per cent by the original stock, of the Edinburgh, Leith and Granton, Lancaster and Carlisle, with the Lancaster and Preston Junction.

Arbroath and Forfar, leased to the Aberdeen, from the 1st Feb. 1848, at a fixed rent of 5½ per cent, and half the surplus profit, after deducting 3½ per cent for working, the lessees have the option after 5 years of working as a basis, to fix the amount of surplus profit to be paid the Arbroath and Forfar Company.

Scottish Midland, agreed to be worked by the United Scottish Central; and Edinburgh and Glasgow Companies, at 37½ per cent on the gross receipts, guaranteeing a dividend of 4 per cent for 5 years, and to amalgamate at the end of that period, on the basis of the receipts of each line for the last two years preceeding. The Scottish Midland purchased the Coupar Angus Line for 15,000*l*., and the Glammis for 21,000*l*.

Huddersfield and Manchester repudiate the lease to the Sheffield and Manchester, and set forth the Leeds and Thirsk, and Leeds and Dewsbury, as their natural allies, and that hereafter better terms may be obtained either from the Manchester and Leeds or the Sheffield and Manchester.

Leeds and Bradford, with Manchester and Leeds, two of the former converted into one of the latter Company's. 675,000*l*., of new Manchester and Leeds fifths to be distributed among the Bradford proprietors. The Midland Branch to belong to Midland, York, and North Midland, and Manchester and Leeds Companies, and the Midland to run their trains to Bradford; equal calls and dividends and contributions to increase of capital and proportionate dividend in the interim.

East Anglian, name taken by the Lynn and Ely, Lynn and Dereham, Ely and Huntingdon, amalgamated Companies, which took place as from 1st January, 1846, the Extension of Lynn and Ely apportioned among the proprietors of each company, one new share for one old. The amount paid is only 3½ per cent until completed, whilst most Companies pay 4 per cent.

Chester and Birkenhead, leased for 7 years to the Chester and Holyhead on the capital Stock, 5 per cent for the first year, 6 for the second; 7 for the third; and 8 for the last four years.

Edinburgh and Glasgow, with Ballochney, Slamannan, Monkland and Kirkintillock Lines, the arrangemen tis taking the Edinburgh and Glasgow at 100, the proportion allowed is respectively 37½ for the first, and 21 for the two remaining lines.

Great North of England, Clarence and Hartlepool Junction, amalgamated at par with the Hartlepool Dock and Railway. Capital 80,000*l*., to pay 3 per cent from July 1846, to 1848, and 5 per cent to 1849.

Hartlepool Dock and Railway, sold to the Newcastle and Darlington Junction, for 220*l*. per 100*l*. share, to complete in 5 years, 10 per cent in the interim, the Share Capital 813,220*l*., and 52,250*l*. of the debt to be converted into ¼ shares, and included in the arrangement. The old shares and quarters to be entitled to the issue of one sixth, possession to be given on the 30th June, 1846.

London and Birmingham Railway, and Birmingham Navigation Company.

The Southampton and Dorchester, with the London and South Western.

The mere projects have not been less active in reconciling conflicting interests, and the following alliances or amalgamations have taken place.

North Staffordshire, with Derby and Crewe.

Reading and Reigate, with Reading, Guildford and Reigate.

Welch Midland, and Newport, Abergavenny and Hereford.

Waveney Valley, and Ipswich and Norwich.

South Eastern, and Dover, Deal, and Cinque Ports.

London and York, and Huntingdon, St. Ives, Wisbeach, and Sutton Union.

Chepstow, Forest of Dean, and Gloucester, with Welch Midland Extension.

Birmingham and Leicester, and Direct Birmingham and Leicester.

Leeds and Carlisle, and Yorkshire and Glasgow Union.

London and Birmingham, with Birmingham, Wolverhampton and Stour Valley; Shrewsbury, and Birmingham; Dudley, Madeley, Broseley and Iron Bridge United Company.

Worcester, Warwick and Rugby, with Rugby, Warwick and Worcester, and Warwick and Worcester.

Manchester and Rugby Direct, and Churnet and Blythe.

Lincoln, Wainfleet Haven, and Boston, and Great Grimsby, Lincoln and Louth.

Goole, Doncaster, Sheffield and Manchester Junction, and South Yorkshire Coal Company.

Sheffield and Lincolnshire, and Manchester and Lincoln Union, and Gainsbro' Canal.

Trent Valley, Midland, and *Grand Junction*, and South Staffordshire.

Worcester, Hereford, Ross and Gloucester, Great Western, with the Worcester and South Wales Junction.

Aberdeen, Banff and Elgin, and Great North of Scotland.

Scottish South Midland, and Stirling and Dunfermline.

Edinburgh and Leith Atmospheric, and Direct Edinburgh and Leith Atmospheric.

Tyne Valley, and East Lothian Canal.

Midland Great Western of Ireland, and Extension to Galway and Sligo, and the Liffey Branch, Longford Deviation.

Scottish Grand Junction, now only from Oban to Lochlomond.

Forth and Clyde, on friendly terms with Scottish Central, and Caledonian and Dumbartonshire.

The following Lines are Abandoned for the Session.

Chepstow, Forest of Dean, and Gloucester.
Liverpool, Preston, and North Union.
Wolverhampton and Birkenhead.
Birmingham, West Bromwich, and Walsall
Hull and Great North of England.
Fleetwood and Clitheroe.
Birmingham and Dudley
Wolverhampton, Chester and Birkenhead.
Birmingham and Worcester.
Huddersfield, East and West Coast,
Great Welch Central.
Trent Valley Continuation.
Whitby, Pickering, Thirsk, and Great North of England.
North and East Riding.
Renfrew and Ayr Counties.
Sanquhar and Muirkirk.
Scottish North Western.
Arbroath and Stonehaven.
Lancashire and Eastern Counties.
North Cheshire.
West End and Southern Counties.
Regent's Canal Railway.
Isle of Wight.
Direct London and Exeter.
Great North and South Wales, and Worcester.

CAUSE OF THE CATASTROPHE AT BARENTIN.

Our professional correspondents write to us expressing their inability to make out the truth regarding the recent catastrophe of the Barentin viaduct, and their desire to obtain such authentic intelligence regarding the facts of the case as may enable us to guard, if possible, against the recurrence of similar casualties, so disastrous to railway enterprise. Similar accidents have happened in this country, generally from injudiciously tipping the stuff out of wagons on the arches while yet very green, and unequally loading them so as to push in the haunch, and raising up the crown so as to destroy the equilibrium of the arch. In other cases, the foundation has given way; but this Barentin case appears still to be a mystery.

From the French papers we have endeavoured, but in vain, to gather consistent intelligence. The statement seems directly opposite, and so mixed with prejudice and manifest ill-feeling, that it is not possible to ground any tolerably consistent opinion on their statements. Even the French railway journal contradicts itself flatly, so as to display either the greatest ignorance or the greatest prejudice, on a subject on which everybody would naturally have expected it to be intelligent and just. We have it one day assuring us that the structure was built in conformity with the plans of the engineer, that the railway company must therefore incur all the loss, and so leading the shareholders in this country to believe that their plans were faulty, and that a design, of course ill-proportioned and injudiciously planned, was the *origo mali*. Then, next week, we find in the same journal a letter from the contractors themselves, giving the lie to the journal, and stating that the work was altered from the plans to suit their wishes, that they held themselves and not the company responsible for the loss, and that they were immediately to recommence their work. This is a little creditable to the English contractors—creditable to Mackenzie & Brassey, of whom we expected no less; it is in every way calculated to enhance their character, which is respected both abroad and at home, and it is also a step which must tend to give the public confidence in whatever they may in future undertake. It also justifies those directors of the company who have reposed in them implicit confidence for the execution of works of enormous extent, and gives confidence also to English shareholders. But what are we, what are the shareholders in England, to say to a French journal, which professes to watch over their interests in France, and yet spreads false alarms among them and the public, so periling the value of their property, by increasing the fears it ought to have assuaged by a judicious and well-timed statement of the truth, and, when obliged to publish an official contradiction from another source, does not even frankly apologize for its former delinquency, nor advert to the injustice of which it had been guilty? Surely, it is manifest the interests of shareholders are not safe in such keeping.

We have, therefore, endeavoured to obtain from our correspondent, from the spot, a true account of the accident; and we now give our readers, with the assistance of his sketches, a fair and tolerably precise account of the matter. But, first we give the contradiction referred to.

The following letter was addressed to the editor of the *Journal des Chemins de Fer*:—"Sir,—In reply to the article in your number of Saturday last, we have the honour to inform you that we take upon ourselves the whole responsibility of the accident, and will begin to rebuild the viaduct without delay. We are not in a condition to say with certainty how the accident originated, but are disposed to attribute it to the substitution (with Mr. Locke's approbation) of stone-work in the bases of the piers for the brick-work prepared in the original plan. This alteration was made at our request, with a view to accelerate the progress of the work, and fulfil the engagement we had contracted with the company.—We have the honour to be, &c. MACKENZIE & BRASSEY."

The arches are semicircular, and designed of ample dimensions and strength—some engineers, whom we know, would have been satisfied with considerably less strength. The whole work was brick, excepting the bases of the piers, which were of stone; and the fact is unquestionable, that on the day before the accident not the slightest flaw had been discovered in any part of the brick-work, but that vertical cracks near the corners had been observed in the stone-work. Now, be it observed, this stone-work was ashlar facing hearted with rubble. Let our engineering reader look at the plan, and then let him think over the probable effect of this—taking into account, as we formerly stated, a little haste and a great deal of wet weather.

We must here notice a sort of professional controversy which exists in France between the English engineers and the French. We English like brick-work—we understand it, and we make it good, so good that from one end to the other of the railway, not a single flaw could be detected by the inspector-general in any part of the brick-work of the line. The French engineers do not like brick-work. They are, perhaps, better acquainted with stone, and certainly like it better. Be this as it may, the consequence, as regards this work, has been as follows:—This bridge was originally designed by the engineer and contracted for as *all in brick*. The contractors partly to expedite the work and partly to please the French engineers, asked leave to make the bases of the piers up to a certain point in stone-work: they obtained the permission of the engineers to do so; and thus, in a desire to expedite the work and to please the French engineers, they have brought on themselves a loss, in which we must all sympathize with them, and which we can attribute to nothing but the best intentions. This casualty, while it entails pecuniary loss, will raise the character of the contractors for honesty and responsibility, both here and abroad.

Well, to return to the accident. This stone base was 19 feet greater diameter than the brick pier resting on it. The chief pressure of the weight of pier and bridge was thus brought to bear on the rubble hearting. The tendency of this to crush the hearting and burst the facing is manifest. The vertical cracks visible that morning in the stone casing were evident symptoms of it; and as the upper work was perfectly sound, and had been some time completed, and as the pile foundations are still perfectly sound as far as can be discerned, the cause is manifest.

The lessons it teaches are also obvious: we are all wise *after* the fact—we can all *now* see that it was weak to yield to an idle prejudice and not use brick throughout as intended—we can all see that it would have been better to wait until the bricks were got, than to build work to tumble down! But who would have ventured to say beforehand, to this point may you go, both in haste and in materials, and no further? No! Contractors and engineers must often make sacrifices of mere opinion to accomplish what they conceive their duty to the companies they serve; and if in doing so, they commit errors, they are but men gaining experience, and they have to pay for it. But in this country, at least, when they bravely set their face to do their work honestly and well—and when taken as a *whole*, the work is honestly and creditably done, as everything is that English engineers and English contractors have done in French railroads—they will meet with that sympathy and support from their countrymen which they have a right to expect, and they will be entitled to that respect and esteem abroad, which their achievements must command from all right-minded and judicious men.—*Railway Chronicle.*

TRACT ON VOLCANOES, SPRINGS OF HOT WATER, AND EARTHQUAKES.

During the period of my altering the hot-water baths, at Buxton, in Derbyshire, I was naturally led to reflect upon the causes of the various hot springs of water, and the regularity of the supply, and temperature at every season of the year. Thirty-five years have since elapsed, and the interval has afforded me many opportunities of judging whether the notions which I then entertained were correctly founded, and whether they deserved to be promulgated.

Reading lately in a Colonial Journal an article on Volcanoes, which contains the following remarks, I have been led to set set down the conceptions alluded to, and in reference to the writer's observations, viz:—

"When these fires were kindled, by what sort of fuel they are still maintained, at what depths below the surface of the earth they are placed, whether they have a mutual connexion, and how long they may continue to burn, are questions which do not admit an easy decision. The greater number of volcanoes rise in a cone, their mouth or crater, has generally the shape of a cap or an inverted tunnel; but in some instances the lava breaks out at the sides. When the fires find no issue they produce earthquakes. When Vesuvius throws off its inflammable contents by moderate and regular eruptions, the inhabitants of Naples have but little to dread on, the occurrence of an earthquake: after a long repose the volcano breaks out with additional force; the extent of its influence is astonishing; that of Tomboras in one of the Islands of the Indian Archipelago, was felt through a circular space of 2000 miles in diameter."

I submit with great diffidence whether it may not be possible to show that the origin of almost all the internal heat of the earth arises simply from the attraction of the particles composing it, in fact constituting an universal pressure, greater in the exact ratio that these particles collectively have to one another. Let me instance, what we all know, that independently of the qualities of the component soil, in every perforation into the body of the earth the temperature increases regularly with the depth of perforation, and that the water when reached has always a warmth proportionate to its depth under the incumbent soil, thus natural rivers have at their original springs (if constant) a warmth which in the coldest weather prevents their freezing, and it has been ascertained that the well at Paris, the deepest we believe ever executed, gave a high temperature much above the heat of any other artificial spring.

Let me endeavour to explain my views by observing, that admitting as a theory, that the attraction or condensation of the materials of the earth, and simply sea sands, I conceive that at some enormously great pressure I believe they would be vitrified, I placed under Bramah's Hydrostatic engine, a short square column of Portland stone, viz. 2ft. 7in. high, and 1ft. by 1·2 at bottom and top; this piece of stone burst asunder with the pressure 173¼ tons, the fragments being then quite hot, and the fracture was attended with a report as loud as that of a pistol. Now admitting that the pressure of each portion of the surface of the earth 1·2 by 1ft., superficies, produced a heat such as described under the pressure of a column equal to the weight of 1737 tons, an increased height may reasonably be supposed to generate heat in the same progression until at length such heat would be produced, that expansion would follow, and at length a volcano takes place in some place of the west of the globe, probably where as at sea there is the least incumbent weight, or in some district of country where the nature of their constituent materials opposed the least resistance to expansion.

With respect to the heat of water, the reflection on the most considerable geissers gives the same inference, for let us admit that water shall percolate the fissures of the earth to a great depth, and that its incumbent weight produces heat to such an extent that it boils over, and that after the heat escapes a temporary subsidence takes place, thus the exceptions of the geisser does not re-occur until heat has been again regenerated by the same pressure which before produced it.

Possibly it may be opposed, that the regularity of Buxton, Baths, and other overflowing hot springs does not lead to this conclusion; I am inclined to think that where there are natural cavities in mountains which are recipients of water, and when the incumbent pressure is not excessive, and where there are orifices which discharge the superabundant water, it is not irrational to suppose that the vents just referred to perform the office of geissers, and as there is no obstruction to them by the narrowness of their orifices, or vast height of columns or water, violent discharges do not take place.

A further observation on volcanoes, and earthquakes may perhaps deserve attention, namely, that in the districts where they have more particularly been attended to, the component soils are in themselves of a nature liable to the action of fire. Sulphur abounds near Etna.

It may be said, that admitting this doctrine of the generation of heat and the self-discharge thereof by its escape by volcanoes, and the invasion of hot water, and hot vapours, yet there must be some portions of the earth where these efforts of nature do not appear to take place. To this I reply that we are so ignorant of the lowermost structure of the earth, as to the inclination of their various beds, that it is possible Hecla the great vent of the North, may serve as the chimney of a great region, and that the other volcanoes mentioned in the remainder of the article first referred to, may discharge the superabundant heat of other portions of the Globe, for it is notorious that earthquakes are felt 20 or 30 degrees of longitude distant from the places where such eruptions have taken place.

It is therefore, I trust, no presumption to entertain those ideas that so long as gravitation exists, there will be a generation of heat, and consequently that this discharge of heat, is an important dispensation in maintaining this Globe, and that although sometimes dreadful visitations are witnessed, yet they are not without their benefits to the great bulk of mankind.

John White.

Paddle Box Boats Abandoned.—The *Retribution* steam-frigate, Captain Lushington, having returned her paddle-box boats to the Portsmouth dockyard on account of their great weight (12 tons,) will not have any more paddle-box boats fitted, and the paddle-box is accordingly already built up in the usual way, it being apparent that the vessel can carry conveniently as many boats as are necessary on board and upon her quarters, without encumbering herself with such heavy appurtenances. The removal of the paddle-box boats has given this fine vessel a much more sightly and light appearance, and no doubt will ease her in sea-going. She is being fitted with a connecting beam to strengthen her paddle-boxes.

REVIEWS.

An Essay on an Improved Method of Construction for Viaducts, Bridges, and Tunnels, being an Application of the Principle of Universal Gravitation, as illustrated in the Solar System. By Messrs. Blair and Phillips, Architects and Civil Engineers. London: Weale, 1845. 8vo. pp. 10.

We are constantly called upon to criticise opinions which evince incorrect conceptions of mechanics, but we seldom or never have criticised any dissertation in which the laws of nature are so gloriously confounded together as in the pamphlet before us. To most (we hope, all) of our readers its title will sufficiently explain its merits: the laws of motion and those of equilibrium are throughout taken as identical; the equilibrium of arches, &c. is referred to the "principle of gravitation as illustrated in the *Solar System!*" *Risum teneatis amici?*

We will not attempt anything like serious argument respecting the views propounded in the pamphlet. It is necessary to a satisfactory discussion that the disputants should have *some* similar views: we should imagine, however, that Messrs. Blair and Phillips have not one idea in common with us respecting the theory of the arch. Dissimilarity of opinion may reach a point beyond which argument is fruitless. It is possible to diverge so far from the highway of received opinions as to render a return to it absolutely hopeless. Our authors seem in this predicament. However, that the reader may judge for himself as to the possibility of their hereafter returning to the paths of orthodoxy, we give one or two short extracts.

"If an arch be turned over any opening, and a wall be built upon it, the arch supports very little besides itself. There is no weight for it to support, because the position which a regular wall takes is that of a continued series of corbels, which corbels meet in the centre, and form a direct line from the centre to each pier. This reminds us of a general law of gravitation by which *all bodies, when unimpeded, fall directly to the earth's centre, and, if impeded, take a direct line tending in some degree towards that centre.*

With this law of nature before our eyes, let us examine—1st, the semicircular arch. This form of arch is used very much, and is by many considered of great strength. Now we wish to show that of itself this arch is very weak. It is weak, because, when a weight is placed on any one part of it, there is great danger of it becoming deformed."

The remarks are illustrated by absurd diagrams in which arches are represented as distorted by a superincumbent pressure into all kinds of impossible shapes. The authors seem to think that when an arch fails it is by the slipping of the voussoirs on each other; whereas in practice it is universally found that the friction of the voussoirs is so great that they cannot slide, and that the arch can only fall by the opening of the joints. The point endeavoured to be elucidated by these diagrams is that *all* curved arches must be distorted by pressure upon them, and that a perfectly flat arch is alone free from this danger. The *reasoning* is as follows:—

"Why is this? The reason is evident. The line of the arch is curved, and as curved (and in proportion to its curve) liable to bend.

"*We come then to our great point, namely, that weight falls in direct lines, and not in curves, as is supposed;* and the nearer our supports approach to a straight line, the more strength we obtain. If this is true and it cannot be denied, the elliptical arch is of all arches the weakest."

It really is no more than charitable to inform the writers that the strength of an arch depends not only on its curvature but also on that which they have altogether neglected to consider—the depth of its voussoirs.

We are informed by our authors that they take no credit to themselves for the plan of building arches flat, but they pronounce the whole body of civil engineers blockheads for not having previously thought of it.

"It may, however, and, we doubt not, will be said, that what we advance is plain and easy, and that we need not claim to ourselves any credit for introducing it. We acknowledge that it is both plain and easy; indeed we stated this at the commencement of our description. But who is he that has applied this plain and easy method? If we cannot claim any credit, surely they that have overlooked what we have now taken up *may be set down as ignoramuses, and not deserving the name and title of civil engineers.* For why should the best method of construction be set aside, and an inferior one adopted? Why should thousands and tens of thousands of pounds be thrown away in that which is worse than useless—injurious? And why should we praise *men who, directly in face of the laws of the universe,* would erect a fabric whose stability they doubted, or which would not stand the test of time and the researches of science?"

After this the least that the Institution of Civil Engineers and the Institute of British Architects can do, is to ordain a fast and go into mourning.

A Complete Treatise on the Oblique Arch. By Peter Nicholson. Third Edition. London: Groombridge, 1846. 8vo. pp. 110; 43 lithographic plates.

This is a new edition of a work reviewed in a former volume of this Journal. The object of the treatise is confined to the explanation of the geometrical forms and position of the Voussoirs of Oblique Arches, and does not comprise the mechanical theory of these structures—the subject is in fact a particular branch of Descriptive Geometry. The three preliminary chapters treat of those principles of plane and solid geometry which are necessary to the explanation of the construction of oblique arches; the theory of which is divided into two portions—the theory of oblique arches, with spiral joints and that of oblique arches with plane joints, the distinction between the two kinds of arches is thus defined.

"*An oblique arch* with spiral joints, is that in which the surfaces of the beds and the surfaces of the joints are both spiral surfaces.

If an oblique arch with spiral joints be executed according to the principles here established, and cut by a plane perpendicular to the axis of the cylinder, the section will exhibit a series of straight lines, dividing the arc of a circle into smaller arcs, and the lines being prolonged, would meet in the centre.

An oblique arch with plane joints is that in which the beds of the stones are planes, passing through the axis of the cylinder. The planes of the joints being parallel to the axis, intersect each face of the arch in very oblique angles, and only one of the joints can be perpendicular to the face. All the other joints, as they recede from the centre, are more and more oblique till they reach the summit of the arch. As every oblique joint causes the angles made by the face and that joint to be very unequal, the obtuse angle will be much stronger than that which is acute, these angles being supplements of each other. Therefore oblique arches with plane joints should never be used where great strength is necessary; and where the angle of obliquity is very acute, the oblique arch with spiral joints should only be employed, as the spiral joints are as nearly perpendicular to the face as the construction will admit."

Of course in a work like this one of the first requisites is simplicity and precision of language. The difficulty of conveying by words (and even by diagrams) clear ideas of solid geometry can only be overcome by the most scrupulous adherence to the plain and uncomplicated modes of expression. Our author seems to have generally paid great attention to this point. Among the new portions of the present edition is a description of an oblique bridge over the river Gaunless, to which the following general observations are appended.

"To construct an oblique arch entirely of stone is, in some countries where it is difficult to procure, very expensive. However, in order to build one which will be sufficiently strong at a moderate price, it is necessary that the imposts or springings should be of stone, and, to have the appearance of good work, the quoins which form the ring-stones and the head of the arch should also be of stone. Then the intermediate parts of the courses may be of brick, (allowing perhaps four courses of bricks to each stone springer,) depending on thickness at the abutment. To work the springers and the quoin-heads, the same templets will be required as if the arch had been constructed entirely of stone. Previous to setting the brick courses, the boarding or laggings should be truly adjusted and fixed; and, for the regulation of the work, the bed-lines should be drawn thereon in their true position. In order to try the work as the bricklayer proceeds, he ought to use a kind of set-square, made of thin board, containing an angle exactly the reverse of the templet; and, consequently, the curved edge will be concave instead of being convex, as in the arch-square. The sides of each course being made to agree with every application of the set-square, will be what it ought to be. In stone courses, if the stones are truly wrought, the spiral surfaces of the beds will all agree with a set-square; and, therefore, in this case it will be unnecessary to provide one."

There are several useful trigonometrical tables appended to the work, in order that the mason may find in it all the information which he requires, without the trouble of referring to other books. The plates are well executed. At the end of the volume we regret to see several "testimonials regarding the success which the author has had in the application of his principles to the execution of oblique arches." These testimonials appear to be satisfactory in themselves, but they are out of place. Geometric principles are not patent medicines.

Concise Tables to Facilitate the Calculation of Earthworks required in the Construction of Railways, &c. By John Hughes, Engineer. London: Effingham Wilson. 1846., 12mo., pp. 26.

This is a very useful little book, and the portable form which it assumes is not its least recommendation. The object is to determine the volume of the solid formed by earthworks in cuttings and embankments.

There is this difficulty in determining this solid, that only one side of it is rectangular or of the same width throughout—namely, the plane surface of the roadway itself,, which, in embankments, is the highest, and in cuttings the lowest side of the prismoid; the other sides of this solid vary in all their dimensions, and though two sides opposite to each other may be of unequal areas. For instance, in a cutting which commences at the foot of a hill and terminates at a tunnel, the depth of the cutting gradually increases, so that the perpendicular face at the mouth of the tunnel is of greater area than the parallel vertical plane, supposed to be drawn at the base of the hill. The two oblique sides of the cutting also necessarily widen as they approach the tunnel. Opposite portions of them may also be unequal to each other, the depth of cutting to the right and left of the railway depending on the original form of the hill. Mr. Hughes takes a very simple method of ascertaining the solid content of the prismoid. He imagines it divided into numerous small portions by vertical planes parallel to the faces at the commencement or end of the cutting: so that, in fact, the solid is considered as made up of numerous thin *slices* of equal *thickness*, but varying in their vertical areas, which are trapeziums. It is clear, that by ascertaining the area of each of these trapeziums, taken at a certain determinate interval, the solid content of each *slice* may be determined by knowing its thickness; and, adding all the solid contents so found, we have the total volume of the cutting. The same method, of course, applies to embankments. It is important, however, to remark respecting the method here adopted, that the more numerous the cross sections are, the more closely will the result approximate to absolute accuracy.

It is clear also, that Mr. Hughes's method contemplates the case in which the upper side of the solid is *curved*. The tables hitherto published have referred only to the particular case in which the solid is bounded by *planes* only. The following extract may be introduced to show how far the present work differs from those of an analogous nature which have preceded it:—

In extensive works, such as railways and canals, the value of the earthwork is about one-fourth of the entire cost of construction; and, therefore we find that engineers have given their attention to correct the approximations with which, in past times, the parties were satisfied, as well who executed road and canal works, as their superintendents. The appearance of the elaborate tables of Macneill, and of those in a more condensed form attributed to Bidder, went far to eradicate the practice, almost universally prevalent, of taking average heights from a longitudinal section, or of averaging the areas of the cross sections; a practice recommended by its facility of application, and having nothing in its form, until reflection was bestowed upon it, to excite suspicion of erroneous results in the minds of those who were deeply interested in its truth. The damage to the interest of contractors, in point of quantity, was, however, in all probability no more than equivalent to the additional price paid to them for executing the work; but all arrangements which depended on balancing embankments and cuttings were frequently found to be unavailable, and the disappointments from this source were set down to a change of bulk in the material removed, which was assumed without sufficient examination, and which, until more competent persons took such arrangements into their own hands, covered the ignorance of the surveyors from the eyes of their employers.

Bidder's table requires that the longitudinal dimensions should be taken with a Gunter's chain, a standard never introduced in the drawings or specifications of the architect; and, as well as Macneill's tables, does not extend to heights greater than 50 feet, whilst cuttings occur on railways more than 100 feet in depth. At the entrance of tunnels they are rarely less than 70 or 80 feet, and embankments of 80 feet in height are not uncommon. I naturally, therefore, directed my attention to the means of obviating this inconvenience by employing the *general formula* for the content of a prismoid, of which Macneill gave a demonstration as applied to a restricted case, and upon which restricted case both his tables and Bidder's were calculated. The particular case taken by Macneill, is that of a solid bounded by a horizontal rectangular plane at the bottom; by two parallel, trapezoidal, vertical planes, of unequal heights, at the ends; by two trapezoidal planes, equally inclined, on opposite sides of the vertical, at the sides; and by a sixth plane at the top, passing through the parallel bases of the end trapezoid.

The Suspension Bridge at the Falls of Niagara.—It is proposed to construct a suspension bridge above the Falls of Niagara, so as to join the Canadian Railway and the United States. The execution of it is to be confided to Mr. Charles Ellett, of Philadelphia, or to Mr. John A. Roebling, of Pittsburg. Mr. Ellet lately visited the spot, for the purpose of examining the locality, and to ascertain the practicability of erecting so great a desideratum. There is a bridge which exists about a mile and a half below the cataract, and near the gulph, or whirlpool, where the distance of the two chief abutments, from one side to the other, does not exceed 640 ft. The expenses for constructing this bridge are estimated by Mr. Ellett at 43,200*l.*, for which sum he offers to build it, and he subscribes himself to the amount of 4,320*l.*

THE BROAD AND NARROW GAUGES.

Report of the Royal Commissioners.

May it please your Majesty,—We, the Commissioners, appointed by writ, under your Majesty's Privy Seal, bearing date the 11th of July, in the ninth year of your Majesty's reign, to inquire whether, in future private acts of Parliament for the construction of railways, provision ought to be made for securing an uniform gauge, and whether it would be expedient and practicable to take measures to bring the railways already constructed or in progress of construction, in Great Britain, into uniformity of gauge, and to inquire whether any other mode could be adopted of obviating or mitigating the evil apprehended as likely to arise from the break that will occur in railway communications from the want of an uniform gauge, beg dutifully to submit, that we have called before us such persons as we have judged to be, by reason of their situation, knowledge, or experience, the most competent to afford us correct information on the subject of this inquiry, and we have required the production of such books and documents from the various railway companies as appear to us to be the best calculated to aid our researches.

We have personally examined into the usual course of proceeding on various railways both at home and abroad, especially those which are incident to a break or interruption of gauge, and we have personally inspected several locomotive engines as well as mechanical contrivances invented, either for the general use of railways, or for obviating the special difficulties presumed to arise from the break of gauge, or otherwise connected with the subject of our inquiry, and as we believe we have now carried our investigation to the utmost useful limits, we feel in a position dutifully to offer to your Majesty the following report.

BREAK OF GAUGE.

1. Our attention was first directed to ascertain whether the break of gauge could be justly considered as an inconvenience of so much importance as to demand the interference of the Legislature.

Gloucester is the only place where a break of gauge actually exists at the present time. It is caused by the meeting at that place of the broad or 7 feet gauge with the narrow or 4 feet 8½ inch gauge. There are other points, however, where a transfer of goods occurs similar to that which must result from a break of gauge, and persons well acquainted with railway traffic have no difficulty in seeing the nature of the inconvenience that would arise from any further intermixture of gauge: and we humbly submit the observations that occur to us as to the whole of this important part of the question.

We will divide the subject of the break of gauge under the following heads:—

1st, as applying to fast or express trains; 2dly, to ordinary or mixed trains; 3dly, to goods trains, and 4thly, to the conveyance of your Majesty's forces.

1st. Fast or express trains.

We believe that the inconvenience produced by a break of gauge will, in some respects, be less felt in these than in other trains, because the passengers travelling by fast trains are usually of a class who readily submit to many inconveniences for the sake of increased speed on the journey, and who are perhaps generally less incumbered with luggage than persons travelling by the slower trains; and as it is understood to be the general practice that no private carriages or horses are conveyed by these trains, the inconveniences of a break of gauge are reduced in this instance to the removal of the passengers and a moderate quantity of luggage; and, although such removal must create delay and some confusion, as well as personal discomfort, especially at night and in the winter season, besides the risk of a loss of luggage, yet we do not consider the break of gauge, in this instance, as being an inconvenience of so grave a nature as to call for any legislative measures, either for its removal or for its mitigation.

2dly. Ordinary or mixed trains.

In these trains the passengers considerably exceed in number those who travel by the fast trains, and they have generally a much greater quantity of luggage. To such travellers a change of carriage is really a serious inconvenience, and it is a well known fact that persons travelling by railways in communication with each other, but under different managements endeavour to make such arrangements as to admit of their travelling by those trains which afford them the accommodation of occupying the same carriage from the beginning to the end of their journey.

The managers and directors of railways are well aware of this feeling, and in some instances where they do not allow their carriages to run through, yet with a view of diminishing the inconvenience to which this exposes their passengers, they send a luggage train from terminus to terminus, to prevent the evil of a removal of the passengers' luggage; and some railway companies incur considerable expense in running trains of return empty carriages, in order to accommodate the public by enabling travellers to avoid a change of carriage on the journey.

It is by the ordinary or mixed trains that private carriages and horses are conveyed, and the removal of either from one truck or horse-box to another, at any part of the journey, would be attended with inconvenience and delay; and with regard to the horses, it would involve considerable risk.

We arrive, therefore, at the conclusion that the break of gauge would inflict considerable inconvenience on travellers by the trains now under consideration, and that this inconvenience would be much increased at points of convergence of more than two lines.

The change of carriages, horse-boxes and trucks, and the transference of luggage of an entire train of much extent, must even in the day time, be an inconvenience of a very serious nature, but at night it would be an intolerable evil, and we think legislative interference is called for to remove or mitigate such an evil.

3dly. Goods trains.

From the statements made to us by carriers on railways, and from our own observation, we are induced to believe, that not only a considerable degree of care, judgment, and experience is necessary in the stowage of merchandise in railway wagons, but also, that it is desirable that when properly packed the articles should, generally speaking, not be disturbed until the journey is completed. We find that in the arrangement of merchandise, the heavier goods are placed at the bottom, and the lighter at the top of the load, and so secured as to prevent friction as far as practicable from the jolting of the wagons; and it is considered very desirable, with a view to prevent loss by pilfering, that the sheeting, which is placed over the load, should not be removed till the completion of the journey. Indeed, acting upon this principle carriers find it profitable to send their wagons partially filled from various stations on the line, thereby increasing their toll to the railway company, rather than incur the risk of loss by theft, to which they would be exposed by uncovering the wagons on the journey to fill up with intermediate local goods wagons that may have started with light loads from one of the termini.

The stations for re-arranging the goods trains are therefore as few as possible; thus, between Leeds and London, the points for unsheeting the goods wagons are only Derby and Leicester, and between Liverpool and London, the re-arrangement is confined to Birmingham and Rugby; and even at those stations the proportion of wagons which are uncovered is very small: indeed, it is stated that at the important town of Birmingham five-sixths of the wagons pass without re-arrangement.

In the conveyance of machinery and articles of a similar class, which are both heavy and delicate, it is of the utmost consequence that the load should not be disturbed between the beginning and the end of the journey; a change of carriage, such as would result in all probability from a break of the gauge, would altogether prevent the transport of such articles by this mode of coveyance.

We believe that the traffic upon the line of railway between Birmingham and Bristol has been greatly restricted by the interruption of gauge at Gloucester.

In respect to the conveyance of minerals, the inconvenience of a break of gauge would be very serious; the transfer being attended with an expense which would be sensibly felt in consequence of the low rate tolls charged on such articles; moreover, many descriptions of coal, such as a considerable proportion of that of the Midland Counties, are subject to great deterioration by breakage.

In regard to various articles of agricultural produce, the loss by removal would be less than on other classes of goods; much inconvenience, however, would be found in the transfer of timber; and the difficulty of shifting cattle would be so great as to present an insurmountable obstacle to such an arrangement, from the excited state of the animals after travelling by railway, and the resistance they in consequence offer when it is attempted to force them a second time into a railway wagon.

4thly. Conveyance of Troops.

There is another use of railways which we have deemed it necessary to consider; we allude to the transport of your Majesty's troops, with their military stores, &c., either in the ordinary movement of corps through the country in the time of peace, or in the more pressing and urgent case of their movements for the defence of coast or of the interior of the country.

We have carefully weighed the important information given to us by the Quartermaster-General of your Majesty's Forces, as well as by the Inspector-General of Fortifications, both officers of great experience; and we deduce from their opinions, that although a break of gauge on the line of route would produce both delay and confusion, yet that, as in time of peace it is usually practicable to give notice of the intended movements of a body of troops, the inconvenience of the break of gauge might be so reduced as not to be an evil of great importance; but, in the event of operations for defensive objects against an enemy, the inconvenience would assume a serious character.

It would appear, that for the defences of the coast, the proper course would be to retain the great mass of troops in the interior of the country to wait until the point selected by the enemy for his attack should be ascertained with certainty, and then to move upon that point such an overwhelming force as should be adequate to the emergency.

It is obvious that the success of such a system of defence must depend upon the means of conveying the troops with great dispatch, and without interruption on the journey.

The troops should be carried with their equipments complete in all their details, and with their artillery and ammunition; and it therefore appears indispensably necessary, in order to insure the requisite supply of carriages where perhaps little or no notice can be previously given, that the whole, should be conveyed in the same vehicles from the beginning to the end of the journey.

The effect of a break of gauge might in this view of the case expose the country to serious danger.

To all classes of merchandise, as well as to all military operations connected with railways, one general remark will apply, that in starting from any one point it is usually practicable to obtain a sufficient number of wagons for whatever may be required to leave that point, however irregular the traffic may be; but, at the convergence of several lines, where the greater number might be of a gauge not corresponding to the gauge of the other lines, if it happened that all were unusually loaded at the same time, it would probably be impossible to provide on the latter an adequate number of wagons to carry off all the loads thus brought; the alternative would be, on the one hand, to submit to great confusion, delay, and inconvenience, on all the converging lines having the majority on the same gauge; or, on the other hand, to maintain on the lines being in the minority a very extensive stock of carriages, which in general would be totally useless.

There is one point which forcibly presses on our attention, and the truth of which must be readily acknowledged, but of which the importance is not at first equally obvious; it is, that the greater part of the inconveniencies to which we have alluded are not inconveniencies of rare occurrence, and which would affect only a small number of persons, but, on the contrary, that many of them would occur several times in the course of every day to a great number of persons at each point at which a break of gauge might exist. The cumulative amount of such inconvenience would of necessity be very considerable, and we feel bound to sum up our conclusions by stating that we consider a break of gauge to be a very serious evil.

II. Mechanical means of transference from one Gauge to the other.

We are now brought to the second stage of our inquiry, which is, to discover the means of obviating or mitigating the evils that we find to result from the break of gauge.

The methods which have been laid before us, as calculated for this purpose, are as follows:—

1. What may be termed telescopic axles; an arrangement of the wheels and axles of carriages, permitting the wheel to slide on the axle, so as to contract or extend the interval between them in such a manner that they may be adapted to either of the gauges.

2. A form of truck adapted to the broad gauge, but carrying upon its upper surface pieces of rail 4 feet 8½ inches asunder, so that a narrow gauge carriage may be run upon these rails without any disturbance of its wheels.

3. A method of shifting the bodies of carriages from a platform and set of wheels adapted for one gauge, to a different platform and set of wheels adapted to the other gauge.

4. A proposal to carry merchandise and minerals in loose boxes which may be shifted from one truck to another and of which only one would probably be carried upon a narrow gauge truck, while two would be conveyed on a broad gauge truck.

1. Telescopic Axles.

Of these various methods, the first—if it admitted of being used safely and extensively—would be, in its application, the easiest of all.—By the operations of detaching the wheels from one limiting hold, of pushing the carriage along converging or diverging rails, until the wheels were brought to the required width, and of then connecting them by another limiting hold, the transformation of the narrow gauge carried to the broad gauge carriage, or *vice versa*, would be completed. But this construction is liable to grave objections. It is stated to us as a matter of experience (and we believe it admits of satisfactory explanation), that very small unsteadiness of the wheels of a railway carriage upon the axle renders the carriage liable to run off the rails. A far more serious objection, however, is, that the safety of a carriage and the whole train with which it is connected would depend upon the care of the attendant, who has to make the adjustment of the axle-slide.

It is true that there are other cases, as in the attendant on the switches and signals, which depend upon the care of the person who is stationed to work them: but the circumstances differ very widely. In these cases the attendant has a single act to perform (or at the utmost, two acts only,) he is not hurried, and his whole attention is concentrated on very simple duties.

In respect to the shifting axles, the attendants would have to adjust a great many carriages in succession (as there are sometimes a hundred wagons in a goods train), the adjustment must be made hurriedly, and often in the night; and the attendant's thoughts would probably have been partly occupied with the loading of goods and other station arrangements.

On the score of danger, therefore, we think that the construction must be at once abandoned. But we think it proper to add, that even if there were no such essential ground of objection, a construction of this nature could not be adequately useful unless it were extended to every carriage which is likely to pass the station where the break of gauge occurs. Under the existing system of interchange of carriages, which is adopted by all the railway companies whose lines communicate, and of which the advantages are recognised in special clauses of the acts of Parliament applying to several railways, carriages belonging to distant railways will frequently be found a the place of junction of the two gauges. This construction therefore, would lose much of its utility unless every railway carriage were made in conformity to it, that is, unless a vast expenditure of capital, and a corresponding annual expense in replacing worn-out carriages, &c., were incurred even on railways very distant from the break of gauge.

2. Shifting Narrow Gauge Carriages on to Broad Gauge Trucks.

2. The plan of placing a narrow gauge carriage upon the top of a broad gauge truck has, on the face of it, this obvious difficulty, that a broad gauge carriage cannot be placed in the same manner upon a narrow gauge truck, and therefore, unless not only the broad gauge railway, but also as others communicating with it, be furnished with trucks proper for carrying narrow gauge wagons, and with narrow gauge wagons also, and unless the loads travelling towards the narrow gauge be placed only in these narrow gauge wagons, the system effects nothing as regards the passage in one direction. But even with regard to the passage from the narrow gauge to the broad gauge, the system will not bear examination. If the trucks are supported on springs, there is practically a difficulty in running the wagons upon them; and if they are not supported on springs, they will sustain great injury on the journeys. If they are loaded singly there will be a great delay; if they are placed in a row, and the narrow gauge carriages are run through the whole series, very great caution will be necessary to secure each carriage both in front and in rear. When heavy loads are thus placed in elevated positions, and when the security of each depends upon adjustments hurriedly made, there will be the danger to which we have alluded in noticing the first proposed construction. Finally, an enormous amount of dead weight will be carried on the broad gauge line. We reject this proposal as entirely inapplicable to the traffic of railways.

3. Shifting the bodies of carriages from one set of wheels to another.

3. The system of shifting the bodies of carriages from road wheels to railway wheels is practised successfully in France, where the diligences from Paris to distant towns, proceeding on road wheels from the Messagerie of Paris to the railway station, are carried on a peculiar railway truck as far as Rouen and Orleans, and are then again placed on road wheels to continue their journey. At the low speeds of the French railways this system is safe, but we doubt whether it would be safe with the speeds of the English railways. Moreover it deprives the railway system of one of its greatest conveniencies; namely, its readiness to receive almost any number of passengers without warning, and to carry them to any distance, small or great. Carriers' carts are also conveyed (but to no great amount) in the same manner. In France, as we understand, it is not thought likely that the system will be in any degree retained when those railways shall have been extended further. The same remarks, we conceive, would apply entirely, or in a great measure, to similar proposals for the shifting of the bodies of railway carriages; but as this plan has never been strenuously urged, it is unnecessary to criticise it more minutely.

4. Conveying Goods in Loose Boxes.

The system of conveying goods in loose boxes, carried upon railway trucks, has been seriously discussed. It has been repeatedly tried, and we are able therefore to give an opinion on it, founded on experience.

The result of this experience is, that in one instance of a temporary character, where the whole operation was under the control of one engineer, it succeeded, in other instances, although always under the control of one engineer or one company, it has usually failed; and these failures have occurred where from the deterioration, caused by hand-shifting, to the mineral conveyed, it was matter of anxiety to avoid transference of the load from one box or wagon to another, and where no expense was spared in the erection of machinery proper for the transference of the loose boxes.

These failures, it is to be remarked, occurred in a traffic which is comparatively regular, viz., that of coal; in traffic of a less regular character the causes tending to produce failure would be very much more numerous.

We consider that this method is totally inapplicable to remedy the inconveniencie of a break of gauge.

Some of the witnesses whom we have examined are of opinion that there would be less difficulty in unloading the wagons of one gauge, and placing the articles in wagons of the other gauge, by having two rows of wagons on the different gauges, marshalled alongside of each other; but having witnessed this process at Gloucester, we are of opinion that such a system is totally inapplicable to an extended traffic.

We sum up our conclusion on this head, by stating our belief that no method has been proposed to us, which is calculated to remedy in any important degree the inconveniences attending a break of gauge.

III. Policy of Uniformity of Gauge.

Considerations on the general policy of establishing an uniformity of gauge throughout the country.

We approach this momentous question with a full conviction of its importance, and the responsibility that rests upon us.

That an uniformity of gauge is now an object much to be desired, there can, we think, be no question. In the earlier period of the railway history of this country the great trunk lines were so far separated as to be independent of each other, as it were, isolated in their respective districts, and no diversity of gauge was then likely to interfere with the personal convenience or the commercial objects of the community; but now that railways are spreading in all directions, and becoming interlaced with each other in numerous places, that isolation is removed, that independence has ceased, and the time has arrived when, if steps cannot be taken to remove the existing evil of the diversity of gauge, at least it appears to us imperative that a wider spread of this evil should be prevented.

If we had to deal with a question not affecting the interests of parties, who are not only unconnected, but who are opposed to each other in a spirit of emulation, if not of rivalry; or if we were dealing with the property of the public, and not of private trading companies, we should merely have to consider whether that uniformity of gauge which we deem to be so desirable would be to dearly purchased by an alteration of one gauge to suit the other, or of both to some fresh gauge which might be considered preferable to either, if any such there be.

But our position is different from this, since we have to consider not only the relative length of the different systems, the comparative mechanical efficiency of each, the general superiority of one above the other, their adaptation to the wants of the country, and the possibility as well as the policy of a change, but also the pecuniary means of effecting it. We have further to ook to the consequences of an interruption of the traffic during the progress of an alteration.

Double Gauge Railways.—There is still another view of the question, and that is, the expediency of having, on lines of railway, additional rails, so as to afford the facility of using engines and carriages on both gauges.

This expedient, in whatever form adopted, cannot be considered as free from difficulties. If two rails, forming a narrow gauge way, are placed between the two rails which form a broad gauge way, carriages of the different gauges may run in the same train, without alteration even of their buffers, which in the ordinary construction of the carriages correspond exactly on the broad and narrow gauges. But the expense of such an insertion would probably be not less than that of an entire change of gauge, including in the latter, the change of engines and carrying stock; and the complication which it would introduce at the crossings might produce danger to rapid trains, unless their speed were diminished at approaching such points. The difficulty of packing the rails, if longitudinal sleepers were used, would also be much greater than if rails of only a single gauge were employed. If a single rail were inserted eccentrically in a broad gauge way, so as to form, in conjunction with one of the broad gauge rails, a narrow gauge way, the expense of the insertion, and the danger of the crossings, as well as the difficulty of packing the rails, would be somewhat diminished, but it would be imprudent to run carriages of the different gauges in the same train, and as it would probably be the policy of the railway company to adopt for their own stock of engines only one of the two gauges, and to interpose these difficulties which amount to a prohibition of the use of other companies' engines, the inconveniences of a break of gauge would exist in almost all their force at every junction of a branch railway on a different gauge.

We consider, therefore, that the general adoption of such a system ought not to be permitted.

We remark however, that the difficulties to which we have alluded may be greatly diminished on any railway where the system of combined gauges is cordially taken up by the company; and we think that great respect ought to be paid to the rights which the companies may be supposed to possess in the methods or systems which they have devised or adopted. At the same time, we lay it down as the first principle, that inter-communication of railways throughout the country ought, if possible, to be secured. If, to obtain the last-mentioned object, it should be necessary to alter or make a change in any existing railways, we think that it may be left as a matter of ulterior consideration for the Legislature, whether in these limited instances the combination of gauges may not be allowed.

Whatever may be the course which at the present time circumstances will permit, it will appear from the opinion we have expressed, that we think, abstractedly equalization desirable; and we shall therefore proceed to consider what gauge would be the best in such a system of equalization.

We shall examine this part of the question under the following heads:—
1. Safety.—2. Accomodation and convenience for passengers and goods.—
3. Speed.—4. Economy.

1. Comparative Safety.

We are of opinion that experience will, in this matter afford a better test by which to compare the systems of the broad and narrow gauge than any theory; and we therefore have made inquiry into the nature of the accidents recorded in the official reports of the Board of Trade, as well as of such as have happened since the last report was published.

We find that railway accidents arise from collisions, obstructions on the road, points wrongly placed, slips in cuttings, subsidence of embankments, a defective state of the permanent way, loss of gauge, broken or loose chairs, fractures of wheels or axles, &c.; and, lastly, from engines running off the line from some other cause.

Of these several classes of accidents, all except the last are obviously independent of the gauge; and with reference to this last class, we have thought it right to endeavour to determine whether the advocates of either gauge could fairly claim, in regard to these accidents, a preference for their respective systems, on the score of greater security to the traveller. In these lists we find only six accidents of the kind we are considering recorded from October, 1840, to May, 1845, whereas there have been no less than seven within the last seven months, and these are attributable to excessive speed, the majority having happened to express trains. Of the whole number of these accidents, three have occured on the broad gauge and 10 on the narrow; the former, however, differ in their character from the latter, the carriages only, in the last two cases, having been off the line, whereas, in all the 13 narrow gauge cases, the engines have run off, and the consequences have been more fatal. We must here observe, however, that the extent of the narrow gauge lines is 1,901 miles, and that of the broad only 274; therefore the comparison would be unfavourable to the broad gauge if considered merely with regard to their relative length; but it must be borne in mind that the general speed of the Great Western considerably exceeds that of many of the narrow gauge lines, and that some consideration is on that account due to the broad gauge.

The primary causes of engines getting off the rails appear to be over driving, a defective road, a bad joint, or a badly balanced engine. If, in consequence of heavy rains or other unfavourable circumstances, any part of the road becomes unsound, the engine sinks on one side as it passes along such part of the rail, suddenly rises again, and is thus thrown into a rocking and lateral oscillatory motion, with more or less of violence according to the rate of speed, and a very similar effect is produced in passing at high speeds from one curve to another of different curvature. A succession of strains is thus thrown upon the rails, and if, before the rocking subsides, the wheel meets with a defective rail or chair, which yields to the impulse, the engine and train are thrown off as a necessary consequence; but, as far as we can see, such casualities are equally likely to happen on either gauge, other circumstances being similar.

It has indeed been stated by some of the witnesses whom we have examined, that the broad gauge is more liable to such accidents, from the circumstance that the length of the engine, or rather the distance between the fore and hind axle, is less in proportion to its breadth than in the narrow gauge engines, and that therefore the broad gauge engine is liable to be thrown more obliquely across the lines, and in case of meeting with an open or defective joint, more liable to quit the rail; but we cannot admit the validity of this objection against the broad gauge lines. It may be that the proportion between the length and breadth of the engine has some influence on its motion, and that the motion is somewhat less steady where the difference between the length and breadth is considerably diminished; but practical facts scarcely lead to the conclusion that the safety of the trains is endangered by the present proportion of the broad gauge engines; for it appears that on the London and Birmingham Railway, where the engines hitherto employed have been, generally, short four-wheeled engines, the distance from axle to axle not exceeding 7 feet, or 7 feet 6 inches, no such accident as we are considering has been reported; and we are informed by Mr. Bruyeres, the superintendent of that line, that no such accident has ever occurred. The same remark applied to some other narrow gauge lines; and if, as has been stated, exemption from these accidents has resulted from the close fixing of the engine and tender adopted on this line, the same system might be adopted on any other line, whether on the broad or narrow gauge. An evil may also sometimes arise in six-wheeled engines, by the centre of gravity of the engine being brought too much over the driving wheels, and the springs being so adjusted for the sake of the adhesion of the wheels to the rails, that the front wheels would have little or no weight to support, and would be thus in a condition, by any irregularity in the road or other obstruction, to be more easily lifted off the rails. But here again, if this fault in the construction or adjustment has been anywhere committed, it is a fault or defect wholly unconnected with the breadth of gauge.

Another cause of unsteady or irregular motion, dangerous to the safety of the train has been stated to be the great overhanging weight beyond the axles of some engines of recent construction, and of the weight of the outside cylinder beyond the axle bearings. So far as this construction is concerned, it certainly appertains to narrow gauge lines only; but at the same time we must remark, that it is not essential to their working.

Upon the whole, therefore, after the most careful consideration of this part of the subject, we feel bound to report, that as regards the safety of the passenger no preference is due, with well proportioned engines, to either gauge, except perhaps at very high velocities, where we think a preference would be due to the broad gauge. On this part of the subject we would beg to point to the nature of the evidence of Mr. Nicholas Wood.

Relative Accomodation for Passengers and Goods.

Passengers.—The first-class carriages of the broad gauge are intended to carry eight passengers in each compartment, and the compartments are sometimes subdivided by a partition and inside door. On the narrow gauge lines the first-class carriages are usually constructed to carry only six passengers in each compartment; and we find that about the same width is allowed for each passenger on both gauges. Some of the original mail carriages were adapted for four passengers, and we believe that the public had a preference for these carriages over both the other descriptions.

Until lately the broad gauge carriages were altogether more commodious than those of the narrow gauge, but recently carriages have been introduced on several of the narrow gauge lines nearly as lofty as those on the broad gauge, and equally commodious; in short, we now see no essential difference as regards accommodation and convenience to individual passengers in the first-class carriages of the two gauges.

In the second-class carriages on the broad gauge, six-persons sit side by side, each carriage being capable of holding 72 passengers. On the narrow gauge generally, only four passengers sit side by side, the total number in each carriage being 32; in this respect we are inclined to consider the latter are more comfortably accommodated.

With reference to the ease of the carriage, and the smoothness of the motion, we have had very contradictory evidence, and it must be admitted that great difference is experienced on the same line at different times, depending upon the state of the road, the springs of the carriage, the number of persons in a carriage, to bring the springs into action, the position of the carriage in the train, and the speed at which the train is propelled, of all which conditions are independent of the breadth of the gauge. We have however, with a view of making our observations on this question, travelled several times over all those lines having their stations in London, and after making, to the best of our judgment, every allowance for the circumstances above-mentioned, we are of opinion that at the higher velocities the motion is usually smoother on the broad gauge.

Merchandise.—It is now to be considered whether either gauge has a superiority over the other in regard to the conveyance of general merchandise.

Under this head we class manufactured goods and their raw material, mineral products, such as coal, lime, iron, and other ores; agricultural produce, such as corn, hops, wool, cattle, and timber.

On these points we have taken the evidence of persons well acquainted with the carrying trade, and from their information, and our observation, it does not appear to be of consequence to the parties sending or receiving goods whether they are transmitted in wagons containing five or six tons, or in wagons of larger capacity, provided that the cost and security are the same, and that the carriers undertake the responsibility of any damage that may result from the size of the load. But Messrs. Horne and Chaplin, and Mr. Hayward, who are largely interested, and have had great experience in the carying trade, have expressed a strong opinion that the smaller wagon is far the more convenient and economical. The same opinion is still more strongly expressed by those witnesses we have examined who have experience of our mineral districts. These persons state that the smaller wagon can be more easily handled, and can be taken along sharper curves than would be suited to a broader wagon; that such sharp curves are very common in mineral works and districts, and that the broken nature of the ground would render curves of greater radius inconvenient and expensive.

Another important difference between the two gauges, in this commercial view of the question, would present itself in localities in which there may be a difficulty of readily obtaining full loads for the wagons at road stations. Here the defect of the dead weight, which we find to apply more particularly to the broad gauge, would be greatly increased unless another evil of still greater commercial importance were created, that of detaining the wagons to receive full loads. On the whole therefore, we consider the narrow gauge as the more convenient for the merchandise of the country.

2. Relative Speed.

With a view to form our judgment on this subject, we have examined the time-tables of the several companies having express and fast trains, and the returns furnished by those companies of the actual speeds attained by the express trains, on 30 successive days, from the 15th of June to the 15th of July, 1845.

We have also, on various occasions, travelled in the express trains, and noted the speed, mile by mile.

The result has been, that we are fully satisfied that the average speed on the Great Western, both by the express trains and by the ordinary trains, exceeds the highest speed of similar trains on any of the narrow gauge lines. But some of the latter have trains which exceed in speed the corresponding trains of the Bristol and Gloucester line, and also of the Swindon and Gloucester line, both of which are on the broad gauge; but these latter, it is to be remembered, are still of recent construction with unfavourable curves and gradients; and we have been informed by Mr. R. Stephenson, in his evidence, that at one period the speed on the Northern and Eastern line even exceeded that of the Great Western.

In treating of a difference in the speed, other circumstances besides the mere gauge must be considered. The inclinations and curves of the Great Western Railway, between London and Bristol, and even for 40 miles beyond Bristol, are, with the exception of the Wootton-Basset and the Box inclines, particularly favourable to the attainment of high velocities; and it is important to remark, that the inclinations and curves on that part of the Northern and Eastern Railway where the competition in speed with the Great Western was the most successful are generally of a similar character.

One of the principle motives professed for constructing the Great Western Railway on the broad gauge was the attaining of high speeds, and the credit of the proposers and defenders of that construction has therefore been deeply engaged in maintaining them.

The effect of gradients on the speed of the Great Western trains, even with the powerful engines used on that line, is shown in the Time Table, page 24, where we find that while the speed from Paddington to Didcot by the express train is $47\frac{1}{2}$ miles per hour, from Didcot to Swindon it is only 41·1, and from Swindon to Gloucester only 31·7; from Swindon to Bath it is 46·2, but returning only 37·2: from Bristol to Taunton the speed is 46·3, and from Taunton to Exeter only 39·2.

Possibility of Future Increase of Speed.—We must observe, however, that while the Great Western Company have not altered in any degree the plan of their engines, the higher velocities of the narrow gauge lines have been attained by the introduction of a more powerful kind of engine than was employed at an earlier period, and probably the new engines now used on the narrow gauge are as powerful as they can well be made within the limits of their gauge; whereas the broad gauge lines have still a means of obtaining an increase in the power of their engines, and of increasing their speed, providing the road be in a condition to sustain the great increased force which must result from any increased weight of the engine moving at such high velocities.

Whether the permanent way is in such a state at present is very questionable, or even whether it be posible in all vicissitudes of weather to maintain it in such a condition. We ought not to lose sight of the fact, that since the introduction of express trains the accidents arising from engines running off the line have been much more common than in former years; indeed, these accidents have been more numerous within the last seven months than within the preceding five years, and it is questionable whether this contest for speed ought to be carried to any greater length. We are, indeed, strongly inclined to the opinion stated by several engineers in their evidence, that it is the stability of the road, and not the power of the engine, that will prescribe the limits of safe speed.

On the first introduction of passenger railways, speeds of about 12 miles per hour only were anticipated; the rails then employed weighed only 35 lb. per yard, and the engines about six or seven tons. As soon as speeds of 20 and 24 miles per hour were attempted, it was found necessary to have rails of 50lb. per yard, and engines weighing 10 and 12 tons. Since that time the rails have been increased in weight progressively to 65lb., 75lb., and 85lb. per yard, and the weight of the engine on the broad gauge exceeds 22 tons, and on the narrow gauge it now approaches 20 tons; indeed, we have seen a narrow gauge engine on six wheels weighing 30 tons. We doubt, however, whether a corresponding stability has been attained in the road itself.

Outside Cylinder Engines.—Amongst other changes for increasing the power of the engine and the speed of the trains of the narrow gauge lines there have been the giving an increased length to the engine, and the placing the cylinders on the outside of the framing; but it is the opinion of some of the witnesses we have examined, that this position of the cylinder has a tendency to produce a greater wear and tear of the journals, and a consequent rocking and irregular motion of the engine on the line. This, however, while the engine is of medium length, has been denied by Mr. Locke, who has had great experience in the working of outside cylinder engines. But it is stated by Mr. Gray and Mr. Gooch, that where the length of the engine is greatly increased, this increased length, by causing the extremities of the engine to overhang very considerably the fore and hind axles, has a great tendency to increase the irregular motion produced by the outside cylinder.

Mr. R. Stephenson admits that in some of the later engines this irregularity does exist, but he attributes it to the weight of the piston and its appendages, observing, "I do not believe that it is the steam that causes the irregular action, but I believe it to be the mere weight of the pistons themselves, and therefore if we could contrive to balance the piston by the weight upon the wheels, we should get rid of that very much."

At all events, from whatever causes the motion may arise, the oscillations are very considerable in some of these long engines, and such as can scarcely be considered safe at high velocities.

This great length of engine is, however, by no means essential to the attainment of high speeds on narrow gauge lines.

We found by timing the express trains on four different journeys on the South Western line, in both directions, that the whole distance was performed very satisfactorily in about 1 hour and 52 minutes, including the time of two stoppages, being at an average rate of 41 miles per hour, on a line which, in one direction, rises for a length of more than 40 miles on a very prevailing gradient of 1 in 330; and in the other rises for several miles on a gradient of 1 in 250. On each occasion a distance of five miles, on a level part of the road, was passed at the rate of 53 miles per hour.

The length of the engine boiler was only eight feet seven inches, the driving wheels six feet six inches in diameter; the leading wheels had both inside and outside bearings. The diameter of the cylinder in one case was 15 inches, in the others $14\frac{1}{2}$ inches, both outside, and attached to the smoke-box.

Evaporative Power of Broad and Narrow Gauge Engines.—In proceeding to compare the locomotive engines, we remark, in the first place, that the fire-boxes, boilers, &c., of the narrow gauge engines still possess a smaller evaporating power than those of the broad gauge engines, although recent attempts have been made to raise the former to the level of the latter; but those attempts have not succeeded; and it is indisputable, that whatever can be done for the narrow gauge, in this respect, can be surpassed on the broad gauge. And we concur in opinion with many of the ablest engineers, who have stated, that the engines of both gauges have nearly obtained the speed and power which it would be justifiable to employ in reference to the present strength of the rails and the firmness of the earthworks.

Diameter of Driving Wheels.—We remark, in the next place, that the diameter of the driving wheels of the broad gauge engines is greater than than that of the driving wheels of the narrow gauge engines, and, although, in many of the narrow gauge engines the use of the external cylinder has enabled the manufacturers to bring the boilers nearer to the driving wheel axles, and has thus permitted an increase of the diameter of the wheel, still it is always in the power of the constructors of broad gauge engines to make a corresponding change, and thus to maintain the superiority; for the larger diameter of the wheel is unquestionably favourable to high speed, both because the steam is used to greater advantage, and because the alternating shocks upon the machinery are less rapid. It is, however, extremely difficult to say at what speeds this advantage becomes appreciable. We think it likely, that as far as the speed of 40 miles an hour, there is no great difference between the two, but that for speeds of 50 or 60 miles an hour the difference may be worthy of notice. It becomes important, then, to inquire what may be the greatest speed that will probably be desired or maintained on railways for ordinary purposes.

It is certain that the wishes of the public will be limited only by considerations of economy and safety. The greater the speed the greater will be the cost; and it appears to be the opinion of many of the officers of railways, that it would be difficult to maintain with safety the present express speeds upon the great trunk railways.

The chief impediments to maintaining the present express speeds are—

1. The difficulty of arranging the trains, where the traffic is frequent, so that the first trains shall be entirely protected from the chance of interfering with or coming into collision with the slower trains, or those that stop at numerous stations.

2. The difficulty of seeing signals, especially in foggy weather, in time to enable the engine-driver to stop the fast trains.

We feel it a duty to observe here, that the public are mainly indebted for the present rate of speed, and the increased accommodation of the railway carriages, to the genius of Mr. Brunel, and the liberality of the Great Western Railway Company.

As regards the applicability of the atmospheric principle of traction, or of any other principle differing from the locomotive, we see no difference between the two gauges.

4. *The Question of Economy.*—Under this head we have to consider the cost of construction, the purchase of the plant, which consists of engines, of carriages, and of other carrying stock; and lastly, the cost of working.

There can be no question that, in the first construction of a railway, the narrower the gauge, the smaller will be the cost of the works. This applies to tunnels, bridges, viaducts, embankments, cuttings, sheds, workshops, turn-tables, transverse sleepers, and ballast, and the purchase of land; but it does not affect the rails, fences, drains, and station-houses. The exact difference, however, must depend in a great degree upon local circumstances, and no opinion can be given of the precise ratio of difference without going into a very minute calculation of each line on which the two systems are to be compared; for instance, in a line free from tunnels or viaducts, and in a flat country, where there are neither cuttings nor embankments, the difference would be limited very nearly to the quantity of land to be purchased (the severance and damage being about equal in both cases), the amount of ballasting, and some increase in the cost of the sleepers; whereas, in a very undulating country, the difference would be more considerable.

As to the cost of the maintenance of way, supposing the construction to be the same, that of the broad gauge must be rather the greater of the two.

Cost of Locomotive Power.—In respect to the cost of the engines and carrying stock, we have to observe that they are generally more expensive on the broad than on the narrow gauge. But, on the other hand, it is asserted by the advocates of the broad gauge system, that as the engines will draw greater loads, as the carriages will accommodate a greater number of passengers, and as the wagons are capable of conveying a larger amount of merchandise, the work can be, and is done, at a less charge per ton, and that a compensation is thus obtained for the increased outlay. How far this is found to be practically the case is the next subject for inquiry.

We were very desirous, if it had been found possible, thoroughly to investigate this part of the subject by means of the official data called for by us, and furnished by some of the principal companies, containing a statement of their working expenses; but we find the circumstances so different, that very little satisfactory information can be thus obtained, that has been obtained, that has strictly a reference to the economy of the two gauges. There are, of course, various matters that have an influence on the actual cost of locomotive power and general traffic charges, that are in no way connected with the breadth of gauge; such as the nature of the curves and gradients, the price of coke, the general nature of the traffic, the mode of working that traffic as adopted by different companies, the employment of engines of greater or less power, that increased accommodation to the public which involves an extra expense for return carriages, &c.

The London and Birmingham, and the Great Western Railway, as metropolitan lines of great traffic and of considerable length, would at first sight appear to furnish the best means of comparison, and there is, in fact, no difficulty in comparing the actual expenses; but these lines differ essentially in the character of their gradients and in the amount of traffic, estimated at per mile, and, above all, they differ in the character of the engines they employ.

Four Wheel Engines.—The London and Birmingham Company have, from the commencement, persevered in the use of light four-wheeled engines, while the Great Western, availing themselves of the facilities their gauge affords, have adopted large and powerful engines, which are worked at nearly the same cost per mile as the former; and if such engines, as those on the London and Birmingham line, were essential to the narrow gauge, the question, as to the economy of working, might be at once decided in favour of the broad gauge; but this is by no means the case; several narrow gauge lines employ engines of great power, and work, in consequence, much more cheaply than the London and Birmingham; therefore, the comparison between the working expenses of this line and of the Great Western can only be considered as a test of the principle of working with light and with heavy engines, and not as furnishing a test of the working economy of the two gauges.

It is a common practice with different railway companies, in their half-yearly reports to their proprietors, to state the per centage of their various expenses, under a few distinct heads, as compared with their revenue; and from these it appears that on the Great Western, the locomotive charges, during a period of three years, have varied between 8.8 and 11.1, averaging 9.7 per cent on their income, and on the London and Birmingham they have varied, within the same period, between 7.0 and 9.36, averaging about 8·6 per cent. on their income; and, therefore, on a superficial view of the question, the London and Birmingham would appear to have worked their line at a cheaper rate; but valid objections have been made to this comparison on the part of the Great Western; because it is obvious, from the several returns we have received, that the London and Birmingham Company has far the more abundant traffic per mile, and ought, therefore, to be expected to perform its work at a less per centage on its income. It has been stated by Mr. Gooch, that as locomotive superintendent on the Great Western, he is called upon to supply a certain amount of locomotive power, and that the cost of such power is almost entirely irrespective of the load or number of passengers it is made to draw; but that these numbers are of great importance in comparing the locomotive expenses with the revenue.

In page 27 of the appendix to this report, an abstract and comparative table are given, founded on returns furnished by the Great Western and London and Birmingham Railway Companies, showing that the revenue derived from the passengers' train is 64 per cent. greater per mile worked, on the latter than on the former line. It must, therefore, be obvious that, as a test of economy for working, we cannot adopt the principle of a per centage on the revenue, neither will the cost per mile run give a more just comparison as to the economy of the two systems, because it is a well-known fact that the London and Birmingham Company have been conveying their traffic with engines of inadequate power, and that great economy would result to them by the adoption of larger engines.

Other difficulties also occur in the comparison of these expenses on different lines, in consequence of the difference in the form of the accounts, and of the circumstance of one company adopting the principle of having a reserve fund for renewals, and other companies having no such fund.

Probable Cost of Locomotion on Great Western if made with Narrow Gauge.—We are, therefore, of opinion that the most satisfactory comparison that can be made of the economy of working the two guages, will be, by applying to first principles, endeavouring merely to determine what the working expenses of the Great Western line, with their present amount of traffic, would have been, provided it had been made a narrow gauge line, and worked with such engines as those employed on the South Western and some other narrow gauge lines.

The average weight of a passenger-train on the Great Western Railway (independent of the engine and tender, which weigh 22 tons) appears, by the returns sent to us, to be 67 tons; and the average number of passengers per train for the half-year ending the 30th of June, 1845, as appears by our comparative table, page 27, is only 47·2, whose weight, including their luggage, may be estimated at about 5 tons.

Mr. Gooch estimates each carriage and its passengers on the broad gauge, to weigh about 9½ tons, and therefore there would be seven carriages to make up the 67 tons above specified. The most commodious carriage on the narrow gauge lines, such as those on the South Western, weigh less than 5 tons; seven such carriages would therefore weigh about 34 tons, and being capable of containing 126 first-class passengers, weighing, with their luggage, 12½ tons, the total load would be only 46½ tons. Now we find, that even with a traffic as large as that on the London and Birmingham Railway, the average per train would only be 84·9 passengers, weighing about 8 tons; so that, under the supposition of a traffic of this extent, the load of the seven narrow gauge carriages so occupied would only be 42 tons.

But Mr. Gooch estimates, from his own experiments, the relative powers of traction of the broad gauge engines, and of the narrow gauge engines of the South Western Railway, when working at the same speed, as 2,067 to 1,398, or as 67 per cent., the load of the broad gauge in tons, to 45 tons which would be the corresponding load for the narrow guage, so that the narrow gauge engine has more power over the 42 tons it would have to draw than the broad gauge has over its average load of 67 tons, both exclusive of the weight of the engine and tender, the narrow gauge carriage in this supposition being supposed to contain 84·9 passengers, and the broad gauge only 47·2.

If, however, it were necessary, 224 first-class passengers might be placed in the seven broad gauge carriages, and, as it has before been said, 126 in the seven narrow gauge carriages; but it appears likely that this extent of accommodation would only be called for on such rare occasions, that the question of providing for it, except by assistant power, cannot be taken into consideration in the present comparison.

It is obvious, from the foregoing statement, that the narrow gauge engine of the class we have been considering has more power over the seven narrow gauge carriages, and a load of 126 passengers, than the broad gauge engine has over the seven broad gauge carriages, and the load of the same number of passengers; and that, therefore, if the Great Western had been a narrow instead of a broad gauge line, the South Western engines would have had the same command over the existing passenger traffic of the Great Western as its own engines now have with the present construction of that railway.

We must remark, however, that this calculation is for trains consisting exclusively of passengers and their personal luggage. In the Great Western average trains of 67 tons there is an allowance of about 16 tons for passengers and luggage, including gentlemen's carriages. Allowing the same weight of luggage on the narrow gauge line, the train would still not exceed 50 tons, which is considerably within the power of the narrow gauge engine. For it appears, by the experiments that have been recently made on the Great Western Railway, the details of which are given in the appendix to the evidence, that the Great Western engine is capable of propelling 18 tons at a greater speed than the average speed of that line; and, consequently, by the proportion above stated, the narrow gauge engine would be capable of propelling 55 tons at the same rate. We conclude, therefore, that the work would be performed at about the same expense for locomotive power.

That there may be cases in which not only the full power of a broad gauge engine is required, but even the assistance of a second engine is quite certain, but such trains form the exception, and not the rule, in railway passenger traffic, and we doubt the soundness of a principle which involves a great expense in construction, for the sake of possessing capabilities so seldom called into action.*

It is proper to observe, that the foregoing comparison would have appeared to stand more in favour of the narrow gauge, had we taken for the engine of comparison, one of those engines, of whose increased capabilities some of the supporters of the narrow gauge system have informed us; but we have preferred the comparison afforded with the South Western engine, from its being the one on which Mr. Gooch of the Great Western Railway, superintended the recorded experiments—hence our deductions are made from data furnished by the advocates of the broad gauge system, without drawing anything from the evidence on the other side; and as these deductions sufficiently demonstrate that there is no economy in the locomotive expenses for passenger-trains resulting from working a line on the broad gauge system, even on such lines as those which have at the present moment the most abundant passenger traffic, any analyzation of the evidence offered in support of the narrow gauge system appears to us to be quite superfluous.

Gross and Net Loads.—There is one point, however, stated in Mr. Gooch's comparative table, and repeated in his evidence, which appears so much at variance with the results we have obtained from other data, as to require explanation.

Mr. Gooch has asserted that the Great Western Company work their passenger-trains at half the expense per ton, at which the London and Birmingham Company work their passenger-trains. The fact is, however, that Mr. Gooch's calculations refer to the gross and not to the net loads; and therefore, the comparison is not applicable, so far as regards the profits of these companies, and affords no proof of economy in working the passenger traffic on the Great Western system.

There can be no doubt, judging both from Mr. Brunel's evidence given to us, and from his report to the directors of the Great Western Railway Company, that he originally expected there would be on the Great Western Railway a demand for carrying great numbers of passengers at high velocities, but from his own evidence it appears that the only heavy passenger traffic upon that railway is between London and Reading, and between Bath and Bristol, being a total distance of about 50 miles, out of 245.

On the remaining part of the line the passenger traffic, per train, is small.

Division of Traffic.—If the convenience of the public would admit of the whole of the passenger traffic of this portion of the line being conveyed daily by two or three large trains, Mr. Brunel's views would have been perfectly correct in providing such powerful means; but experience has proved that the public require passenger-trains to be run many times during the day, and with this frequency of trains, such numbers of passengers as Mr. Brunel has provided for cannot be expected even on railways of the largest traffic, so that practically there is a waste both of power and of means. In the case of "goods' traffic," the circumstances are not the same, railway conveyance for merchandise seems only to be required a few times in each day, and the trains are generally large. The "through" wagons have, for the most part, a full load, and the disproportion between the gross and the net weight is consequently much less than in the passenger trains; still, however, it appears from the evidence of Mr. Horne, and of other persons connected with the carrying trade, that on the London and Birmingham Railway it frequently happens that wagons are forwarded to a considerable distance, to "road-side stations," containing not more than a ton of goods: and there can be no doubt that this must happen on any long line of railway. The same also occurs in wagons coming in from branches along the trunk line, and in all such cases the heavy large wagon of the broad gauge must be disadvantageous; but although the evil is not so great with goods' wagons of the broad gauge as with their passenger carriages, still the loss by dead weight is greater with these than with smaller wagons, and we do not perceive any advantages in the broad gauge to counterbalance it; for where speed is not an object, and this is the case with goods' trains, we believe from the evidence we have received, that engines of nearly the same tractive power are to be found on many narrow gauge lines as those in use on the broad gauge.

* It appears that during the half-year ending June 30, 1845, the number of miles run by coupled and assisting engines for passenger-trains on the Great Western Railway, amounted to 11,628, and for goods trains to 51,155. The total number of miles run by the former trains being 761,493, and of the latter, 159,324.

New Railways.—Thus far we have considered the question with reference to the railways as they now exist, and composed, in a great measure, of trunk lines of considerable traffic, but the railways to be made in future will, in some degree, be branches or lines in districts having traffic of less magnitude than is to be provided for in the existing railways; and hence, if for the greater trunk lines a superiority were due to the broad gauge system, that superiority would be less for lines yet to be constructed of a smaller amount of traffic; and, necessarily, if the preference were given to the narrow gauge for the existing lines, that system would be still more entitled to the preference for the railways of smaller traffic to which we look forward.

Experiments on Broad and Narrow Gauge.—We must here add that towards the close of our inquiry, Mr. Brunel requested, on the part of the broad gauge companies, to institute a set of experiments to test the power of their engines, and Mr. Bidder, on the part of the narrow gauge companies, undertook, in consequence of such application, to make corresponding experiments on the narrow gauge. After sanctioning these trials, and being present at the performance of them, a record of which will be found in the appendix, we may observe, without entering into a minute detail of the results, or the discrepancies between the returns as furnished by the two parties themselves, that we consider them as confirming the statements and results given by Mr. Gooch, in his evidence, proving as they do, that the broad gauge engines possess greater capabilities for speed with equal loads, and, generally speaking, of propelling greater loads with equal speed; and, moreover, that the working with such engines is economical where very high speeds are required, or where the loads to be conveyed are such as to require the full power of the engine. They confirm, also, the evidence given by Mr. Bidder as to the possibility of obtaining high evaporative power with long engines for the narrow gauge; but under somewhat peculiar circumstances. It appears, moreover, that the evaporation thus obtained does not produce a corresponding useful effect in the tractive power of the engine; a circumstance that would probably be differently explained by Mr. Gooch and by Mr. Bidder; but as we do not refer to the power of this description of engine in the deductions we have made, it is unnecessary for us to allude further to them.

Conclusions.—After a full consideration of all the circumstances that have come before us, and of the deductions we have made from the evidence, we are led to conclude—

1. *That as regards the safety, accommodation, and convenience of the passengers, no decided preference is due to either gauge, but that on the broad gauge the motion is generally more easy at high velocities.*

2. *That in respect of speed, we consider the advantages are with the broad gauge, but we think the public safety would be endangered in employing the greater capabilities of the broad gauge much beyond their present use, except on roads more consolidated and more substantially and perfectly formed, than those of the existing lines.*

3. *That in the commercial case of the transport of goods, we believe the narrow gauge to possess the greater convenience and to be the more suited to the general traffic of the country.*

4. *That the broad gauge involves the greater outlay, and that we have not been able to discover either in the maintenance of way, in the cost of locomotive power, or in the other annual expenses, any adequate reduction to compensate for the additional first cost.*

Therefore, esteeming the importance of the highest speed on express trains for the accommodation of a comparatively small number of persons, however desirable that may be to them, as of far less moment than affording convenience to the general commercial traffic of the country, we are inclined to consider the narrow gauge as that which should be preferred for general convenience; and, therefore, if it were imperative to produce uniformity, we should recommend that uniformity to be produced by an alteration of the broad to the narrow gauge, more especially when we take into consideration that the extent of the former at present in work is only 274 miles, while that of the latter is not less than 1,901 miles, and that the alteration of the former to the latter, even if of equal length, would be the less costly as well as the less difficult operation.

Intermediate Gauges.—We are desirous, however, of guarding ourselves from being supposed to express an opinion, that the dimensions of four feet eight and a half inches is in all respects the mosts suited for the general objects of the country. Some of the engineers who have been examined by us have given it as their opinion, that five feet would be the best dimension for a railway gauge; others have suggested 5 ft. 3 in., 5 ft. 6 in., and even 6 ft., but none have recommended so great a breadth as 7 ft., except those who are more particularly interested in the broad gauge lines. Again some engineers of eminence contend that a gauge of 4 ft. 8½ in. gives ample space for the machinery of the engine and all the railway requirements, and would recommend no change to be made in the gauge.

We may observe, in reference to this part of the question, that the Eastern Counties Railway was originally constructed on a gauge of 5 feet, and has since been converted into a gauge of 4 feet 8½ inches, to avoid a break of gauge; and we have been informed that some lines in Scotland, originally on the gauge of 5 ft. 3 in., are about to be altered to 4 ft. 8½ in. for the same reason.

Gauge of Foreign Railways.—Whatever might be the preferable course were the questions now to be discussed of the gauge for an entire system of railways, where none previously existed to clash with the decision, yet, under the present state of things, we see no sufficient reason to suggest or recommend the adoption of any gauge intermediate between the narrow gauge of 4 ft. 8½ in., and the broad gauge of 7 ft., and we are peculiarly struck by the circumstance, that almost all the continental railways have been formed upon the 4 ft. 8½ in., gauge, the greater number having been undertaken, after a long experience of both the broad and narrow gauge in this country; nor must the fact be lost sight of, that some of these railways have been constructed as well as planned by English engineers, and amongst that number we find Mr. Brunel, the original projecter of the broad gauge. Mr. Brunel was also the engineer of the Merthyr Tydvil and Cardiff Line, which is on the 4 ft. 8½ in. gauge; and we think that the motives which led to his adoption of the narrow gauge in that instance would equally apply to many English lines.

We are sensible of the importance, in ordinary circumstances, of leaving commercial enterprise as well as the genius of scientific men unfettered; we therefore feel that the restriction of the gauge is a measure that should not be lightly entertained; and we are willing to admit, were it not for the great evil that must inevitably be experienced when lines of unequal gauges come into contact, that varying gradients, curves, and traffic might justify some difference in the breadth of gauge. This appears to be the view which Mr. Brunel originally took of the subject; for the Great Western proper is a line of unusual good gradients, on which a larger passenger traffic was anticipated, and as it touched but slightly on any mineral district, it embraced all the conveniences and advantages of the broad gauge system, and was comparatively free from the influence of those defects on which we have commented; but such a breadth of gauge, however suitable and applicable it may have originally been considered to its particular district, appears wholly inapplicable, or at least very ill suited to the requirements of many of our Northern and Midland lines.

In references to the branches already in connexion with the Great Western Railway, we may observe. that the greatest average train on the Oxford branch, for two weeks in July and October, was only 48 tons; on the Cheltenham branch, it did not exceed 46; between Bristol and Exeter, 53; and between Swindon and Bristol, it was under 60 tons. With such a limited traffic the power of the broad gauge engine seems beyond the requirements of these districts.

Expense of Altering Broad to Narrow Gauge.—We find from an estimate furnished to us, and the general grounds of which we see no reason to dispute, and the expense of altering the existing broad gauge to narrow gauge lines, including the alteration or substitution of locomotives, and carrying stocks, would not much exceed 1,000,000*l.*; yet we neither feel that we can recommend the Legislature to sanction such an expense from the public monies, nor do we think that the companies to which the broad gauge railways belong can be called upon to incur such an expense themselves (having made all their works with the authority of Parliament), nor even the more limited expense of laying down intermediate rails for narrow gauge traffic. Still less can we propose, for any advantage that has been suggested, the alteration of the whole of the railways of Great Britain with their carrying stocks and engines, to some intermediate gauge. The outlay in this case would be very much more considerable than the sum above mentioned; and the evil, inconvenience, and danger to the traveller, and the interruption to the whole traffic of the country for a considerable period, and almost at one and the same time, would be such that this change cannot be seriously entertained.

Guided by the foregoing considerations, we most dutifully submit to your Majesty the following recommendations:—

1. *That the gauge of 4 ft. 8½ in. be declared by the Legislature to be the gauge to be used in all public railways now under construction, or hereafter to be constructed, in Great Britain.*

2. *That unless by the consent of the Legislature, it should not be permitted to the directors of any railway company to alter the gauge of such railway.*

3. *That in order to complete the general chain of narrow gauge communication from the north of England to the southern coast, any suitable measure should be promoted to form a narrow gauge link from Oxford to Reading, and thence to Basingstoke, or by any shorter route connecting the proposed Rugby and Oxford line with the South Western Railway.*

4. *That as any junction to be formed with a broad gauge line would involve a break of gauge, provided our first recommendation be adopted, great commercial convenience would be obtained by reducing the gauge of the present broad gauge lines to the narrow gauge of 4 feet 8½ inches, and we, therefore, think it desirable that some equitable means should be found of producing such entire uniformity of gauge, or of adopting such other course as would admit of the narrow gauge carriages passing, without interruption or danger, along the broad gauge lines.*

Broad and Narrow Gauges C

Return of Railways furnished by the Board of Trade, 1845.

RAILWAYS	Narrow Gauge, 4 ft. 8½ in. miles.	Broad Gauge, 7 feet. miles.	Irish Gauge, 5 ft. 3 in. miles.
Completed	1901	274	69
Sanctioned in 1844	602½	63	122½
Passed the House of Commons, Sessions 1845 and seem likely to be sanctioned in Session 1846	1628	440	772
Total length ..	4,131½	777	963½

The Broad Gauge includes the Great Western, Cheltenham branch, Oxford branch, Bristol and Exeter, and the Bristol and Gloucester completed. The South Devon now progressing, and the Bristol and Exeter branches, Cornwall, Exeter, Crediton, South Wales, Wilts and Somerset, now in parliament.

The Narrow Gauge includes 32 miles of the Arbroath and Forfar and Dundee and Arbroath Railway, 6 ft. 2 in. gauge to be altered to 4 ft. 8½ in., and the Irish gauge is confined to railways in Ireland.

Table exhibiting the Expenditure of the Great Western and London and Birmingham Railways for Locomotive Engines, Carriages, and Wagons, from the commencement of the traffic to the present time; also the Revenue Returns of each for the last two years, and the Expense of Locomotive Power, as deduced from the Half-yearly Reports of each Company.

	£	s.	d.
Great Western.—Total cost of locomotive engines, tenders, carriages, and wagons, to 30th of June, 1845	622,078	12	0
London and Birmingham.—Total cost of locomotive engines, tenders, carriages, and wagons, to 30th June, 1845	494,408	5	
These sums are exclusive of the charges for locomotive, carriage, and wagon repairs, included in the half-yearly accounts. These latter have amounted in the last two years to—			
Great Western.—From 1st July, 1843, to 30th June, 1845 ..	56,962	17	
London and Birmingham.—From 1st July, 1843, to 30th June, 1845	57,578	3	
The cost of locomotive power, including repairs of locomotive engines, coal, coke, wages, and all incidental charges, have amounted in the same period to—			
Great Western.—From 1st of July, 1843, to 30th of June, 1845 ..	156,962	2	
London and Birmingham.—From 1st of July, 1843, to 30th of June, 1845	146,172	8	
The revenue for the same two years, for the carriage of passengers, mails, goods, &c.—			
Great Western.—From 1st of July, 1843, to 30th of June, 1845 ..	1,617,995	8	
London and Birmingham.—From 1st of July, 1843, to 30th June, 1845	1,785,795	14	2
The total mileage of every passenger for the last two years amounts to—			
Great Western.—Total mileage from 1st of July, 1843, to 30th of June, 1845	128,524,232		
London and Birmingham.—Total mileage from 1st of July 1843, to 30th of June, 1845	121,529,896		

	Great Western and London and Birmingham.
Ratio of cost of engine and carriage plant	1 to ·763
Ratio of repairs of engine for 2 years	1 to 1·021
Ratio of cost of locomotive power for 2 years	1 to ·049
Ratio of passengers' mileage for 2 years	1 to ·945
Ratio of total passengers' revenues for 2 years	1 to ·1072

During the periods which these returns embrace, the lengths of line worked by the Great Western have varied by the opening of different lines and branches; but from the 30th of December, 1844, to June 30th. 1845, the number of miles worked have been constant, viz., 222 miles. The length worked by the London and Birmingham has also been constant during the same period, and Mr. Creed in his evidence states (excluding the branches) that the distances worked was 113 miles, and the revenue and mileage on this length, that is still excluding the branches, he gives as below.

Similar statements are given in the appendix of the revenue, mileage, &c., on the Great Western for a like period; from which we have the following comparisons:—

	Miles.
Great Western, length of line worked	222
London and Birmingham, length of line worked	113
Great Western, total passengers' mileage	35,967,713
London and Birmingham, total passengers' mileage	38,758,260
Great Western, miles run by passenger trains	761,483
London and Birmingham, miles run by passenger trains	456,826
Great Western, average number of passengers per trains	47·2
London and Birmingham, average number of passengers per trains ..	84·9
Great Western, average passengers' revenue per trains per mile ..	9s.
London and Birmingham, average passengers' revenue per trains per mile ..	14s. 9d.

Improvement of the Severn.—The River Severn, which is subject to alternate floods and droughts, has, during the last two years, been greatly improved by dredging, and by the erection of gigantic weirs and locks. These works are now completed from Bewdley to Worcester, a distance of seventeen miles, and from Worcester to Gloucester the river is being deepened by dredging and closer enbankment, the Severn Act limiting the erection of weirs within the county of Worcester. By the operation of dredging, long rocky shoals have been entirely removed. The hardest rocks are first blasted under water, and, therefore, easily removed by the dredging machines. Upwards of 200,000 tons of marl, rock, gravel, and soil have already been raised from the bed of the Severn by Messrs. Grissell and Peto's dredging machine alone, besides what has been removed by another contractor. At Gloucester it has been necessary to remove the entire foundation of one of the piers of the old bridge, and in the course of this operation some curious relics of ancient coins have been discovered.

Sheerness.—The whole of the guns for the old fortifications have now arrived from Woolwich. They are 63 in number, and are of the following description:—4 eight-inch guns, 98 cwt. each, 11 feet long; 29 eight-inch guns, 65 cwt. each, 9 feet long; 26 6½-inch guns, 56 cwt. each, 9 ft. 6 in. long; and 4 6½ inch guns, 82 cwt. each, 6 ft. 6 in. long. The workmen now await the arrival of the carriages and platforms from Woolwich; the masonry on which they are to rest is all ready to be laid down. The guns are to be placed as follows:—20 on the Halfmoon Battery at the Point, 13 on the Admiral's platform overlooking the said battery, and the remaining 30 along the works protecting the barracks. The new works progress rapidly; the battery forming opposite the dockyard gate is now carried to the height of the platform; its further progress has, however, been deferred till the formation of the deep ditch by which it is to be protected, and on which all the workmen are now concentrated. Wooden profiles are now up for another battery, with which this is to be connected by a musketry wall, while to the eastward it will be continued into the bastions extending from the Thames to the Medway.

NEW CHURCHES.

All Saints, Rise, Yorkshire.—Consists of a nave and chancel in the First Pointed style, and cost about 4000*l*; it is capable of containing 200 persons. The chancel is ascended by one step at the nave and two more at the altar. The stalls and the fittings throughout are of oak; the floor is laid with encaustic tiles; the wall as high as the string-course is inlaid with tiles. A recess in the wall is used for a credence. The east window of three lancets, is filled with stained glass by Wailes. The stonework between has received decorative colouring, and the walls are ornamented with scrolls. The spaces between the beams of the roof are painted blue with gilt stars. The capitals of the pillars are gilt.

Homerton.—A new church is building in Homerton from the design of Mr. Ashpitel. When we have praised its material, Kentish rag with the dressings, &c., in Caen stone, and its general plan, chancel, nave, south-aisle, porch, and west tower, we have said all that we can in its favour. The chancel is very short, and a sacristy is added to the north-west, instead of the north-east of the chancel. Again the style chosen is Third Pointed, but with a poor attempt at tracery of the Middle pointed period. The mouldings throughout are very inaccurate. The west tower is square, with a corner turret; all on too small a scale. The aisle is to have a separate gable, with great haunches.

St. John, East Chislehurst, Kent.—The ground plan of this church is a wide oblong, without any pretence to a chancel. There are north, south, and west galleries, the latter containing the organ. At the east end of the south cloister there is a door labelled "*Chapel Clerk's Office.*" Corresponding with this on the north side, is another door, with the inscription "*Minister's Vestry*" upon it. The altar, an old oaken table well carved; altar chairs the same; an altar-piece of Carrara marble; altar-rails of massive grey marble; a pulpit of oak paneled with bas relief, a hexagonal font of white marble; a brass lectern; a litany desk (turned the wrong way), these form a catalogue of gems seldom met with in this country. Indeed the whole have been imported from the continent. There are two thin western towers capped with short shingled spires. One of them contains six bells. The style of the church is intended to be Italian. The windows are all roundheaded triplets glazed with ground glass; that at the east end is included in an enormous arch of construction. The masonry is of flint, with dressings of red and white brick, and white ashlar. The roof is of stained deal. The church is said to have cost nearly 8000*l*, and holds 500 worshippers. The architect is a Mr. Wollaston. Here one has again to lament the lavish expenditure of money upon an unworthy design.

West Meon, Hampshire.—Consists of a chancel, (30feet,) nave, (70,) with aisles, south porch, and west tower. The style is the transition between First and Middle Pointed, and yet there is not to be a spire. The material is flint dressed with stone. The reredos is a trefoiled arcade. There are sedilia, only however two in number, and a credence. The roof and seats are of deal. The flooring of the chancel is blue and white lias. Messrs. Scott and Moffatt are the architects, and the building partakes too much of the fineness conspicuous in their designs. In particular we object to the pert-looking unmeaning window over the north door.

Loughton.—We have seen a lithographed view of "the new church, Loughton," taken from the N.E., to which Mr. S. Smirke's name is attached as architect. It is a most unsatisfactory production: of English Romanesque style, cruciform, with low square central tower, having no capping whatever above its parapet. The windows are all large and round-headed: the side walls high: the strings clumsy: the buttresses very unlike Norman: and the whole effect quite different from that of any ancient church we ever saw. The view shows a north-west porch, a door in the north transept, and a third door into a kind of belfry turret, which occupies the angle between the north transept and chancel. The faces of the two gable-fronts shown in the view are recessed, not under corbel tables, but under a flatsided triangular head following the lines of the low gable, in the most remarkable way. We thought it had been long ago admitted that all Romanesque towers ought to have a high capping; nothing can be imagined worse than the flat parapet in this example.

Brockham, Betchworth, Surrey.—Consists of chancel, (not long enough, but very much better than the ordinary run,) nave, transepts, an eastern aisle to each transept, north porch, and central tower. We have often protested against the adoption (except under peculiar circumstances,) of the cruciform arrangement. In this case it was especially bad, because the funds, we understand, fell short. The style is First Pointed. The lancets are not too broad, but too short, and far too high up: the east end contains a triplet of a very nondescript kind. The north porch is immensely too large, and absurdly elaborate. The string-course is grievously faulty. And, worse than all, the piers, both of these aisles and the belfry arches, are made indeed of local stone, but are to be cased, and all the mouldings, run, in plaister. On the whole, this church is very unworthy of Mr. Ferrey.

Tubney, Berkshire.—A small church, the shell of which did not cost more than 600*l*. or 700*l*, has been built here from the designs of Mr. Pugin, at the expense of St. Mary Magdalen College, Oxford. The most striking feature is the roof, of unusually sharp and lofty pitch: which has been censured as excessive by many who are most disposed to favour high roofs. The well-known example of the roof of All Saints, Skelton, may be pleaded as a precedent. The west end displays a bell gable of two arches, and a quatrefoil pierced between the heads, with a floriated cross above. All the windows on the north are of one narrow light with trefoil heads; the east window of the chancel has three lights with flowing tracery, and those on the south side are of two lights in form and proportion like those on the north. The plan consists of chancel, vestry in the north side, nave, and south porch, the whole paved with small tiles of a dark red colour. The altar and pulpit are of stone, both plain, as is almost every detail of the church, with the exception of the font, which is very richly and beautifully carved.

St. James, Woodside.—We have seen a wood-engraving of this church from the north-west. The architect is Mr. C. W. Burleigh, of Leeds. The style is Middle Pointed; and the plan consists of a chancel, nave with west bell-cote and west door, north aisle, with a separate gable, and north porch. All the gables are coped in stone, and have crosses. Upon the whole we are well satisfied, and hope to meet Mr. Burleigh again.

Sandown Brading, Isle of Wight.—We have seen a lithograph of the new church about to be erected at Sandown Brading, Isle of Wight, in the First Pointed style. There is a south aisle under a separate gable. The east window of the aisle is a triplet, and too much like a chancel east window. The tower with broach spire is engaged in the aisle at its west end. The roofs are of a good pitch. Mr. Woodman is the architect of Sandown church.

CHURCH RESTORATIONS.

St. Mary, Battel.—Some very interesting wall-paintings, were lately discovered in the semi-Romanesque nave of the decanal church of St. Mary, Battel. In spite of earnest remonstrances the churchwardens have again whitewashed them. The splays of the clerestory windows were filled with whole length figures. The works in the chancel and its aisles will be done in the right direction, these being free from churchwarden's influence.

St. Mary, Snettisham.—The magnificent Middle Pointed west window of this church has been opened and repaired by the exertions of the curate. It is to be filled with stained glass by Mr. Warrington.

St. Michael, Sowton, Devonshire.—The church of St. Michael, Sowton, Devonshire, has been recently rebuilt, at the sole charge of J. Garrett, Esq. Mr. Hayward is the architect. The style is Third Pointed. The plan consists of chancel, nave, north aisles, and western tower. The stone is red-sandstone ashlared; the dressings are of Caen stone. The exterior effect is described as being religious and unobtrusive. There is no saving of expense externally, and there is much enrichment within. The windows are filled with stained glass chiefly by Willement.

St. Leonard, Beeford, Yorkshire.—This church consisted of a chancel, nave, and south aisle, and presented all the disfigurements of sash windows, pagan Tate-and-Brady galleries, with a low ceiling entirely hiding the wood-work. The restoration has been undertaken and carried out in an excellent spirit. A new north aisle has been added, containing four windows. In the nave the ceiling has been removed, and the old roof has been enriched with cusps, &c. The gallery which occupied the western end, and completely blocked up the tower, and a very beautiful arch, has been pulled down, and opens to view a fine Third Pointed window. A large stack of pulpit and reading desk is shortly to be replaced by new ones of proper proportions.

St. Mary, Romsey.—The magnificent abbey church of St. Mary, Romsey, is under restoration by Mr. Ferrey. The spirit with which the work has been undertaken is deserving of all praise. We are grieved however to see such little respect paid to the peculiar character of the Romanesque masonry. The new work is fine-dressed and close-jointed. Such an alteration goes far towards destroying the genuineness of any building. The offensive gallery which spanned the church has been already swept away, and the lantern is about to be opened.

St. Mary, Eastwell, Kent.—The church which is mainly Middle Pointed, is of that peculiarly unmanageable form, a chancel and nave, with a single aisle (a south one) wider than the nave itself, and with a separate roof. The nave has a chancel arch, not the aisle. A rood-screen has been put up, and the east end of the aisle parclosed off. The parclose has no opening at all, leaving the chantry to be entered perforce through the chancel. The wood-work is very costly and well-intentioned, wanting however in simplicity and in force. The prayer-desk we are sorry to say looks west. There are altar chairs, arranged however north and south. We may in passing, remark the extreme shortness of the chancel. The nave and aisle are filled with open seats of oak, with poppy-heads.

St. Botolph, Boston.—The restoration of the magnificent church of St. Botolph, Boston, under the superintendence of Messrs. Scott and Moffatt, has commenced. The interior of the nave has already been denuded of whitewash, and some architectural restorations have been made in the exterior.

St. Denis, Rotherfield, Kent.—The shingle roofing of the spire (surmounted by a noble cross and a cock), and the interior of the chancel have been repaired: the piscina, sedilia, and the stoup at the Priest's door, all in the south wall, have been restored. The piscina is circular-headed; the sedilia are First Pointed, and composed of two arches of unequal span, separated by a single shaft, and apparently intended for one and two occupants respectively. The pavement of the entire sacrarium has been raised.

St. Julian, Wellow.—The oak open benches in the nave have been carefully restored, and the fine rood-screen cleaned. The chancel has been rebuilt and its roof leaded. Its fittings are unfortunately of deal. A west gallery is permitted to remain. The font is removed to its proper place and a north door is opened.

St. Nicolas, Cranley, Surrey.—The chancel is seated stallwise, but without returns: the details are poor. The paving is of encaustic tiles. The sedilla have been restored, but are not used, nor can they be while the altar rails remain. There is a poor eagle, a pulpit wanting height, (a fault on the right side), and a reading-pew that faces south. In the nave are two horrible but elaborately panelled galleries between the first and second pews.

St. Margaret, Lynn.—The parclose of the chancel of St. Margaret, Lynn, is in course of restoration by Mr. Patterson, carver, of that town; under the superintendence of the Lynn and West Norfolk Architectural Society.

Jesus College, Cambridge.—We are delighted to be informed by a correspondent, that the master of Jesus College, Cambridge, has announced his intention of presenting five stained glass windows for the lancets on the north side of the choir of the college chapel. The "Five Sisters." of York, will be the model.

THE COLLECTION OF SEWAGE MANURE.

In connection with the efforts that have recently been made to improve the sanatory condition of large towns, one of the most important propositions is the plan entertained, *applying to agricul ure the refuse and drainage of London.*

It is argued, and apparently with good reason, that by this plan not only would large quantities of valuable manure, which is now wasted, be usefully applied, but that also, the plan would involve more effectual means of removing it, than by the flow of the Thames, and that a fruitful cause of miasma would be removed.

Two modes of effecting the requisite object have been suggested. In the First Report of the Health of Towns Commission are published various reports and estimates made by Mr. Smith, of Deanston, in which he suggests the practicability of dispersing sewage water of lands in the vicinity of London by a system of fixed jets or hose pipes, and more recently details are given in a prospectus issued by the Metropolitan Sewage Company, to which Mr. Smith's name appears as consulting engineer. The scheme is stated by the prospectus to have been *matured* for conveying the sewage water of London, by means of a system of *pumping-engines* and *pipes analogous* to that of the *great Water Companies*, and thus distributing the fertilising fluid all over the land, in such manner and proportions as may be best adapted to the various kinds of field and garden cultivation. The average quantity required for agriculture is estimated at 80 *tons per acre*, which can be supplied within about 20 *miles round the metropolis* at less than a quarter of the cost of stable or farm-yard manure, and at *one-tenth of the expense.*

The contents of these sewers are to be raised by powerful steam-engines and distributed by pipes over an extent of *sixty square miles*, through the gardening and agricultural districts to the *westward.* A sum of 300,000*l.* only will be required to carry this part of the plan into effect. On comparing the relative expense of conveying solid and liquid manure, it is calculated that the cost of the conveyance of liquid manure by pipes, is, at the very outside, *one-twentieth* of the transport of solid manure *by carts.*

The authority quoted is Mr. T. Hawksley, Engineer, of Nottingham; he states in evidence that the cost of transmitting water to a distance of *five miles*, and to a height of 200 feet, including wear and tear of pumping machinery, fuel, labour, interest of capital invested in pipes, reservoirs, engines, &c., amounts to 2½d. per ton; the cost of *cartage* to the same distance and height will, under favourable circumstances, amount to 4s. per ton.

This plan depends chiefly upon the authority of Mr. Smith's report and estimates, published by the Health of Towns Commission.

He appears to have made several experiments respecting the diffusion of water by jets; in applying the results of his experiments to the case of sewage manure. He states that the water must be at a pressure of from 100 to 150 *feet at the point where it is to be distributed by hose* over the land. With a pressure at the hose of 120 feet, he found that he could, through a 2¼ inch hose and a one inch nozzle, distribute water over an area of *two* statute acres—but to be safe, say one statute acre, and if the land rises an addition must be made to the pressure equal to the rise in the land. Mr. Smith states that for his estimate he assumes 200 feet total height to raise the water.

Great doubts have however been expressed as to the practicability of distributing the sewage water by jets. In a report to the London Sewage Company Mr. Wicksteed, C.E., proposed an altogether different plan, and brought forward powerful arguments for condemning *in toto* Mr. Smith's scheme. The following extracts embody the principal points of his reply:—

"The quantity of sewer water to be supplied is equal to 17,920 gallons per acre per annum, one-third of which Mr. Smith says can be delivered in one hour, or 99.55 gallons, or about 16 cubic feet, per minute. At this rate the engine would supply 5 jets only at a time. Mr. Smith provides for 64 jets, and 8 lines of services each two miles long, which gives 8 plugs to each line of service pipes. Mr. Smith says he never intends more than two jets to be playing at one time on a service. But if, instead of the jets playing for an hour over an acre, they are playing for rather more than three hours; then two jets on each service, or 16 jets, may be playing together, and the engine will supply them.....The additional head required to overcome the friction of the water passing through the main, services, and hose, will be equal to 24 feet; but if only 8 jets, or half the number in the former estimate, are playing at the same time, then the water must travel through the hose at twice the velocity, (to deliver an equal quantity of water) and the head of water to overcome the friction must be 35 feet, and if only 5 jets are open at the same time, as proposed by Mr. Smith, to deliver the same quantity of water in the same time, the additional head required to overcome friction would be still further increased to 67 feet. Mr. Smith however seems to have lost sight of the fact that friction of water through pipes increases as the squares of the velocity, and that to force double the quantity of water through the same sized pipe, is equivalent to doubling its velocity, and would therefore require four times the pressure, and consequently an addition must be made to the proposed head (viz. 200 feet) of 24 feet, 35 feet, or 67 feet, depending upon the number of jets opened at one time, which regulates the delivery; and if in the latter case the level of the ground proposed to be manured should be 133 feet above the town,* there would be *no pressure* at the nozzle to create a jet at all, unless the head or pressure be increased beyond the 200 feet, and which head, to produce the effect Mr. Smith proposes, must be 224 feet, or 235 feet, or 267 feet, depending upon the number of jets playing at *one* time. But taking the most favourable arrangement for working the jets, which will be when the greatest number are playing at one time, the proposed head must be increased to 224 feet, and the power to 33 6-10 horses, and this will be putting the scheme in a much more practicable form, and will enable me to check the estimates.

Mr. Smith however further asserts that the twelve inch pipe is ample for *double* the extent of country, and therefore considers he may reduce his estimate of the cost of the main to one-half.†—If the main is ample for *double* the extent of country, it must be capable of conveying *double* the quantity of water, and of supplying the additional number of services for *double* the extent, and the head required to overcome the friction will be increased; with sixteen jets playing *on each plot*, it will be equal to 92 feet instead of 24 feet; with eight jets *on each plot*, it will be 104 feet instead of 35, and with five jets on each plot, 135 feet instead of 67. It is evidently erroneous therefore to suppose that the same sized pipe *could* convey *double* the quantity of water "to supply other sections of land of equal extent."

Again: Mr. Smith gives another estimate of the cost of supplying *double* the quantity of sewer water to the *same* section, and assumes that this can be done for the *same* outlay, forgetting that the head for friction must be quadrupled; and that if 16 jets are to be supplied with double the quantity of water, it would require a head of 96 feet instead of 24 feet; and for 8 jets it would be 140 feet instead of 35 feet; and for 5 jets 268 feet instead of 67 feet; but taking, as before, the most favourable case, that of the 16 jets, the head of water must be 296 feet instead of 200 feet; and the power required for raising *double* the quantity of water, under this *increased* pressure, must be equal to 88.8 instead of 30 horses power.

The next point for consideration, and a most important one, in reference to the supply of sewer water by pipes, is the actual number of days during the year, on which the engines can be kept at work pumping the sewer water on to the lands—as it is evident that upon this point must depend the power of the engine, the size of the pipes, and the capacity of the reservoir for preserving the sewage, at periods when it cannot be thrown over the land. Assuming the periods for this purpose to be on the aggregate equal to six weeks in the year; and that the engine will be constantly pumping sewer water during this time, 7 days per week, for 12 hours each day, the quantity of water raised by the engines must be equal to 6,300 cubic feet per minute.

As the sewage water is constantly flowing every day throughout the year, while the period for delivering it upon the lands is but six weeks—i.e. 504 hours in 8,760, it is evident that the reservoir must be capable of holding the supply afforded during 8,256 hours, or 5,020,278 tons; consequently the capacity of the reservoir will be 6,663,917 cubic yards, and at a depth of 12 feet, or four yards, its area at the mean water line will be equal to 344 acres—if a square, the length of each side will be 1,290 yards, OR NEARLY THREE-QUARTERS OF A MILE.

Taking Mr. Smith's standard of 200 feet as the whole pressure at the engine, which, as he proposes to raise the water over a standpipe column, may be considered sufficient,‡ the power of the engines required will be equal to 2,389 horses, and should it be thought advisable to increase the pressure, the power must also be increased in the *same* ratio.

In explaining the plan proposed to be substituted, Mr. Wicksteed adduces some general reasons for supposing that the cleansing of the metropolis would be secured effectually by mechanical means, than by the tidal action of the river. At present it is necessary to make the main sewers of great capacity, because their contents can be delivered into the river, at or

* That this elevation may be expected in cases where it is necessary to go to a distance from the town, seems to have been anticipated by Mr. Smith himself, in his statement quoted in page 12 of this Report, where he states "That the water of most towns can be disposed of at from 50 to 100 feet, and will seldom be required to be raised more than 400 feet.

† "One-half of the cost of the main pipe is only charged, as, from its position and capacity, it is sufficient to supply other sections of land of equal extent."—See Mr. Smith's Report on the Application of Sewer Water to Agricultural purposes. Published by the Health of Towns Commission.

‡ The height of the standpipe lately erected by me at the Grand Junction Water Works, near Kew Bridge, is about 210 feet,—the height of the Monument is about 202 feet.

near low water only—a period at which the delivery upon the shores most offensive to the public; and although this part of the evil might in some measure be remedied by the adoption of the plans proposed by Mr. Walker and Mr. Page, for extending the existing sewers into low water, still the contamination of the river would remain the same. At all other states of the tide, the sewage is pent up and held back, these large sewers becoming reservoirs, to contain the quantity collected during those periods in which the height of the tide prevents its discharge into the river.

Another evil now arises, not more offensive than injurious: the foul air not being carried off with the current into the river, necessarily and naturally rises through any openings it can find, and a stream of noxious effluvia is evolved.

A further disadvantage resulting from this penning up of the sewage, is, that the current through the sewers being checked, the water becomes quiescent, and the heavy particles previously held in mechanical suspension are deposited, and accumulate. When the current in the sewers re-commences, it is slow, depending upon the rate at which the tide falls into the river. Until it has fallen below the level of the pent-up sewage, there is no fall in the sewer. Then as the tide falls inch by inch, so does the fall in the sewer increase, but not in the same ratio, because the water being always running, the relative difference between the two levels is always diminishing. The case would be different were the sewer water held back by mechanical means, until there was a sufficient fall of tide in the river; but it is not so—the process is gradual, and no fall is obtained sufficient to scour away the accumulated deposits. Hence the necessity of manual labour to clear away these offensive deposits, which must be brought to the surface, or for machinery for carrying it off by flushing, and the demand for larger supplies of water, which would be useless unless there was an uninterrupted current in the sewers.

The following is an outline of Mr. Wicksteed's own plan of making the sewage manure available. He proposes to collect it in one large reservoir where it is to be dried and packed like guano for sale. As regards the northern side of the Thames, it is proposed to construct a Circular Sewer of eight feet diameter: to extend from the end of Grosvenor-road, to pass through, in an easterly direction, Tothill-street, Westminster Abbey-yard, King-street, Whitehall, Strand, to the end of Fleet-street; from thence a sewer of twelve feet diameter in continuation across through Ludgate-hill, the south side of St. Paul's Church-yard, Watling-street, Cannon-street, Tower-hill, Ratcliffe highway, Commercial-road, under the river Lea, above the Iron Bridge, and from thence in a straight line through the West Ham Marshes, to the proposed works, in an angle formed by the western banks of Barking Creek and northern banks of the Thames.

The necessary communication between the present sewers and the intercepting sewer will be effected by means of shafts from the top of the proposed sewer to the underside of the existing sewers, so that whatever so flows through the present sewers must flow into the intercepting sewer; unless in case of long continued rains or storms, when if much more than double the usual quantity of water should pass down, then as soon as the intercepting sewer is fully charged, the surplus water would run off through the old channels into the Thames. The sewers will, however, at these times, be relieved by an additional outlet of large capacity, the proposed sewer forming a communication with the Thames at Barking. All the flaps at the mouths of the present sewers will have to be made water-tight, to prevent the water of the Thames flowing at high water into the intercepting sewer, *unless required*, although this, of course, will not prevent their being available for allowing the surplus waste to flow into the Thames when necessary.

The new sewer has a fall of 12 inches per mile, which will give a velocity of 120½ feet per minute in the 12 feet sewer, and 98 2-10 feet per minute in the 8 feet sewer. The main sewer will terminate in a receiving reservoir, in the Barking Marshes. The engines will be equal to an aggregate power of 1,000 horses, and will be capable of raising, when worked at their full power, 56 feet high, 18,112,320 cubic feet in 24 hours, equal to more than 2½ times the present ordinary quantity of sewer water. The sewer water will be raised into reservoirs sufficiently elevated to allow of its solid contents being deposited at a level above the Trinity high water mark, so that it can easily be shipped, or loaded into railway trucks, and that the refuse liquid may be discharged at all states of the tide. And lastly, the deposit in the reservoirs will be removed periodically, and dried by artificial means, and then compressed and packed up, ready for transmission by land or water.

TUBULAR BRIDGE OVER THE MENAI.

The following is an abstract of the report on this gigantic undertaking, made by Mr. Robert Stephenson to the Chester and Holyhead Railway Company, and read at their last meeting.

"I have throughout the experiments carefully studied the results as they developed themselves, and I am satisfied that the views I ventured to express twelve months ago were in the main correct, and that the adoption of a wrought-iron tube is the most efficient, as well as the most economical description of structure that can be devised for a railway bridge across the Menai Straits.

"In the course of the experiments, it is true, some unexpected and anomalous results presented themselves; but none of them tended, in my mind, to show that the tubular form was not the very best for obtaining a rigid roadway for a railway over a span of 450 feet, which is the absolute requirement for a bridge over the Menai Straits.

"The first series of experiments was made with plain circular tubes, the second with elliptical, and the third with rectangular. In the whole of these, this remarkable and unexpected fact was brought to light, viz., that in such tubes the power of wrought-iron to resist compression was much less than its power to resist tension, being exactly the reverse of that which holds with cast-iron; for example, in cast-iron beams for sustaining weight, the proper form is to dispose of the greater portion of the material at the bottom side of the beam, whereas, with wrought-iron, these experiments demonstrate beyond any doubt that the greater portion of the material should be distributed on the upper side of the beam. We have arrived therefore at a fact having a most important bearing upon the construction of the tube, viz., that rigidity and strength are best obtained by throwing the greatest thickness of material into the upper side.

"Another instructive lesson which the experiments have disclosed is, that the rectangular tube is by far the strongest; that the circular and elliptical should be discarded altogether.

"This result is extremely fortunate, as it greatly facilitates the mechanical arrangements for not merely the construction, but the permanent maintenance of the bridge.

"We may now, therefore, consider that two essential points have been finally determined—the form of the tube and the distribution of the material.

"The only important question now remaining to be solved is, the absolute ultimate strength of a tube of any given dimensions. This is, of course, approximately solved by the experiments already completed; but Mr. Hodgkinson very properly states, that others, with tubes of more varied dimensions, should be continued, in order to clear up some anomalies which still exist.

"The formula, as at present brought out by Mr. Hodgkinson, gives the strength of a rectangular tube of the dimensions I proposed—viz, 450 feet long, 15 feet wide, by 30 feet high (assuming the plates to be one inch thick) equal to 1,100 tons applied in the centre, including the weight of the tube itself; but, deducting the latter, equal to 747 tons in the centre, or double this, supposing the weight to be uniformly distributed over the whole 450 feet.

"This amount of strength, although sufficient to carry any weight that can in practice be placed upon the bridge, is not sufficiently in excess for practical purposes. It is on this ground, therefore, I have requested Mr. Hodgkinson to devise a few more experiments in the shape best calculated to free the formula from all ambiguity. In the meantime, however, as I consider the main question settled, I am proceeding with the designs and working plans for the whole of the masonry, which I expect to have the pleasure of submitting to you in a fortnight from this time.

"You will observe in Mr. Fairbairn's remarks, that he contemplates the feasibility of stripping the tube entirely of all the chains that may be required in the erection of the bridge; whereas, on the other hand, Mr. Hodgkinson thinks the chains will be an essential, or at all events a useful auxiliary, to give the tube the requisite strength and rigidity. This, however, will be determined by the proposed additional experiments, and does not interfere with the construction of the masonry, which is designed so as to admit of the tube with or without the chains.

"The application of chains as an auxiliary, has occupied much of my attention, and I am satisfied that the ordinary mode of applying them to suspension bridges is wholly inadmissible in the present instance; if, therefore, it be found hereafter necessary or desirable to employ them in conjunction with the tube, another mode of applying them must be devised, as it is absolutely essential to attach them in such a manner as to preclude the possibility of the smallest oscillation.

"In the accomplishment of this I see no difficulty whatever; and the designs have been arranged accordingly, in order to avoid any further delay.

"The injurious consequences attending the ordinary mode of employing chains in suspension bridges were brought under my observation in a very striking manner on the Stockton and Darlington Railway, where I was called upon to erect a new bridge for carrying the railway across the river Tees, in lieu of an ordinary suspension bridge, which had proved an entire failure.

"Immediately on opening the suspension bridge for railway traffic, the undulations into which the roadway was thrown, by the inevitable unequal distribution of the weight of the train upon it, were such as to threaten the instant downfall of the whole structure.

"These dangerous undulations were most materially aggravated by the chain itself, for this obvious reason,—that the platform or roadway which was constructed with ordinary trussing for the purpose of rendering it comparatively rigid, was suspended to the chain, which was perfectly flexible, all the parts of the latter being in equilibrium. The structure was, therefore, composed of two parts, the stability of the one being totally incompatible with that of the other; for example, the moment an unequal distribution of weight upon the roadway took place, by the passage of a train, the curve of the chain altered, one portion descending at the point immediately above the greatest weight, and consequently causing some other portion to ascend in a corresponding degree, which necessarily raised the platform with it, and augmented the undulation.

"So seriously was this defect found to operate, that immediate steps were taken to support the platform underneath by ordinary trussing; in short, by the erection of a complete wooden bridge, which took off a large portion of the strain upon the chains. If the chains had been wholly removed, the substructure would have been more effective; but as they were allowed to remain, with the view of assisting, they still partake of these changes in the form of the curve consequent upon the unequal distribution of the weight, and eventually destroyed all the connections of the wooden framework underneath the platform, and even loosened and suspended many of the piles upon which the framework rested, and to which it was attached.

"The study of these and other circumstances connected with the Stockton-bridge lead me to reject all idea of deriving aid from chains employed in the ordinary manner.

"I have therefore turned my attention to other modes of employing them in conjunction with the wrought-iron tube (as suggested by Mr. Hodgkinson), if such should be found necessary upon further investigation.

"As I have already stated in this I perceive no difficulty whatever; indeed there is no other construction which has occurred to me which presents such facilities as the rectangular tube for such a combination.

"Having, I trust, clearly explained my views in reference to this important work, I have only to add that in two months I expect every arrangement will be completed for commencing the masonry, which shall be conducted with the utmost activity and vigour.

"I can scarcely venture to say, until after these arrangements are finally completed, at what period we may calculate upon the completion of this bridge; but I cannot recommend you to calculate upon the whole being accomplished in less than two years and a half."

WEIRS ACROSS RIVERS.

Report by the Committee of the Clyde Trustees on the Weir Question.

The Committee believe the present position of the Clyde Trustees, as regards the question of the weir proposed to be erected across the Clyde, is as follows:—From the Act procured last Session of Parliament by the Bridge Trustees, containing clauses to the following effect:

1. That the Bridge Trustees are entitled to form a new dam or weir at or about one hundred and forty yards above Hutcheson's Bridge, having a lock or work therein, or connected therewith, at the expense of the Clyde Trustees.

2. When these works are erected, the Bridge Trustees are then authorised to remove the weir or works placed at the Stockwell Street Bridge by the Clyde Trustees, at the Clyde Trustees' expense

3. The Clyde Trustees are obliged to contribute a sum towards sinking and building the piers and foundations of the new Bridge at Stockwell Street. And the Clyde Trustees are obliged to maintain the weir and lock constructed by the Bridge Trustees, at their expense, in all time coming. No detailed plans or estimates exist of the weir and lock. The Act provides that the cost to the Clyde Trustees, of the whole works for which they are made liable, shall be fixed by two Engineers or Arbiters appointed by the Sheriff.

Whether the Clyde Trustees ought to contribute to the building of a Bridge over the Clyde, is not within the remit to this Committee; and having stated the present position of the Clyde Trustees as regards the weir, the Committee proceed to the consideraton of the effect of the proposed dam or weir upon the navigation of the Clyde.

The Committee believe that all Engineers now act upon the principle of giving the greatest possible freedom of admission to the tidal waters, as the best means of improving navigable rivers,—the recession of these waters carrying down with them to the sea, the alluvial matter held in suspense by the waters of the river; and in proportion to the quantity and velocity of the retiring tidal wave, is the benefit derived from its cleansing and deepening power.

In order to carry out this principle, now well understood and universally acted upon, Engineers widen, straighten and deepen the channel of rivers, from the sea upwards, as far as the tidal wave can be enticed to come, and break up and remove all obstacles to its progress, whether natural or artificial. The tidal wave in the Clyde, according to the report of the late Mr. M'Quiston, confirmed by subsequent observation, can be made to flow seven miles above the City of Glasgow, and give an additional pressure and impetus to the retiring tidal wave of not less than eighty-millions of cubic feet of water at ordinary tides; and if the river be properly deepened, even this quantity of water may be increased. The Committee therefore take leave to recommend that no weir or dam be erected across the Clyde within the reach of the tidal flow.

The Trustees are aware that the largest portion of their stated outlay is upon dredging in the River and Harbour; and the Committee are satisfied that a very large proportion of this outlay might be saved by the employment of the powerful natural agency of the tidal waters. The expense of dredging from July, 1840, to July, 1844, amounted to a very large sum, and it constitutes by much the largest item of our annual expenditure. The heaviest portion of this expenditure was upon the Harbour, where dredging is performed at great inconvenience to the shipping, and to the business of the Port. Nor will it in the opinion of the Committee, ever be otherwise, until the River above be cleaned and deepened, and a body of water procured sufficient to scour the Harbour, which at present serves as a settling pool for the upper waters.

It will be said that the Clyde Trustees have no power under their Acts to operate upon the River to the eastward of Stockwell Street Bridge, and that their Acts bind them to maintain the present level of the River.

The Committee believe that if the Clyde Trustees can show that the Navigation of the Clyde is to be benefited by an extension of their powers, say for seven miles above the Stockwell Street Bridge, penetrating into the heart of the mineral districts, Parliament will grant these powers; and in regard to their obligations to maintain the present level of the River to the east of Stockwell Bridge, for the protection of certain public works, the Committee believe that the Clyde Trustees were coerced into the admission of these clauses into their Bill, and that there are other and better modes of protecting these works than by a weir across the Clyde. The Committee refer to the analogous circumstances and condition of similar works along the course of the River, beneath the Stockwell Street Bridge, because, if a like protection to these public works had been sustained, there could have been no deepening or improvement of the Clyde Navigation. The Committee, in short, believe, that no public companies, whether constituted by Act of Parliament as Canal Companies, or Water Companies, Joint Stock Companies, or private individuals having works on the banks of a navigable river, using its waters, or having a right of access thereto, can for their interests control or prevent the improvement of a public navigable river, as far as the tidal flow reaches.

From the absence of all detailed plans or descriptions of the works to be erected at the weir, the Committee can give the Trustees no information as to the height or *elevation* of the intended weir; but from its containing or being connected with a lock, the committee are led to believe that the weir or dam must be elevated to *such a height* as to enable the lock to be wrought at all times of the tide, and in all conditions of the river, or it is evident it must be useless for navigation purposes. The Committee cannot believe that so bold and injurious a measure *as the elevation* of the channel of the Clyde would be attempted, although there is an indication of such an intention on the very small plan submitted to Parliament; and without such elevation, the works described appear to the Committee to be either useless or impracticable.

The Committtee, therefore, take leave to recommend that the Clyde Trustees apply to Parliament next Session for powers to open up the navigation of the Clyde to a distance of say seven miles above the City of Glasgow, to construct all necessary works, and levy such dues as shall be judged fitting and proper. They will thus, in the opinion of the Committee, give great facility for the conveyance of minerals, country produce, and traffic of every description to and from the Harbour; and what is of equal, if not of greater importance, they will, by the recession of the tidal waters, be enabled to keep the whole channel of the river clear at a very moderate expense, and thereby be enabled to devote several thousands a year, now expended in dredging the River and Harbour, to other purposes.

The Committee farther recommend that the Clyde Trustees intimate to the Bridge Trustees their intention of going to Parliament next Session, in order to prevent the Bridge Trustees from constructing a weir across the River Clyde, with a lock or works therein, and that the Bridge Trustees, in the erection of their Bridge, do not in the meantime interfere with the bed of the River, so as to prejudice the Clyde Trustees in their position as regards the Water Company and other parties.

Before concluding their Report, the Committee also beg to direct the attention of the Trustees to what is already partially before the Trustees, viz.—the attempt upon the part of a Canal Company, to take possession of the River Clyde at and above the proposed new weir at Hutcheson's Bridge, and to make additional works in connection with that weir. The Committee have not been able to procure a sight of the plans of the works which the Canal Company propose to attach to the weir; but as the whole scheme implies the existence and continuance of a weir across the Clyde, the Committee trust the Clyde Trustees will not be consenting parties to any such scheme, but will oppose it with all their power and interest, and compel the Canal Company to terminate their works within the northern line of high water.

And the Committee farther recommend that a copy of this Report be sent to the Lords of the Admiralty, and another copy to the Tidal Harbour Commissioners.

Archd. M'Lellan, *Convener of Committee.*

PROCEEDINGS OF SCIENTIFIC SOCIETIES.

INSTITUTE OF BRITISH ARCHITECTS.

January 26.—J. B. Papworth, V.P., in the Chair.

The Very Rev. W. Buckland, D.D., was elected an Honorary Member, and F. C. Penrose, Esq., an Associate.

A letter was read from Herr Zanth (honorary and corresponding member of the Institute), at Stutgard, descriptive of a Casino, now nearly completed from his design and under his superintendence, for the King of Wirtemburg. The structure—named after the royal owner, "Wilhelma," is of stone, in the Moresque style, the courses of the masonry being coloured white, yellow, and red violet, and covered with copper, partly gilt. It is situated in a winter garden, in the midst of four conservatories with porticoes, steps and terraces, and parterres;—it consists of a vestibule, an Oriental court, with a fountain, a picture gallery, a divan, a saloon, an eating-room and appurtenances, a sleeping and dressing room, and a bath with an arched roof, decorated with pendants. The conservatories and porticoes are of cast iron, very slender, and richly ornamented;—in the same taste, the conservatories divided into two aisles, containing various rare flowers, abut against two pavilions, surmounted by glazed octangular cupolas, for tropical plants;—the entire extent is about 350 feet; at the end of the conservatories the porticoes commence, which form the enclosure of a flower-garden, for the private use of the king.

Mr. C. Fowler, Fellow, on presenting some plans and designs relative to the proposed Thames Embankment and railway street, read a paper on the projected lines of railway in the metropolis about to be submitted to Parliament. Mr. Fowler stated that he was indebted for most of the details to Mr. Austin, the engineer (Hon. Secretary to the Metropolitan Improvement Society), who had been at considerable pains to prepare a plan of the whole of those lines for which the deposits had been completed. He need scarcely say, that there had been a number of other schemes, which had not survived the fatal effects of the panic; of those that remained, it appeared from the plan *that there were twenty-one different lines*, comprising 100 miles of proposed railway. within a circle of five miles from St. Paul's. The spaces scheduled for termini within a circle of fourteen miles of St. Paul's, together with that necessary for the construction of so much of the lines, constitute an area of little short of 200 acres, being equal to that portion of London extending from High-street, Whitechapel, to St. Paul's Cathedral, included between Leadenhall-street, Cornhill, the Poultry, and Cheapside, on the north, and the river Thames on the south: nearly equal to one-third of the City, and little less than one-half of that devastated by the conflagration of 1666. On a moderate calculation, it would involve the destruction of between 9,000 and 10,000 houses, and cause an expenditure, for the purchase of property alone, of about fifteen millions sterling. Mr. Fowler stated, that a memorial on the subject had been forwarded to the First Commissioner of Woods and Forests by the Metropolitan Improvement Society, suggesting that the Metropolitan Improvement Commission should take the subject into their consideration at an early period; and observed that it behoves not only all professional men, but all who desire to see a right direction given to this extraordinary movement, to assist in promoting the same in order that this branch of railway communication may be dealt with separately and distinctly, so that a comprehensive and systematic plan may result from what at present is a heap of confusion, arising from the fact that each line has been separately laid down, without reference to, or the knowledge of, what is proposed by any other. Mr. Fowler alluded to the new principle of railway streets, and to the double object that the Thames Embankment and Railway Junction Company had in view in adopting it, namely, that of carrying out a great public improvement in conjunction with the extension of railway communication; likewise that, in the event of Government acceding to a separate and distinct consideration of metropolitan lines, an opportunity was at present afforded which could never again occur of effecting the improvement of this great metropolis, as to salubrity, convenience, and splendour, without, probably, any sacrifice on the part of the Government. Mr. Fowler adverted to his design for carrying a railway over London-bridge, as one of the means proposed to connect the lines now terminated at the south end of the bridge with that projected through the City from Hungerford-market to the Blackwall line. This was proposed to be effected by the addition of arcades; covering the footways with iron framework, extended over the carriage-way to carry the rails: the former of these additions had been projected by him in one of the designs submitted to the House of Commons, when the reconstruction of the bridge was under consideration.

February 9.—Mr. Tite, V. P., in the Chair.

NEW MODEL OF THE PARTHENON.

A discussion took place which excited more than ordinary interest, and attracted a very crowded meeting of the members of the Institute, the subject being the consideration of certain questions respecting the original architecture of the Parthenon, suggested by Mr. Lucas's models recently deposited in the British Museum.

Mr. Lucas commenced the discussion by reading the following paper, of which he has obligingly furnished us with a copy.

Mr. President and Gentlemen,—I beg to offer you my best thanks for your obliging courtesy, in the opportunity thus afforded me of introducing the subject of the Restoration of the Parthenon, before it may be, the most severe, but at the same time certainly, the most competent tribunal—and I bring this subject before you with much anxiety, conscious as I am that the portion of my work you are most likely to sit in judgment on, is that to which my previous studies had been but cursorily directed, and but that I appear before you rather to court correction than to impart information, I should now feel as though I were bearding the lion in his own den. Sir, it is our lot to live at a period when improvements in every department of science have been carried to great results; and though in the fine arts, a commensurate development of successful energy is not yet apparent, the time is now come when the artists whose works are the most enduring chronicles of the great events of their period, should bestir themselves, for it cannot have escaped our observation, that within the last few years simultaneously and apparently without any connection, a general tendency to revive the study of high art has sprung up in the most intellectual parts of Europe, in Germany, England, Denmark, France—while in England, from many happy circumstances, art appears likely to assume a high position.

I have, Sir, in the course of my reading met with the observation that to have a difficult subject thoroughly investigated, we should set to the task one who has a fitting amount of natural qualifications, but who is entirely ignorant of the theme; place at his disposal all means and appliances of study, and if it be his aim (as mine is) to investigate solely for the production of the truth, you may then get the subject treated with all the zeal of the advocate, united to the calmness and sobriety of the judge, even though the subject matter be so important as the master work of Ictinus, or the profound science displayed in the triumph of Phidias; a theme so glorious immediately rouses in the mind of the investigator all the latent or dormant energies of his nature, with no inaccurate early impressions to remove from his mind, no erroneous foregone conclusions to bias his judgment, he surveys with ardour and enthusiasm, but records with calmness and indifference, untramelled by the vividness of early impressions; he is competent to seize and to analyze all the salient points of controversy, and to arrive by induction at sound conclusions.

But from this mode of proceeding one defect may be anticipated which ought to be guarded against, namely, that in investigating the details of an interesting subject, a few points already too partially investigated may be taken for granted, and therefore some matters not apparently important to the high bearings of the case may be overlooked or underrated; but it is my good fortune to introduce the result of my labours where the spirit of them will be fairly appreciated, will for minor blemishes not materially effect the whole performance in its general appeal to the understanding, and I am sure that you, Sir, will always appreciate a work according to its merits, and judge the artist with respect to his intentions, and the peculiar circumstances under which his work was executed. Our subject, Sir, appears naturally to resolve itself into a recapitulation of the known and admitted facts of the case, including its general history, architectural construction and sculptural adornments, with a consideration of the doubtful or uncertain portions, included in which is to be placed the question relative to the interior of the Temple, its polychromatic adjuncts, the Chrys-elephantine statue of the Goddess, the central portion of Eastern Pediment, with the missing metopes frieze-shields, &c. and having examined these matters I propose very briefly to investigate the principles that guided these great artists in the adornment of their works. It is necessary for the unity of the subject I should notice the known parts, but only very briefly.

It is well known that the Parthenon was erected at Athens about B.C. 440, in the most flourishing and glorious period of that great republic, under the auspices of her greatest statesman, Pericles, and from the designs of the greatest sculptor and of the most celebrated architect of the ancient world, Phidias and Ictinus. It stood on the summit of the Acropolis, was a Doric temple, 227 feet in length on the upper step, by 101 feet in breadth. It was constructed entirely of Pentelic marble, and, including a stylobate of four steps, was 66 feet in height; it was called Hecatompedon, or the building of a hundred feet; and from its united excellencies of design, decoration and material resulting from the fine taste, unbounded means and munificence of Pericles, it may be recorded as the most perfect that was ever executed. In the Parthenon was consummated the noble triple union of architecture, sculpture and painting; in it was the artist's triumph complete, and art reached its acmè.

In the construction of the columns of the exterior much subtlety of management appears to have been used, such as the well known facts of the inclination of the columns 1½ inch inwards, and that of the outer or angular ones of the exterior being larger by 2½ inches diameter than the others; and I have also been informed that the enstasis or swell is dissimilar in the different columns, and that the diameters of others besides the end ones are also different; but the most curious circumstance is the last I have heard, and which I believe a talented member of your Institute, recently arrived from Athens, can testify to you, viz., that *all the capitals* on the south side of the temple are 6 inches smaller than any others, and I hope also now to learn if the diminution of these capitals be confined to the ovolo under it, or whether it serve to increase the entasis of the columns generally; other further peculiarities of structure may here be alluded to. Mr. J. Pennethorne in his work observes, that he found the upper step of the Parthenon to form a simple curve rising 3 inches in the centre, that higher in the front the curve changes its character, and in the architrave becomes a curve of a double curvature. And Mr. Bracebridge informed me that on stretching a string from the two ends of the front lower steps he found that the centre of it receded two inches from the string.

[Mr. Lucas then detailed at some length the history of the Parthenon from the time when the Acropolis was beseiged by the Venetians in 1687, to the time of Lord Elgin—the general character of the sculpture, &c., but as these points are fully considered in Mr. Lucas's published observations, they are here omitted. After a minute examination of the designs of the sculpture in the pediment, the lecturer proceeded as follows.]

In restoring the Parthenon the question that is most difficult to grapple with, and least likely to be successfully investigated, is the interior of the Temple, it having undergone so many transformations, each possibly leaving some trace or vestige, and those vestiges so comminated together that little satisfactory information can be expected to result from the most determined application. Those most competent to judge on this matter generally arrive at different conclusions. As regards the roof, some suppose it was open, and others that it was entirely closed, and that the natural light of the heavens was supplied by artificial light, but both these suppositions appear to be untenable; the open roof hypothesis being met by an ancient epigram on the statue of Jupiter in ivory and gold, in a temple similar to the Parthenon, namely, that *if the god rose he would carry the roof with him;* while the entire closing the roof and consequent exclusion of the best light for a statue, the light of day, seems very improbable. A partial opening admitting light, by the means of some semi-transparent substance, appears in the absence of all proof the most feasible supposition.

As to the columns that supported the roof equal obscurity exists, the most probable supposition being the last one on the subject, and which has only been lately brought to light on destroying the mosque, in 1844. M. Pittakis, in a letter to me on the subject, gives it as his belief, that the traces of Doric columns found on this removal of the mosque, with a diameter of five feet, supported an upper tier of the Ionic order. This statement of the diameter of the lower or Doric tier, being of the proportions of five feet in diameter, is confirmed by the personal observations of Mr. Bracebridge, and of Mr. Penrose. On the other hand, in letters read at this Institution, from Mr. Knowles, a month since, the diameter is given at 3ft. 7½ in. I am at a loss to account for this great discrepancy on a subject so interesting, and apparently so easy to be ascertained. Now admitting the Doric to have been the original structure, and five feet the diameter, it then appears from the following diagram that there would be no space for an upper tier, for if it be an Ionic one, it must have been disproportionately small compared with the bulky Doric below. Supposing the Doric to have been used, I am rather disposed to believe that an upper tier could not have been used, but that some other architectural feature must here be substituted.

With regard to the chief sources of authentic information as to the use of colours by the ancients, the subject has been exhausted by the able remarks of the various writers on this matter; Mr. Hamilton, in his translation of the report of the committee who investigated the marbles of the Parthenon, appears to have had no bias on the subject, and the inferences I derive from his translation are, that some of the early temples must have been white, and that others were certainly painted, but no hint is given as to the period, and as to the actual tints on the most perfect specimens of remaining colour in the temple of Theseus, Semper found some blue colour under the necks of one of the antæ, and therefore drew the conclusion that the whole of the wall of the cella was blue. Scheubert on the other hand says he found on the same spot colour, and that it was yellow, and yellow in his opinion was the colour of the cella. Another observer found what he considered red, and draws similar conclusions. But although this discrepancy exists on this point, all agree in stating that above and below the frieze, in the Parthenon, the meander ornament was painted in a reddish brown. On that brown, gold has been discovered, and therefore some suppose the colour to have been the ground for the gold, and this also applies to the elegant palm leaves, on the facia, below the triglyphs and the ornament on the pediment.

Admitting as we must, from the amount of evidence that the Greeks did use much colour on their works, yet with regard to the actual mode of applying it, or the period of its most general use, we are in a state of great uncertainty.

It has been observed respecting the purity or impurity of taste in the use of colour by the Greeks, that this consideration was foreign to a restoration, that it was for us to decide on the question by the proofs as adduced, and that in restoring we must restore colour as *demonstrated*, and that we have no right to set any fastidious idea of our own in the use of colour in opposition to the practice of the Greeks, where that practice admits of proof. To this however I would beg to demur, that from our practice in the use of colour, we have no right to assume, that the ancient Greeks used colour as we now apply it, especially in their application of it to their highest uses in painting their divinities. We have it in evidence that the columns of the Parthenon were painted red, but the circumstance that the paint exists in the *opening of the joints* of the columns demonstrates that the colour was applied at a late period, subsequent perhaps to some earthquake or other commotion, because on the completion of the temple the joints were so close as to prevent the insertion of colour. Now it does appear to me, that of a style of art so severe and chaste as the architecture and sculpture of the Parthenon, the high excellence can only be comprehended and appreciated, by our having still in existence enough of the precious fragments to form some conception of the effects of the whole. What kind of idea could we have formed of the architecture and sculpture from mere description or fragmentary evidence? Let us reflect—what idea does our own art give us of the perfection of Greek art, except as a close imitation of that which actually exists. Without the actual work of the Greek artists before us, who could have propounded any resuscitation of its high excellence either in form or execution? And in like manner from the nature of things, I am entitled to contend that in the best times of Greek art, where colour was applied, it was used with equal severity, chastity, skill and purity, as the sculpture and architecture demonstrate, and therefore reasoning from analogy as from fragments alone, we could not hope to restore as a whole, neither can we in colour hope to reconstruct with our limited opportunity of observing, not so much perhaps as to the actual tints as to the mechanical application of them, after the beautiful sculpture had received all its wonderful discriminative touches, the marking of bone, tendon and muscle. Does it seem probable that men of such cultivated tastes would have smeared over these highly wrought forms with oil and earth? Does it not, Sir, seem more probable that the surface was *stained* with colour, not coated with a pigment? in using colour to embody the forms of their deities, we may be assured that the same amount of skill, pure taste, and beautiful appliance would be used as was shown in producing and finishing the actual form. Viewed in this light, it is by the power of the imagination, and this power alone, that we of these latter days can comprehend the glorious aspect of the Parthenon, in its integrity of colour as well as form. It may be that my bias may render me an incompetent judge on this subject, but I have searched with much assiduity, and I believe that all the colour I have seen results from the surface being stained, not painted. In some parts colour remaining, shews the pure surface of the marble where it has been protected by the pediment; and where exposed. In some parts the original surface is still preserved by the means applied to tint it, and as the other surrounding portions are deeply corroded by time or drip, so I believe that the process of tinting hardened and preserved the semi-transparency of the marble; and of that mode of execution as applied to sculpture, I do not think we have acquired the secret.

Having thus briefly explained the structure and decorations of the Parthenon, we proceed in our endeavours to investigate the principles of design that characterise this great work of Phidias and Ictinus. The effect which their work creates on our minds appears everywhere to be produced by the same means,—variety and contrast in unity—whether in its architectural construction, in the selection of the subjects for the sculptures, or in their composition and treatment. In the architecture, the solemn and rigorous uniformity of its masses, and the severe proportions of the columns, contrast marvellously with the boundless diversity of the lines of the sculpture. And while unity is thus preserved by the symmetrical character of the whole structure, clearly and intelligibly stated to the eye, and commanding the observance of the mind, the attention is enchained and preserved by the beautiful and harmonious play of light and shade resulting from the inner columns of the pronaus being smaller than the outer, and being placed on steps, which carry the inner architrave higher than the outer. The beautiful frieze is thus placed above the spectator's first glance, and reserves for him beauties veiled from his first impression, and therefore far more effective in their unobtrusive display at the proper period.

It was thus, by an inexhaustible power of invention that Phidias produced that great impression, which all minds gifted with a perception of the beautiful acknowledge, in the contemplation of the Parthenon; and, for ourselves, let it be our study to dwell on these noble works, and to seek to imbue ourselves with their spirit and power, in the choice of noble theme, in composition and treatment. This, then, is the proper influence these noble examples should exercise on our art, to produce a truly National School of Sculpture; for we cannot be blind to the circumstance, that merely repeating the *forms* of Greek art; must altogether fail in producing such a desideratum. Greek art was perfect because it was national, because its peculiarities suited alike the national feeling and the national religion. An attempt to repeat the mere forms, whether united to their myths or without that appendage, must fail to satisfy in any department of art, as far as regards the producing an English School, either in poetry or sculpture, painting or architecture; yet the contemplation of the myths of the Greeks is full of interest and use, as adding to the amount of our knowledge of the operations of the human mind, and here we may learn how man sometimes produces results so perfect as to become laws, and as it were to form an eternal model of fitness and propriety, the result of wants perfectly supplied, of ideas perfectly embodied, of national feelings incorporated with and represented by national emblems.

It requires indeed a considerable knowledge of Greek art to be able to appreciate the full amount of influence it may exercise, and a still more thorough acquaintance with their works, to comprehend their real scope and depth, and it is not therefore surprising that a high general estimate of this art should prevail, and yet that it should be but little understood, or that its influence should *be limited.* It may be said—what are the excellencies we are to seek and to use, to form as it were part of our nationality? I answer the general comprehensiveness of plan, its fitness, its grandeur, its profound science, and general nobility of treatment, so unlike the meanness of plan, rigidity and utter prostration of science, so often discoverable in works, produced out of the pale of Greek art.

The whole chain of dependent facts was evolved and laid out to be examined; the most delicate shades of truth scrupulously distinguished, and as no science can exist without demonstration, the whole existed as one. *Architecture* and *Sculpture*, and *Painting* blended into consummate harmony: the Parthenon was a magnificent poem, comprehended at a glance, and in this poem of a thousand stanzas, every separate verse was a poem in itself, but subdued and aiding to the general effects by the fitness of its application, and the harmony of its proportion. This accurate systematic form which gives to Greek art its utility as an example, indeed is to be found no where else, and without it we cannot understand the science of art in its truth. Now to speak of a general system as applied to Mediæval art sounds rather curious. I speak here of the adornments rather than construction; they seem a collection of fragments—here a consistency, there an absurdity, hint and hypothesis, doubt and dogmatism, feeling and reason, cold mathematical *abstraction*, and the most gorgeous poetry, the drama and the lecture, the serious and the ridiculous, all thrown together by a hand careless in its profusion of riches, both disjointed, and constituted—these are the characteristics of the most perfect specimens of Mediæval art, and in this art they often seem to have overlooked that great advantage in Greek art, the exquisite beauty of their forms. Whether it was climate or natural temperature, or education, or social circumstances that gave the Greeks their delicate perceptions of universal beauty, no people ever existed in whose happiness it was so necessary an ingredient, or to whom it was so profusely ministered by the genius of their composers. Their whole nature was so refined that truth stripped of grace and beauty, could no more touch their minds than religion their hearts, unless veiled under a gorgeous mythology.

The Greeks succeeded in producing perfection in the art or science of pourtraying the human form in its most perfect beauty: this we also must use; for without it our art must retrograde. But we require something more than the science of beautiful form: we must use the form, and superadd a spirit of nationality. The sculpture of the ancients is the most faithful, the most eloquent, the most enduring chronicle of their greatness. If, in his solemn discourse over those slain in battle for their country, Pericles could say that *of illustrious men all earth was their tomb, and that their names were not merely graven on the sepulchral marble among their own kindred, but stored up for ever, in the unwritten registers of memory in other lands;* so may we say, at the close of this our essay on Phidias, that though the glory of it, manifested to his countrymen in distinct and familiar characters and in the fulness of its meaning, is to our distant age only dimly and distantly revealed; if we know it only by the few fragments we have preserved, or by those scattered in foreign lands, or by cold delineations and still colder descriptions, yet the image of the art survives in the mind of man, to be reflected again and again in the thought of remote posterity, an unwritten record and silent witness of the greatness of the Athenian people, and the genius of their sculptor.

"They so sepulchered in such pomp do lie,
That kings for such a tomb might wish to die."

When Mr. Lucas had finished, Mr. Donaldson read the following remarks:

You will doubtless, gentlemen, have been struck with the energy and fixedness of purpose with which Mr. Lucas has followed up his project of working out a reputation for himself by a restoration of the Parthenon, the fame of which, he hoped, would bring him favourably before the notice of the public, and no less pleased by the frankness with which he has communicated to us his ideas on the subject.

But there are other considerations of very great importance, which offer themselves in connection with so vast an undertaking. The boldness of the attempt must be justified by the qualifications of the enterprising artist. The taste and practical skill of the sculptor must be seconded by the learning of the antiquary, the professional experience of the architect, and the precision of the modeller. It seems beyond the range of human probability, that any thing less than a visit to this noblest of ancient monuments, and many weeks, nay months, devoted to the study of it on the spot, could enable any one, however gifted, to solve satisfactorily the many doubtful questions which hang over its complete restoration. We know that Palladio thrice visited Rome ere he ventured to publish his monuments of Roman architecture. Brunelleschi returned again and again to study the baths, the temples, and the ruins of that ancient city ere he felt satisfied to undertake the construction of the dome of Santa Maria dei Fiori, at Florence. Mazois repeatedly went to Naples to measure and draw the remains of Pompeii, in order to ensure a scrupulous and faithful record of the excavated buildings.

If Mr. Lucas had published his model and descriptions of it, as a restoration of the *sculptures* of the Parthenon, if the laudatory paragraphs, inserted by his admirers and friends in the public prints, had confined their eulogies to this, and had laid no higher claim than to the merit of having restored the work of the immortal Phidias, I should have left to others more competent than myself, and better acquainted with that sister art, to have examined into the proprieties of the restoration in that department. But the title-page of Mr. Lucas's own pamphlet, copies of which we owe to his friendly courtesy, states that one of the models exhibits *the temple as it appeared in its dilapidated state in the seventeenth century, and executed from the existing remains, or from authentic drawings.* The other *being an attempt to restore it to the fulness of its original beauty and splendour.* It is upon the fallacy of these statements, as regards its architecture, that I feel obliged at once to protest against the models—the one as not being a faithful representation of it in its dilapidated state, not executed from existing remains nor from authentic drawings—the other being inaccurate generally in its architectural details, and being *deficient*, instead of exhibiting the *fulness* of its original beauty and splendour.

I feel called upon to examine the subject thus specially, for the architectural errors are so contrary to the canons of the art, that the character of the profession is implicated, when we see that the Trustees of the British Museum give the stamp of approbation to these mistakes by purchasing the models, and exhibiting them in juxta-position with the very marbles of the Parthenon itself. We must give them full credit for wishing to do full justice to the high reputation of Phidias; it is only to be regretted that, from parsimony or ignorance in themselves or those around them, they should have forgotten the claim of Ictinus to the character of the first architect of his own or any age, and as having produced in the Parthenon a work free from every defect, pure in every detail, graceful in every proportion.

In the model of the Parthenon in its dilapidated state, Mr. Lucas has erroneously represented on the architrave over the columns of the Posticum, the fillet caps over the guttæ. He has not placed them at the angles, and has continued them along the flanks. They now exist at the angles, and at equal spaces along the front, as shown by Stuart, and there were none as usual along the flank.

Mr. Lucas has continued the antæ cap mouldings along the wall of the Posticum, and along the flank wall of the cella, in both which positions they never existed. Mr. Lucas has represented cornices on the inner face of the cella wall where they do not exist, nor according to the most probable mode of restoration, ever could exist.

These introductions are totally at variance with the drawings of Stuart, and cannot possibly be extant in any other authentic drawings as stated in the title-page of the pamphlet.

I must now venture to allude to the restored model. In the first place, it is less accurate as regards the steps, than that of the ruined temple. In the latter there are only three, in the former four. Upon referring to my own studies made on the spot, I find three steps of marble, and below the lowermost a slab of the same height and about the same projection of stone, and thus specifically stated in my sketch. There is then a much wider slab of stone, and a drop beyond of 3 ft. 4 in. It appeared conclusive to my mind, that the stone slab was a portion of the pavement of the area around the temple, which was laid with slabs of stone, the upper surface being level with the upper face of the stone slab under the third marble step. In fact, it would have looked incongruous to have had one step of stone and then three of marble. Besides which we have the testimony of Vitruvius, who says, Book III. c. 3. "The number of steps in front *should always be odd*, since in that case the right foot, which begins the ascent will be that which first alights on the landing of the temple." We know that our great master borrowed all his canons from the Greeks, and that the superstitions of the ancients had a common origin and a common acceptation.

The restored model shows no traces of the plinth which existed between the lower parts of the columns of the Posticum, and of which there are indisputable signs in the Parthenon. This plinth, which was 9 feet 1 inch high, and half as wide again as the centre fluting, received the standards of the metal grating which inclosed the intercolumniations up to the summit of the capitals, as is ascertained by the mortice holes still existing in the antæ. This metal work was for the purpose of giving security to the Posticum, as within it were exposed to public view many of the votive offerings of beauty and value, the riches of the temple, and being placed within the metal railing, they were prevented being injured by accident or purloined by the evil disposed. This grating was probably of bronze gilt, and many Roman bas-reliefs offer authority for a restoration.

The next inaccuracy to which I wish to call attention, is the doorway. The old aperture had been narrowed long since, either by the Venetians or Turks, by the introduction of slabs in irregular courses; beyond these slabs the wall is perfectly plain. Reasoning from the magnificence and importance of the Parthenon, which would be evidently deficient in effect if the doorway were a mere square aperture; reasoning from the analogy of the Erectheum, which has a magnificent doorway, although an edifice of less importance than the Temple of Minerva, and reasoning from the evidence to be found on the apertures of the Propylea, which had evidently bronze dressings, I have little hesitation in stating my opinion, that the dressings of the Parthenon were of bronze, and that the model is singularly unfortunate in having consoles or trusses, which support nothing, are accompanied by no corresponding embellishment, and are contrary to all reason, propriety, and example. I have already alluded to the continuation of the mouldings of the antæ caps, retained in the restoration, and quite contrary to fact. We now come to the interior of the cella, and considering the complexity of the opinions offered by Messrs. Pittakis, Finlay, and others, who were consulted by our author, it is not surprising that he should have found himself involved in a maze of difficulty. It appears that Mr. Cockerell, in the seventh volume of the Museum Publications, has restored the interior with two orders of columns; the lower are Corinthian, the upper are Doric. All the rules of the art, all analogy, and all probability have run counter to this daring arrangement. In the temples of Pæstum we find a double tier of columns, one over the other, to support the roof of the hypethrum, both Doric; but the casual statement of Mr. Inwood, that a portion of a Corinthian capital was brought by him from the Parthenon, and a similar fragment discovered in the Temple of Apollo Epicurius, at Bassæ, near Phigalia, seem to have been considered sufficiently grave authority for the introduction of the Corinthian, as one of the inner orders of the Parthenon. Assuming at once that Mr. Inwood got it from the Parthenon—How did it get there? Was it there originally? Had any other traveller—the precise Spon and Wheller, or the laborious Stuart and Revett ever seen it? Among the strange metamorphoses by Venetian, Turk, and Greek, may it not have been converted to the purpose of construction from some stray fragment beyond the verge of the Parthenon, as being lighter and more easily applicable for their purpose than the ponderous blocks of the construction of Ictinus? May it not have been purposely placed there by some wily Greek to give it additional value in the eyes of one, who was eager for any fragment of Attic art, and profusely liberal to every one who contributed to his collection? The introduction of the Corinthian order into the Parthenon involves so many serious questions in the art, that its adoption must rest upon some more authentic proof than that which accompanied this questionable fragment. But let us assume that it came from the Parthenon, and was always there; is it too much to require the restorer to pause and consider whether this may not have been a fragment from some object quite distinct from the architecture? for we know, from Pausanius, that all the Greek temples of any size and reputation were filled with statues, groups, pedestals, candelabra, ears, tazzæ, tripods, vases, seats, and other articles of wood, metal, and bronze; the votive offerings of the conqueror, the supplicant, and the superstitious. Mr. Lucas has introduced the Ionic as his lower order, and the Corinthian above; a restoration more consistent with our preconceived notions, yet still open to serious objection. However, he has given a regular entablature to his lower order, whereas, judging from the Pæstan Temple, and the reason of the thing, a mere architrave or beam were more fitting. But a more serious objection presents itself in the arrangement of the ceiling, which is made to overhang the upper range of columns for the purpose of contracting the aperture of the hypethrum. This presents so much difficulty of construction, and seems so much in advance of the science of the Greeks at that period, that I cannot but consider it as apocryphal, as also the pedimental form of some of the compartments of the ceiling, and the sloping roof over the aisles of the cella.

I have not wished to lengthen my remarks by allusions in detail to some questionable portions of the sculpture. I may, perhaps, be venturing on ground for which I am as little qualified to judge, as Mr. Lucas is to form an opinion of the architecture: but I must own, that I could have wished that the sculpture had been modelled with a refinement and finish more corresponding with the exquisite execution of the matchless original. I could have wished that one's ideas of the dignity, the splendour, and proportion of the Chrys-elephantine statue, and the grave majesty and beauty of Minerva herself had been more realized than it is in this conception; and it appears to me that the want of pure drawing, the total absence of Attic elegance and correct proportion in the rude illustrations of his pamphlet, do little justice to the intelligence of the author in the letter-press. I could have desired that the modelling and putting together of the architectural details had been less characterised by coarseness and want of delicacy. And I must own, that the prominence given to the sculptures of the pediments, the projections of the heads and limbs of so many of the figures, seem to me so much to interfere with the lines of the architecture, and themselves to be so much cut up by the intersection of the corona, as to produce a most unsatisfactory intricacy, and disagreeable contrast. Neither the drawings of Carry (perspective views taken from a low point), nor the casual signs of a water drip, which may have arisen from a misplaced slab above, nor the solitary instance of a questionable indentation of a fragment head—more than probably a rebate to receive the bronze helmet, nor the projection of the horse's jaw at a part where no shadow broke the continuous line of light, seems to me to justify the solitary instance of so marked a principle, which would have itself established a rule in all future cases, but which has never, that I am aware, been followed in any succeeding instances in ancient or modern times, that have pretensions to be considered as classic works of art. I shall conclude with one more reference, and that is to the polychromatic embellishments timidly indicated over certain parts. Mr. Lucas states, that he is not called upon to run any risk of making a *gaud* of this restoration of the Parthenon, or to depart from the severe simplicity, which is the characteristic of all the art of Phidias. The testimony of tradition as recorded in the Transactions of this Institute, the evidence on the monument itself, the fragments recently dug up, all prove that polychromy had its full development in the Parthenon. The fragments discovered in the foundations, attested the antiquity of the practice. Will Mr. Lucas venture to say, that the Parthenon, when so embellished, was a gaud? Will he assume the question, and say that the simplicity characteristic of all the art of Phidias was colourless? What is the testimony borne by the monuments of ancient Egyptian architecture? What by the productions of mediæval art?

If, in regard to the extent of polychromatic embellishment, Mr. Lucas hesitated among conflicting opinions to go to the full extent of some of the advocates for unqualified adoption of colour, I could understand his prudence; but it seems equally rash to reject all colour as to adopt it throughout: and reasoning does not seem to justify the introduction of colour in one or two parts only, which by their very solitariness contrast most harshly with the rest of the model.

In submitting to your notice these observations upon these models, I have felt called upon to do so, in order to vindicate the professional character of the English architect, which is perrilled by the conspicuous position given to a work of art, professing to be a restoration of the noblest monument of antiquity, and uniting the knowledge, science, and learning of this country. The accuracy of the English architect has been acquired by many personal sacrifices, laborious investigations, and pains-taking accuracy. The work of Stuart and the productions of the Dilettanti Society, had established the fame of the English, as the revivers and best illustrators of Greek art. But what will be the opinion of foreigners upon English architects, if this defective and erroneous restoration be assumed, as the proof by which to estimate the research, and knowledge, and skill of the English architect in 1846. In this I do not so much allude to Mr. Lucas, as to the Trustees of the British Museum. Mr. Lucas has been imprudent in calling this a restoration of the Parthenon in all the *fulness* of its original *beauty and splendour*. He has looked at it merely as a sculptor; and the architecture he has considered as subordinate to that his first object. The Trustees should have called in the advice of some one or more of the many architects who have measured the Parthenon stone by stone. They should have provided Mr. Lucas with the most perfect model of the building that modern research could have produced; and our sculptor could have worked on his restoration of the sculpture, unembarassed by considerations of the details of the architecture, for which he was neither prepared nor fitted by previous study, as he has himself modestly avowed.

I now conclude these remarks, put together in the brief interval of numerous and important professional avocations, not to detract from the merit of Mr. Lucas's courageous attempt, but, as I have said before, to vindicate my profession from the imputation of those unfortunate blemishes, which, although they may not affect the reputation of the author as a sculptor, seriously peril the fame of the English architect, scholar, and antiquary, in the estimation of the accomplished and learned foreign artists of Europe.

Mr. Lucas in reply, observed that he felt much indebted to Mr. Donaldson for his valuable suggestions, and for the obliging manner in which they were conveyed. He was not prepared to accede to the propriety of all the alterations proposed by that gentleman, but he readily allowed that in several points his own opinions were modified by what he had just heard. Much applause was expressed by the meeting at the frank manner in which Mr. Lucas made this avowal. He said that with respect to the introduction of four steps instead of three at the base of the temple, he had been guided by the authority of Colonel Leake. In the small model which was made as a preliminary to the execution of the larger work now in the British Museum, there were but three steps: but the alteration had been made in consequence of the statement in Colonel Leake's book, that the number was four, and his determination had been confirmed by a letter which he had received from Mr. Walter Grenville, stating that there was a fourth step now obscured by rubbish. He felt however the full force of Mr. Donaldson's argument, and in fact he had, from an anticipation that an objection might be made on this point, so arranged his model that the requisite alteration could be immediately effected if he should hereafter feel himself sufficiently authorised in making it.

With respect to the continuation of the mouldings of the antæ all round the temple, he had been guided by the drawings of Stuart. As the fascia and string course certainly went all round, and as in the plates published by Stuart, the lines beneath those members were also drawn as continued, he considered that he had accurately interpreted the intention of the drawings by the arrangement observed in the model. It was also necessary to observe that his original models had been submitted to the inspection of many highly competent persons, but though he was indebted to them for several valuable suggestions, no objections had been expressed as to the particular architectural features in question.

With respect to the strictures on the inclination of the doorway and the form of the consoles, he had no defence to offer. He was convinced of the propriety of Mr. Donaldson's remarks, and intended to adopt his suggestions. With respect however to the introduction of railings at the entrance he could not express the same concurrence. It appeared to him that these features were purely matters of detail, and it was obvious that there were many mere details of the interior which it would be not only impossible, but improper also, to represent in a model. In cases of this kind, especially where the artist had no guide from the remains of ancient fragments, some liberty must be given to him of using his own discretion. It certainly appeared to him that the railings in question might be with propriety omitted.

The first part of his work which he had finished was the Chrys-elephantine statue of the goddess. In the course of this work the idea had occurred to him of making a model of the temple, but he had originally entertained no higher aim than that of making the model a sort of cover for his statue. He observed that he agreed with Mr. Donaldson in not liking the present statue, and had pledged himself, without solicitation, to the trustees to replace it by another containing the result of his latter experience. The objection that he had made, that some parts of the sculpture in the pediment intersected and protruded beyond the corona, and had thereby broken the continuity of the cornice, was the objection of an architect rather than of a sculptor. His answer was this—on examining the shoulder of the Ilissus, it would be found that this part of the statue was marked and worn by the constant dripping of water, and it was therefore clear that this part of the figure could not have been sheltered by the projection of the cornice. The Ilissus was only a fragment, still from the attitude it could at once be seen that the head must have been higher and more forward than the shoulder; and as the shoulder must have been, at the very least on a line with the cornice, the head must have projected considerably beyond it. His reasoning was confirmed by the drawings of Carrey, who had represented the sculpture as intersecting the line of the cornice. The case of the Ilissus was by no means a solitary one, as, for instance, the horse's head and the fragment of the head of the Minerva of the western pediment, and Carrey represented the same state of thing as existing in numerous instances throughout the temple. Mr. Lucas said he was therefore by no means prepared to assent to any change in this respect, but firmly maintained his original opinion.

He had made preparations for shortly visiting and minutely examining the temple. He felt very much indebted to the Institute for the suggestions which had been expressed there, and for the manner in which his explanation had been received. His great and anxious desire was to render the model as perfect as possible, and he earnestly assured the members that he was desirous of hearing every objection that could possibly be brought against it, as by these means errors would be corrected and doubtful points as far as possible explained. For his own part, he promised that no effort should be wanting towards the fulfilment of these important objects.

The PRESIDENT expressed in warm terms the obligation of the society to Mr. Lucas and Mr. Donaldson for the information which they had afforded. He would observe respecting the railings of the Opisthodomus, that as that part of the temple served as the treasury, and contained the votive offerings which were of immense value, it seemed necessary that it should be guarded by railings, and he thought they might properly be represented in the model. He invited Mr. Lucas to examine some models of the Parthenon in his own possession, which had been made by a gentleman who had measured every square inch of the ground. A great benefit arising from the exhibition of Mr. Lucas's models would be the enlightenment of public taste, and the illustration it would afford to those not conversant with architecture, of the form of the Parthenon. He was convinced that many who visited the British Museum, had an impression that the Elgin Marbles were hung round the interior walls of a room resembling that in which the remains are now deposited. The new model would serve to correct this error. The President concluded by expressing in very happy terms the thanks of the meeting for the papers which had just been read.

Mr. DONALDSON said that he must make one remark before the meeting separated. He trusted that the Institute would render every assistance to Mr. Lucas in the investigation which he was about to commence, and would use its influence with the Trustees of the British Museum, that they might liberally offer to Mr. Lucas every possible facility and assistance in the prosecution of his undertaking.

Feb. 23, Mr. TITE, V. P., in the Chair.

Mr. Penrose read a paper on the entasis and other carved lines observed in the architecture of the Parthenon, but as the paper of Mr. Lucas, on a somewhat similar subject occupies a large part of our present number, we must defer the report of Mr. Penrose's paper till next month.

ROYAL SCOTTISH SOCIETY OF ARTS.

January 26.—The PRESIDENT in the chair.

The following communications were made:—

In place of Mr. Lawson's Paper on Hurricanes, which was postponed till next meeting, the Secretary gave an Account of Mr. Jacob Owen's (of Ireland) Paper on the Results of Experiments on the relative Strength of different forms of Retaining Walls.

2. *Accounts of some Experiments on Electro and Galvano Culture.* By WILLIAM FRASER, Esq., Aberdeen. In this Paper, Mr. Fraser gave an account of the results of numerous experiments he had made on the effects of electricity and galvanism on the growth of seeds and vegetables. In one set of experiments, he had passed a current of electricity through the seeds before sowing, and in others, he passed the galvanic current through the earth in which the seeds were sown, and he also applied it to the plants. He experimented in various ways, but with no benefit to vegetation, either from electricity or galvanism; for, although the seeds through which he had passed a current of electricity previously to sowing, sprung up quicker than those not subjected to that process, just as seeds do which have been previously steeped in water, yet, after a while no perceptible difference could be seen betwixt the plants from electrified seed and those from seed not subjected to that process. Mr. Fraser, in conclusion, suggests the form of an apparatus by which he thinks, it could be clearly seen whether galvanism produces any benificial effect upon plants.

3. *Description of a Drawing of a Horizontal Condensing Pump, for horizontal condensing Steam Engines.* By Mr. WILLIAM D. MEIKLEJOHN. In this condensing pump, Mr. Meiklejohn states that the condensation will take place much more rapidly, and that there would be a very considerable saving in the first cost of the condenser.

4. *On a Substitute for Railway Bridges.* By Mr. JAMES MILLER, Watchmaker, Perth. Mr. Miller submits, that in small bridges for railways there is too great a rigidity, when built of stone or brick, and that they are liable to be destroyed by their want of elasticity, and their not yielding to the vibration of the train; and he suggests that they should be made of strong rings of iron, upon which longitudinal iron bars should be rivetted—somewhat in the form of a cooper's chaûffer. They could be made at a distance, in pieces, and carried to the spot, and there bolted together.

February 9.—GEORGE WILSON, M.D., F.R.S.E., in the chair.

The following communications were made:—

1. *Description of a New Clock, impelled by a combination of Gravitation and Electro-Magnetism. Invented by* Mr. ALEXANDER BRYSON, Chronometer, Watch, and Clock Maker, Edinburgh. In this clock the common pendulum is used. It is kept vibrating, in equal arcs, by a small falling bar, or detent, which is raised every second by the attraction induced in a soft electro-magnet. The magnetism is excited by constant batteries placed in the bottom of the clock-case, which may be kept in action for any desirable period, and when changed it is not necessary to stop the clock; as before the spent battery is out of action, the other, which is newly charged, is in full operation. The wheel work, showing minutes and seconds, is moved by the gravitating bar or detent immediately on its being attracted by the electro-magnet. When this clock is made to show minutes and seconds only, as in observatory clocks, it consists of two wheels only, and when it is made to show hours, three wheels are necessary. The contact-breaker is suspended on knife-edges immediately above the pendulum bob, having a gold concentric arc, on which press two very slight gold springs. In this arc is inserted a piece of ivory, which breaks the current, and permits the falling bar or detent to fall on the pendulum so as to keep up its vibration. By the method of coincidences it was stated, the pendulum was found to keep its motion with the utmost steadiness, as compared with a compensation mercurial pendulum beating seconds.

2. *On the Causes of Hurricanes in the West Indies, with illustrative Diagrams.* By ROBERT LAWSON, Esq., Assistant-Surgeon, 47th Regiment. Communicated by Alexander Bryson, Esq. In this paper Mr. Lawson gives further instances, both from personal and recorded experience, of hurricanes in the West Indies, exhibiting phenomena not conformable to the laws of Hare, Espy, Reid, or Redfield; and while adopting as true many points insisted on by these eminent observers, endeavours to prove the dependence of those mighty convulsions on the moon's influence, which seem to have escaped all observers in this field of inquiry except the indefatigable Howard.

3. *Description, illustrated with Drawings, of an Improved Method of Manufacturing Pyroxilic Spirit (Wood Naphtha of Commerce), Pyroligneous Acid, and other products, from the destructive distillation of Wood.* By Captain GEORGE DACRES PATERSON. This communication contained a description of the manufacture of Pyroxile Spirit and Pyrolignite of Lime, with various improvements, the principal of which consisted in a new manner of stifling the charcoal, so as to free it from the noxious gases, and in the distillation, which is conducted on the principle of distillation *in vacuo*. The arrangements were stated to effect great saving in fuel and labour. The vacuum is formed by steam, and by a simple arrangement the condensed vapour is entirely drained off from the still prior, to the supply of liquor being forced up from the charging Back. A simple apparatus was described for guiding the workmen as to the different strength of the liquor; and a plan of a rectifier, by which the essential oil is more easily separated from the spirit, was also given, by which means, and others farther described, the Pyroxilc Spirit, it was stated, could be procured in great purity.

SOCIETY OF ARTS, LONDON.

January 28.—W. F. COOKE, Esq., in the Chair.

The first paper read was by Mr. Claudet, on "*some principles and practical facts in the art of Photography*," and contained a series of very interesting scientific researches, and communicated several important discoveries in this new and curious field of research. It was a sequel to a communication read by Mr. Nott on a previous evening, in which he had endeavoured to establish that the rays which make the photographic picture are different from those which produce light, and this he thought he had proved by means of pictures formed with a polarized ray reflected from parallel plates. Mr. Claudet contends that the rays of light are the agent. He had made many experiments on forming pictures by reflection, but had not been able to discover any essential difference betwixt them and such as are formed by the direct ray.—His next series of experiments regarded the photographic qualities of light of different colours; blue proved to be the most powerful photographic agent, yellow the weakest. One of the most beautiful experiments by which this was proved, consisted in throwing the prismatic spectrum on paper and on the silver plate, the colours being marked on the paper and the effect remaining on the photographic plate—he thus showed that the photographic prism presents effects very different from the apparent intensity of the prismatic spectra. A remarkable specimen was shown of a silver plate, on which the rays of light had brought out a powerful picture without the action of mercury.—Another series of experiments made was on the photographic action of the rays of the moon, which had formed a powerful picture by five minutes exposure; he hoped to be able to obtain a very accurate Daguerréotype of the moon's surface, drawn by herself, on a silver plate.

Considerable discussion followed, and the announcement in the paper as received with much approbation.

"*On a New Code of Signals and the Construction of the Signal Lamps.*"—By Mr. RETTIE, and illustrated by models and experiments. By the simple use of a pair of slides attached to an ordinary lantern, a combination of signals is effected, by which the loss of life and property by the collision of steam boats and sailing vessels, might be simply and cheaply avoided.

February 4.—WILLIAM POLE, Esq., F.R.S., Vice-President in the Chair.

The following papers were read:—

The first communication was "*On the Theory of the Construction of the Portland Vase.*" By MISS P. ENSELL.—Miss Ensell considers the Portland Vase to have been constructed in the following manner. A jar of blue glass was formed in the usual way by the glass blower, and its whole surface roughened—it was then enclosed in a mould similar to those used for the formation of alabaster relievos; the jar and mould were then exposed to the action of one of the petrifying springs of Italy, and thus a clear transparent substance was deposited on the vase, in such proportions as to form the figures in that beautifully white semi-transparent material, which is exhibited in the Portland Vase. She then gave various details for the practical carrying out of the operation, and suggested the propriety of undertaking a series of experiments, with a view to constructing vases of a similar description.

Mr. Doubleday, the gentleman who was charged with the restoration of the Portland Vase, and which is now under his care, having examined its structure most minutely, proceeded to give the following account of the manner in which it had been formed. The base is of blue glass and has been made in the usual manner by the glass-blower, the white figures are also of glass and perfectly united with the base. The blue jar having been formed, was dipped into a pot of white metal, and so the lower part of it became entirely covered with a uniform coating of white glass. The material to work upon, which is thus described is in all respects similar to the cameo, and has been operated on in the same manner. With some talent and considerable artistic skill, by a process like that of gem engraving or cameo cutting, the white glass has been cut away in different forms, and various thicknesses by the artist; he considered that not less than 3 or 4 years of continuous labour would be required in order to produce such a work of art.—Several other gentlemen then joined in the discussion, the result of which was to establish the fact that we possess in this country both materials, mechanical means, and artists capable of executing similar works to the Portland Vase, and that those works, if executed, would necessarily, from the length of time and skill required to execute them be the most rare and most costly that art can produce.

"*On a New Theory of the Formation of Meteoric Stones.*" By ARTHUR WALL, Esq. He considered they were derived from subterranean origin; he showed by analysis that abundance of materials and means are presented for the formation of those meteors in the bowels of the earth, and their descent from the atmosphere without going into the planetary spheres to seek for their cause.

February 18.—E. SPEER, Esq. in the Chair.

The discussion on the *Portland Vase* was resumed.

Mr. Doubleday, of the British Museum, who has repaired the Portland Vase in a manner so admirable that the fractures are scarcely visible, presented a number of specimens of ancient manufactures in glass, illustrative of the theory which he deduced on the true principles of its construction. Mr. Apsley Pellatt, who was present, exhibited to the society, through Mr. Blashfield, a very beautiful model of the Vase, it being one of the original and most perfect copies made by Wedgwood. He explained fully to the meeting, as a practical manufacturer of glass, the exact process by which he conceived that that vase was originally formed. He explained how such objects of art might be constructed at the present day, and the difficulties which stood in the way of their construction. Mr. Christie, of the Vauxhall Glass-works, explained another mode in which the two colours of glasses might have been originally united.

"*On Railway Locomotion, with reference to the effects of Centrifugal and Centripetal Forces.*" By Mr. C. H. GREENHOW. He proposes for the purpose of increasing the safety of railway trains to suspend the bodies of the carriages upon an horizontal axis, in such a manner that the centre of gravity being equal, shall equipoise the centrifugal force. He gives to the rails the form of a hollow circular tube, and to the flanges of the wheels a corresponding form, by which he conceives that the forces tending to throw the tram off the line would be counteracted. The wheels also are so constructed that the spokes form a straight line passing between the rails and the centre of gravity of the body; all these arrangements are designed by him to give increased safety and stability to the railway trains. A long discussion ensued, in which many practical engineers and scientific gentlemen took an active part. It was maintained by some of them that no increased stability was given by permitting the centre of gravity to oscillate, but on the contrary it would thereby be considerably weakened, and; that the wheels would not adjust themselves to the partial variations and irregularities in the condition of the railway; that there would be attrition between the rails and the flanges of the wheels and that of the circular form of rail being of cast iron would not be safe. To these allegations Mr. Greenhow gave various replies, and the discussion was prolonged to a late hour when it was adjourned.

AMERICAN PATENTS.

(From the American *Franklin Journal.*)

"*Improvement in the Coupling and Stuffing Box for shafts, specially intended for submerged propellers for Ships.*" By R. F. LOPER, Philadelphia. Oct. 9, 1845.

The outer tube of the stuffing box, instead of being permanent, is tapped into a metallic casing surrounding it so as to admit of screwing it over the lapped or other joint of the shaft, so that when this tube is drawn in, the two shafts can be separated, and if desired, the propeller drawn out of the water, and when screwed out, passes over and prevents the two shafts from being separated.

"*Improvement in the Current Water Wheel.*" By J. D. ROBINSON, Illinois. Oct. 24, 1845.

The buckets are each composed of several narrow strips attached to chains binged to a cylinder, so formed as to permit them to fold in one direction, but not to go beyond a line radiating from the centre of the cylinder to which they are jointed—when acted upon by the current, these buckets are thrown open, but so soon as they begin to make back water they fold on the periphery of the cylinder, and prevent undue resistance.

"*Improvements in Tide Mills.*" By JOHN GERARD ROSS, New York. Nov. 9, 1845.

The wheel is placed in a race, at one end of which there is a tide gate hinged to a wall beyond the end of the race and shutting against either side of the race; and at the other end of the race there are two current gates, one termed the "inner current gate," and the other the "outer current gate;" these are binged to the ends of the race way wall, and shut against a pier placed beyond the end, and in a line with the middle of the width of the race way. The current in passing along opens the "current gate," and after acting on the wheel, passes out through the "outer current gate," and on the return tide the pressure of water closes this "outer current gate," which causes the current to pass around to that side of the tide gate opposite to that at which it entered on the rise of the tide, throws it against the opposite side of the race-way, acts on the same side of the wheel as on the rise of the tide, and passes out through the "inner current gate." The dam walls are formed with pits, open at the sides for the free ingress and egress of the water to act on floating caissons which sustain the wheel and always keep it at the required elevation. The shaft of the wheel (or wheels) is connected with the frame-work of the mill by bars radiating from the axis of a cog wheel, into which work the cogs of the master wheel.

"*Improvements in the Means of Removing Mud, Sand Bars, &c. from the Beds of Rivers, &c.*" By DENNIS VERMILION, Washington, D. C. Nov. 9, 1845.

A mass of logs are put together in the form of a boat, to be moved down by the current, tide, or otherwise, and which from its great weight and strength will acquire great momentum. Iron breakers sharpened at the lower end, pass obliquely through apertures in the mass, and extend down to the depth required to act on the obstruction to be removed. At the stern there is suspended a drag rake, connected with the boat by means of two arms that slide freely in apertures in the ends of a cylinder which is hung on appropriate journals; and for the purpose of raising this rake, cords extend from it to a windlass on the boat. The operation of the apparatus is this—the boat being put in motion by the current, or otherwise, is directed towards the sand bank, or other obstruction, and the breakers and rake having been set to the required depth, the breakers cut up and loosen the sand, mud, &c., which is then raked into deeper water.

"*Improvements in Horizontal Wind Mills.*" By DANIEL DENNET. Nov. 13, 1845.

The wing or vanes of this are jointed to radial arms, and are suspended by cords to vibrating levers that pass through, and are jointed to, the shaft above the arms to which the wings or vanes are jointed, so that by this arrangement the moment one vane begins to make "back wind," (as it is termed,) it is blown down, and by its connection with the one on the opposite side of the shaft draws it up to catch the wind.

"*Improvements in Water Wheels.*" By JOHN L. SMITH. Dec. 10, 1845.

Two of these wheels are put on a horizontal shaft, one on each side of the trunk or tunnel through which the water is applied to the wheel, the face towards the tunnel being open for that purpose. The apertures or issues for the water extend from the shaft to the outer rim, which is scolloped for that purpose, and are formed by the forward edge of one bucket, and the back edge of the other, these being placed diagonally for this purpose. And to the back edge of each of these buckets there is a flanch radial in its length, and parallel with the shaft in the direction of its width, which extends to the inner face of the wheel, or to the floor.

"*Improvements in the mode of preparing, applying, and using certain fluxes for the reduction of Ores in the Blast Furnace.*" By JONAS TOWERS, Madison, Lake county, Ohio, Dec. 7, 1845.

What I claim as my invention, and desire to secure by letters patent, is the application of those earths or minerals which are dissoluble or diffusible with water, and have an adhesive nature, and can be made into a paste, pap, or grout, with the above or other liquids, and can be applied as other fluxes for the reduction of ores or minerals in the blast or other furnaces. I claim the application of the above preparation, as herein described, to other minerals as well as iron, which have a similar objectional tendency, while smelting, that is found with iron. I do not claim any special right to the use of the above fluxes in a dry or natural state; it is only after they have been mixed or diffused with water or other liquids, and formed into a paste, pap, or grout, and applied as a coating or adhering substance, as herein described, that I claim as my invention, or discovery, and desire to secure by letters patent.

"*Opening and closing Waste Water Gates.*" By ROBERT ROBINSON.

The gate is provided with a chain which passes over a roller, and is attached to one end of a lever, the other end having a box suspended to it. When the water rises too high, it passes over a dam, and fills the box, which, by its preponderance, sinks, and opens the gate; and the box being provided with small holes, after the water has ceased to flow over the dam, it runs out of the box, and thus gives the preponderance to the gate, which is then closed by the pressure of the water.

"*Hydraulic Gate, for Locks, Docks, &c.*" By GEO. HEATH. Antedated July 3, 1841.

This improvement consists in using for the gate, singly or in two parts, the segment of a cylinder for the front of the gate, with the radius which cuts the centre line of the arch of the segment lying horizontally, and with the arch next the water which is to be passed. This front of the gate rests for its support against the pressure of the water, on gudgeons at the centre of the cylinders, which are connected with the front, either by arms, or by the sector of a circle, at the two ends of the segment.

For a composition of matter for "*lubricating the rubbing surfaces of machinery.*"—Increase S. Hill, and Joseph Dixon, the former of Boston, and the latter of Taunton, Massachusetts, January 31, 1845.

The patentees say, "our composition consists mostly of zinc, (which as is well known belongs to the class of cheaper metals) hardened by being compounded with what we denominate a *hardening composition.* This latter composition is formed of the following metal, mixed in a state of fusion in the proportions hereinafter specified, viz., 15 parts of tin to 35 parts of copper. This composition in a state of fusion is to be mixed with molten zinc and tin, (although tin is not absolutely essential) in the proportion of the two parts of the said hardening composition, of 19 parts of zinc, and from three to five parts of tin, according to the peculiar purpose for which the composition is to be used, the tin specified to be added last, having the tendency to render the compound when cold more or less ductile, according to the quantity of the same incorporated therewith. The metal formed without the addition of the last named proportion of tin, when broken, will have the appearance of cast steel of coarse quality, but the addition of tin will make it stronger and cause it to be finer in grain until four parts of the same will be added, when the appearance of the metal on its being broken, will be like that of fine cast steel and more closely resemble the same than any other metal. The great strength of the composition combined with a certain degree of softness which it possesses, renders it highly useful in the construction of bearings for rubbing surfaces of machinery, as it is capable of resisting for a great length of time, the effects of wear and attrition. The large proportion of zinc used in forming the compound renders its use in the mechanical arts, much less expensive than the metal ordinarily employed for these purposes, the cost being much less than any other composition in which copper and tin are the principal metals."

REGISTER OF NEW PATENTS.

If additional information be required respecting any patent, it may be obtained at the office of this Journal.

ATMOSPHERIC RAILWAYS.

WILLIAM SYKES WARD, of Leeds, gentleman, for "*Improvements in exhausting air from tubes or vessels for the purpose of working atmospheric railways, and for other purposes.*"—Granted June 25; Enrolled December 25, 1845.

The object of these improvements relates to the arranging and working of the valves of air-pumps for the purpose of exhausting the air from the traction-tubes of atmospheric railways, and also for the purpose of exhausting air from any vessels or tubes upon a large scale. In using air-pumps as hitherto practised for working atmospheric railways, power is lost in opening the inlet and outlet valves, by the action of the air entering into, and expelled from the cylinder of the pump, and the violence with which such valves close is objectionable.

The inventor's mode of constructing air-pumps is such, that the power required for opening and shutting the valves is supplied by gearing, or mechanical movements, from the engine, or other source of power by which the air-pump is actuated, so that the inlet valves are opened and shut alternately, almost immediately after the commencement of the stroke of the piston of the pump, and the outlet valves are respectively closed, or pushed home, at the end or conclusion of the stroke of the piston. The gearing afterwards releases the valve, which is retained on its seat by the pressure of the external air, until the air within the cylinder of the pump becomes nearly of the same density as the external air, when the valve (if the lower outlet) falls by its own weight, or (if the upper outlet) is raised by a counterpoise of greater weight than the valve, or by a spring, thus moving rather in advance, or as though in anticipation of the current of expelled air, and affording a free passage for it.

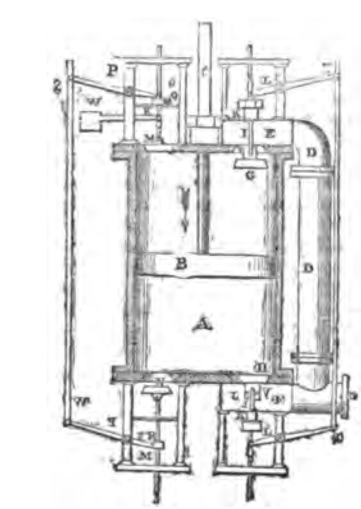

Fig. 1, A, represents the cylinder of the pump, B, the piston, C, the piston-rod, D, D, D, pipes communicating between the main, or vessel to be exhausted, and the upper inlet valve-box, E, and the lower inlet valve-box, F. G, represents the upper inlet valve, and H, the lower inlet valve, which valves, G, and H, are attached to the rods, I, and I, at V, and V, by joints, allowing a slight motion, so that the valves may the better close on their respective seats. The rods I, move air tight, in stuffing-boxes K, in guides, by levers L, and connected by the rod T, part of which only is shown. M represents the upper, and N the lower outlet valve, attached to the rods O, and O, moving in guides, and which valves, M and N, may be respectively closed by the levers P, fixed and acting upon the tappets Q, so as to close the valves M and N alternately, but not to open them. The upper valve M is counterpoised, and somewhat overweighted by the lever R R, and the weight S. The lower valve N opens by its own gravity, when not closed by the lower lever P, or supported by the pressure of the atmosphere against a partial vacuum in the lower part of the cylinder A. The levers P are connected with an excentric by the rod W, part of which only is shown.

The mode of action is as follows:—Suppose the pump has already exhausted the main, or vessel connected therewith, to half vacuum, and is making the down stroke; the air from the main, therefore, enters at the upper valve, which was opened by the lever L, immediately after the commencement of the down stroke, and the lower valve H, was closed at the same time. The upper outlet valve M, was closed simultaneously with the conclusion of the ascending stroke, and remains closed during the down stroke; and, at the same time, the end, P *a*, of the lower lever P, released the stud, or tappet Q, leaving the lower valve N, at liberty to open by its gravity; but the air in the cylinder of the pump having had, at the commencement of the stroke, only half the density of the external air, the valve N, will have been supported until the piston descended to about the middle of the stroke. The gravity of the valve N, will then overcome the cohesion of its surface, and of the valve-seat, and open, leaving a free passage for the air to be expelled from the bottom of the cylinder. When the piston approaches the bottom of the cylinder, the valve N, will begin to be raised by the lower lever P, the motion of the piston, from its connexion with the crank of the engine actuating or driving it, will have become slower, so that the aperture will, nevertheless, be adequate for the expulsion of the air; but, at the turn of the stroke, the last-mentioned lever P, will close the valve N, quietly, so as to avoid any detrimental concussion consequent on the change of the stroke. The upper inlet valve G, will be closed, and the lower inlet valve H, will be opened. The upper outlet valve M, will be left free, but, as before explained, will remain closed, until the density of the air above and below it are nearly equal, when it will be raised by the counterpoise or weight S.

Another part of the improvements consists in the combination of large vessels with air-pumps, so that such vessels, having been previously exhausted, shall assist the pumps in the exhaustion of the traction-tube. The cylinder of the pump must be of such dimensions, as to be capable of restoring the exhaustion of the reservoirs in the interval between the running of the trains on the section of railroad it is required to work. And the steam engine is to be of such power as to work the pump, and restore such exhaustion of the reservoirs with facility, in the before-stated period, after the first reservoir has been exhausted, but such exhaustion need not be continued to a very high gauge; for example, the first reservoir may be exhausted until a barometer gauge attached thereto shows the height of about fifteen inches of mercury; by a change of position of the cock Q, the second reservoir may then be exhausted to about twenty inches of its gauge, and lastly, by a further change of the cock, the third reservoir may be exhausted to about twenty-five inches of its gauge.

Another part of the improvements consists in the construction of the pistons of large air-pumps, by making the packing of the pistons of leather cut into bands, of the breadth of about one-sixth part of the diameter of the cylinder of the pump. Such bands are united by sewing, and also with the well-known cement of isinglass or fish-glue dissolved in weak spirit, or are united by other suitable means, so as to form a continuous circle of about the same diameter as the pump cylinder, but considerably conical, so as to facilitate the bending hereinafter mentioned. The bands of leather, after being softened by water and placed upon a block of similar size to the piston, are then bent and contracted so that about one-third part of the breadth may fit the cylinder and the other two-third parts may be attached to the piston, and secured by plates of metal screwed to the main part of the piston.

The claim is for so arranging apparatus or gearing with the valves of air-pumps, as to close the outlet valves but not to open them, the gearing leaving such valves at liberty to open when relieved from the pressure of the air. Secondly, the so combining vessels or reservoirs with air-pumps in working atmospheric railways that the air may be pumped from the traction-tubes of atmospheric railways into partially exhausted vessels or reservoirs, and, when desired, the pressure of the air passing from such traction-tubes into such partially exhausted vessels or reservoirs may be used for giving motion to air-pumps. And thirdly, the mode of packing pistons of air-pumps as herein described.

William Palmer, of Clerkenwell, in the county of Middlesex, manufacturer, for "*Improvements in working atmospheric railways, and in lubricating railway and other machinery.*"—Granted June 5; Enrolled December 5, 1845.

This invention consists in applying tallow, oil, or other fatty matter, or of oil prepared in the form of soap, insoluble in water, to line the tubes and to aid atmospheric railways; and the said invention also consists in applying such materials to the lubricating railway and other machinery. Any quantity of the tallow-oil is taken and heated in a copper or boiler to the point of boiling, or nearly so, and then litharge is stirred in so long as the same is taken up by the tallow-oil, and until the litharge falls to the bottom and is not taken up by the tallow-oil; after stirring for half an hour from the time the last quantity of litharge has been introduced, the melted matter is removed into casks or other suitable receptacles. By this means a soap insoluble in water, will be produced, suitable for the purposes of the invention.

The claim is for the application of tallow-oil or other fatty matters, or oils prepared in the form of soap insoluble in water, by means of litharge or other metalline matters, to line the interior surfaces of the traction-pipes of atmospheric railways, and also for lubricating machinery as herein described.

Joseph Cliff, of Wortley, Yorkshire, fire-brick manufacturer, for "*Improvements in the manufacture of alum, and of aluminous compounds, from a substance not hitherto used for that purpose, and in the production of an improved fire-clay from the residuum thereof.*"—Granted June 5; Enrolled Dec. 5, 1845.

This invention relates to fire-clays containing a great quantity of alumina, especially the "Wortley fire-clay." For extracting the whole or the greater part of the alumina, and converting it into alum and aluminous compounds, and in using the purified clay, either alone or combined with other fire-clay, for making fire-bricks, glass-house pots, crucibles, gas-retorts, and similar articles. Any fire-clay containing alumina in excess, is first ground, then calcined, and afterwards submitted to the action of sulphuric, nitric, muriatic, or other acid, diluted with water. The mass being lixiviated with water, the alumina is obtained in solution, and this solution is freed from iron by the employment of prussiate of potash, gallic acid, sulphuretted hydrogen, or some other suitable agent, the solution is then evaporated by itself, to get the sulphate, nitrate, or muriate of alumina, according to the acid used; or the sulphate or muriate of potash, soda or ammonia is mixed with the solution, and evaporated or crystallised to obtain the alum salts, and then, by roaching, the alum of commerce is formed. After he whole or greater part of the alumina has been extracted, as above described, the purified and residuary earth may be employed, alone, or combined with other clay, in the manufacture of fire-bricks, glass-house pots, crucibles, gas retorts, and similar articles.

John Hopkins, of Brand-street, Greenwich, in the county of Kent, surveyor, for "*certain improvements in rails and trams for railroads and tramways.*"—Granted July 3, 1845; Enrolled Jan. 3, 1846.

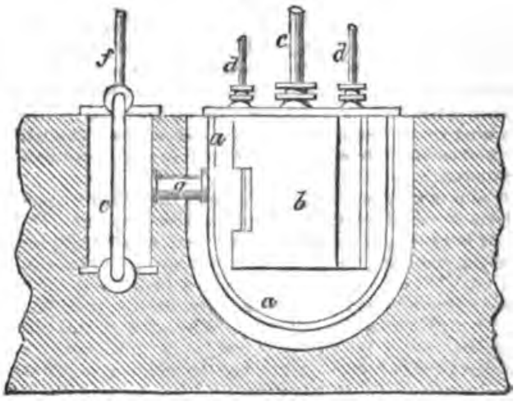
The object of this invention is to employ rails, trams, or continuous surfaces of wood, upon which the wheels of engines and carriages may travel as on the ordinary rails or trams, consisting of a piece of timber, placed longitudinally and bolted between two cheeks of iron.

HOT AIR ENGINE.

Isham Baggs, of Great Percy Street, Claremont Square, engineer, for "*Improvements in obtaining motive power by air.*"—Granted June 26, 1845; Enrolled January 26, 1846.

The first part of this invention is to cause condensed air to pass from a vacuum placed within a flue, and surrounded by fire, to the cylinder of an engine, so as to give motion to the piston of the same by its elastic and expansive power, the condensed air being supplied from time to time by means of a double acting pump. The heated air after having worked the engine is conducted by means of a pipe to the furnace or fire, for the purpose of increasing combustion.

The apparatus consists of a cylinder, constructed somewhat in the ordinary manner, having induction and eduction ports with suitable valves. This cylinder is placed vertically within a closed receiver, or strong iron vessel, fixed in such manner that it is surrounded by a flue, and can be heated by a fire for the purpose of expanding the air within it, which after having worked the piston of the engine passes through the eduction port, and is conducted to the fire if desired. The piston rod is attached in the ordinary manner to the crank, and upon the same shaft is a second crank for working the force, or air-pump, which at every stroke forces into the receiver a quantity of air equal to that expended in moving the piston. The specification is accompanied with three or four sheets of diagrams, showing sections of the cylinders &c., which would be too elaborate to give in detail. The annexed rough sketch shows the position of the working cylinder, receiver, and air pump, which we have no doubt the reader will understand by the following description—*a a* is the



receiver or reservoir, fixed in brickwork and surrounded with a flue proceeding from the furnace; *b* is the cylinder of the engine placed within the same; *c* is the piston rod connected with the crank-shaft in the usual manner by a connecting rod; *d d* are the valve rods worked by means of excentrics; *e* is a double-acting air pump for forcing air into the receiver *a*; *f* is the piston rod connected with a second crank formed on the crank-shaft, which latter crank is placed about 140 degrees in advance of the other crank, in order that the resistance may not be greatest when the power is least. In starting this engine atmospheric air is to be forced into the receiver equal to 4 atmospheres, by means of hand pumps or otherwise; the fire is then to be lighted, which will have the effect of expanding the air which is then admitted into the cylinder; when motion will be given to the piston, and crank shafts, (not shown in the diagram,) and by means of the second crank such motion will be imparted to the piston rod *f*, of the air-pump *e*, which is provided with two induction and two eduction valves, and intended to force into the receiver *a* just as much common atmospheric air as has been expended in giving motion to the piston in the cylinder *b*, the slide valves of which are worked expansively; *g* is the eduction pipe of the air-pump, and is connected to the receiver, the induction pipe being open to the atmosphere, by closing which the engine will be stopped, in consequence of the supply of air being cut off.

HIGHTON'S SAFETY RAILWAY CHAIRS.

The peculiarity in the fastening of the rails by means of the Safety Chair and Key Wedge, consists in making the side of the chair next to the key with a concave instead of a plane surface, and using a peculiarly shaped cast iron wedge, in connection with the key. After the timber is inserted into the chair, a safety wedge is to be driven into the key near to the side of the chair as shown in the drawing. This forces the key into the concavity of the chair producing perfect contact between the key and the interior of the chair. The key being thus made larger in the middle than at the ends, is unable to leave the chair until forcibly driven out by the hammer. The wedge is prevented from splitting the key by the combined action of the two projections cast in the sides of the wedge at its lower end, and the shape of the interior side of the chair. When the wedge is being driven into its place, these projections cut all the fibres of the wood across as the wedge enters the key; and as many as five or six wedges may if required, be driven into the key without splitting or injuring it in the least degree.

The end attained by this description of fastening for the rails of a railway, consists in the impossibility of the keys shaking out by the combined action of the shrinkage of the keys in dry weather, and the passage of the trains: an advantage of the greatest importance on all lines of railway using chairs.

The accompanying engraving shows that it is impossible for the key to shake out until it has shrunk at least a quarter of an inch; this a well-seasoned key will never do: but should the shrinkage in very dry weather amount to anything near this, the driving in of an additional safety wedge will make the key as fast as ever; and it will then become more perfect than at first, as its fibres will be more closely compressed, and consequently, less subject to alteration in size by change of weather. The weight of each safety-wedge is less than 2 oz.; and the inventors state that more iron is saved in the concavity of the chair, than is sufficient to make a safety-wedge.

Fig. 1 Fig. 2

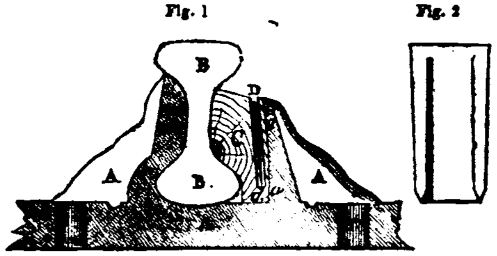


Fig. 1 is a vertical section of the chair, showing its key and wedge. Fig. 2 is a flat or front view of the fastening wedge. A is the chair. B the rail. C a wooden key driven in a horizontal direction between the rail and chair, and transversely across the chair. D is the metal wedge driven vertically downwards into the, key with its width laid in the direction of the length of the key, forcing a portion of the key against or into the hollow side *d d* of the arm *a a* of the chair, the key is thus secured between the rail and its chair.

We understand that this improvement has been adopted with success on three miles of the Taff Vale Railway, and after being in use for three months, and upwards of 1,200 trains passing over the line not a single key was removed.

RAILWAY PROCEEDINGS.

We propose to give under this head selections from the decisions of the sub-committee on the standing orders. It must be understood that the decisions are not always final, as the petitioners may go before another committee on the standing orders, who may if they see fit, recommend the House to waive the conformance to the standing orders.

House of Lords, Feb. 6.

"Resolved, that it is the opinion of this committee that such portion of the standing order No. 224 as requires a deposit of one-tenth of the amount subscribed, should be suspended with respect to all such railway bills as shall commence in the House of Lords during the present session.

"That no such railway bills shall be read a first time in this house unless a deposit of one twentieth part of the amount subscribed should have been paid on or before the 6th of February.

"That no such railway bills shall be read a third time until a further deposit of one-twentieth part of the amount subscribed shall have been in like manner paid.

"Resolved also, that it is the opinion of this committee that this house should not receive any petition for a railway bill after Monday, the 23rd of February."

House of Lords, Feb. 13.

The House of Lords resolved that the standing orders be amended as follows:—

That it is the opinion of this committee that the standing orders of this house with regard to railway bills, should as respects railway bills commenced in this house during the present session, be altered in the following particulars.

That standing order No. 219 be altered in the following particulars, viz., that on the bill being reported to the house from the committee on the bill, or at any time previously, on the petition of the parties to such bill, or any of them, the bill shall be referred to the Standing Orders Committee, which shall inquire whether standing orders, the compliance with which is directed to be proved before or reported by the Standing Order Committee previously to the third reading of the bill, have been complied with; and the committee shall report on the matters referred to them in the same manner as they are directed to report on other matters referred to them by the standing orders.

That five clear days' notice be given of such meeting of the committee, and that it be proved to the satisfaction of the committee, that the standing orders had been complied with five clear days before such meeting of the committee.

That the Standing Orders Committee shall not meet to consider the compliance with such of the standing orders as are directed to be proved before them until after the expiration of seven clear days from the presentation of the petition if the bill relate to England, or until after the expiration of 10 clear days if the bill relate to Scotland or Ireland.

That every petition complaining of a non-compliance with such of the standing orders as are directed to be proved before the Standing Orders Committee subsequently to the first reading of the bills, shall be presented three clear days before the meeting of the committee to consider such standing orders.

That standing order No. 220 be altered in the following particulars, viz., that the service of every application required to be made to the owners or reputed owners, lessees or reputed lessees, and occupiers, by the fourth paragraph of the said standing order, may, unless a petition complaining of the want of due service of such application shall have been referred to the Standing Orders Committee, be proved by the evidence of the agent or solicitor for the bill, stating that he gave directions for the service of such application in the manner and within the time required by the standing orders, and that he believes that such application was so served; but in case the Standing Orders Committee shall not be satisfied with the evidence of the agent or solicitor, the service of such application shall be proved in the usual manner.

That no bill commencing in this house and empowering any company already constituted by act of Parliament to execute any work other than that for which it was originally established, shall be read a third time, unless the Committee on Standing Orders shall have especially reported that the requisitions contained in paragraph No. 5 of such order have been complied with.

That standing order No. 224 be altered in the following particulars, viz., that as respects all railway bills which shall commence in this house during the present session of parliament, it shall be proved to the satisfaction of the Standing Orders Committee that a sum equal to 1-20th part of the amount subscribed has been deposited, in the manner required by the said standing order, on or before the 6th day of February inst.; and it shall likewise be proved to the satisfaction of the said committee, before the third reading of such bill, that a further sum, equal to 1-20th part of the amount subscribed, has been deposited in like manner.

That standing order No. 225 be altered in the following particulars, viz., that it shall be sufficient if the proof required to be given by the last mentioned standing order be adduced before the Standing Orders Committee at any time previous to the third reading of the bill.

That all the standing orders applicable to railway bills, except such of them or such part of them as are altered by or are inconsistent with the aforesaid standing order, shall apply to the railway bills commenced in this house during the present session of Parliament, and to the proceedings on such bills.

House of Commons.

First Report, Feb. 5.

The select committee appointed to consider the mode in which the house shall deal with the railway bills proposed to be submitted to the House during the present session, and who are empowered to report from time to time to the House, have considered the matters referred to them, and agreed to the following report:—

That for the purpose of facilitating the dispatch of railway business during the present session, it is expedient that a portion of the railway bills should commence in the House of Lords.

That with respect to any railway bills which, in pursuance of these resolutions, shall commence in the House of Lords during this session, this House will not insist on their privilege with regard to the clauses fixing and regulating rates and tolls in such bills.

That with a view of affording early and increased means of employment in Ireland, it is expedient to give facilities for the early consideration of Irish railway bills.

That, for the attainment of this object, it is expedient that all Irish railway bills should, in the present session, commence in the House of Lords.

That it is expedient that all bills which compete with or ought to be considered in connexion with any bills, the promoters of which shall prove themselves entitled to the privileges agreed to be granted in certain cases by the resolutions of this House of the 7th July last, shall commence in the House of Lords.

That the parties promoting railway bills which, by the above resolutions, are to commence in the House of Lords, may (notwithstanding any proceeding respecting such bills in the House of Lords) prove before the committee on petitions of the House of Commons that they have complied with the standing orders of this House, and the report of such committee shall be ordered to lie on the table. If the committee should report that the standing orders have not been complied with, their report shall be referred to the committee on standing orders, whose report shall be ordered to lie on the table.

That when a railway bill shall have commenced in the House of Lords, and shall be sent down to the House of Commons from the House of Lords it shall be read the first time in the House of Commons, and shall then be referred to the committee on petitions, to ascertain whether the railway bill so sent down is substantially in accordance with the standing orders, as determined by the House of Commons.

SECOND REPORT, FEB. 10, 1846.

1. That a committee of five members be appointed, to be called the Classification Committee of Railway Bills, and that three be the quorum of such committee.
2. That copies of all petitions for railway bills presented to the House be laid before the said committee.
3. That the committee of classification shall inquire and report what railway bills compete with, or ought to be considered in connexion with any railway bills, the promoters of which shall have proved themselves entitled to the privilege agreed to be granted in certain cases by the resolutions of this House of the 7th of July last.
4. That the committee of classification shall form into groups all other railway bills which, in their opinion, it would be expedient to submit to the same committee.
5. That as soon as the committee of classification shall have determined what railway bills are to be grouped together, they shall report the same to the House, and all petitions against any of the said bills shall be presented to the House three clear days before the meeting of the committee thereon.
6. That no railway bill be read a first time later than the next day but one after the report of the committee on petitions or of the standing order committee on such bill, as the case may be, shall have been laid on the table, except by special order of the House.
7. That there be not more than seven clear days between the first reading of any railway bill and the second reading thereof, except by special order of the House.
8. That the breviate of every railway bill shall be laid on the table of the House, and be printed and delivered one clear day before the second reading.
9. That such railway bills as shall have been read a first time before the House shall agree to these resolutions, shall be read a second time within seven clear days thereafter.
10. That such of the standing orders as relate to the composition of the committees on private bills, and the orders consequent thereon, be suspended so far as regards railway bills pending in the course of the present session.
11. That committees on railway bills during the present session of Parliament shall be composed of a chairman and four members, to be appointed by the committee of selection.
12. That each member of a committee on a railway bill or bills, shall, before he be entitled to attend and vote on such committee, sign a declaration that his constituents have no local interest, and that he himself has no personal interest for or against any bill referred to him; and no such committee shall proceed to business until the whole of the members thereof shall have signed such declaration.
13. That the promoters of a railway bill shall be prepared to go into the committee on the bill on such day as the committee of selection shall, subject to the order that there be seven clear days between the second reading of every private bill and the sitting of the committee thereupon, think proper to appoint, provided that the classification committee shall have reported on such bill.
14. That the committee of selection shall give each member not less than 14 days' notice of the week in which it will be necessary for him to be in attendance, for the purpose of serving, if required, on a railway bill committee.
15. That the committee of selection shall give each member a sufficient notice of his appointment as a member of a committee on a railway bill, and shall transmit to him a copy of the 12th resolution, and a blank form of the declaration therein required, with a request that he will forthwith return it to them properly filled up and signed.
16. That if the committee of selection shall not within due time receive from each such member the aforesaid declaration, or an excuse which they shall deem sufficient, they shall report to the House the name of such defaulting member.
17. That the committee of selection shall have the power of substituting at any time before the first meeting of a committee, another member for a member whom they shall deem it proper to excuse from serving on that committee.
18. That power be given to the committee of selection to send for persons, papers and records, in the execution of the duties imposed on them by the foregoing resolutions.
19. That no member of a committee shall absent himself from his duties on such committee, unless in the case of sickness, or by leave of the House.
20. That all questions before committees on railway groups or bills shall be decided by a majority of voices, including the voice of the chairman; and that whenever the voices shall be equal, the chairman shall have a second or casting vote.
21. That if the chairman shall be absent from the committee the member next in rotation on the list (who shall be present) shall act as chairman.
22. That committees shall be allowed to proceed so long as three members shall be present, but not with a less number, unless by special leave of the House.
23. That if on any day within one hour after the time appointed for the meeting of a committee three members shall not be present, the committee shall be adjourned to the same hour on the next day on which the House shall sit, which had been fixed for that day.
24. That in the case of a member not being present within one hour after the time appointed for the meeting of the committee, or of any member absenting himself from his duties on such committee, such member shall be reported to the House at its next sitting.
25. That each committee shall be appointed to meet on each day of its sitting, not later than 12 o'clock, unless by the regular vote of the committee.
26. That committees on railway bills have leave to sit in the present session, notwithstanding any adjournment of the House, if the committees shall so think fit.
27. That every committee on a railway bill shall fix the tolls, and shall determine the maximum rates of charge for the conveyance of passengers (with a due amount of luggage) and of goods on such railway, and such rates of charge shall include the tolls, and the costs of locomotive power, and every other expense connected with the conveyance of passengers (with a due amount of luggage) and of goods upon such railway; but if the committee shall not deem it expedient to determine such maximum rates of charge, a special report, explanatory of the grounds of their omitting so to do, shall be made to the House, which special report shall accompany the report of the bill.

THIRD REPORT, FEB. 17.

The number of petitions for railway bills, which have been presented this session, have been stated by your committee to amount to 562, viz.:—

For railways in England and Wales	395
„ Scotland	120
„ Ireland	47

The above numbers include petitions for amalgamation bills, and in some cases there are more petitions than one for the same scheme. After the deduction to be made on this account, the number of distinct railway shemes appears to be—

For England	351
Scotland	83
Ireland	47
	481

As, however, many of these schemes may fail, from non-compliance with the standing orders, the number of bills presented to Parliament may possibly fall considerably short of this amount, and your committee are of opinion that it will not be necessary or expedient in the present session of Parliament to refer mere projects to committees, as was done, owing to peculiar circumstances, in the last session.

From a statement prepared by the officers of the Board of Trade, it would appear, that if the same principle of grouping which was adopted last year should be followed in the present session, the railway schemes in England and Wales might be formed into 51 groups, and those for Scotland into 10; about 61 select committees would therefore be required.

As the house has already ordered, that all Irish railway bills, and a certain limited class of English bills, (the latter of which are included in the foregoing statement), should commence in the House of Lords, it is impossible to say how many of these may be sent down to the House of Commons. The number of groups into which railway schemes for the United Kingdom were divided last year was 52; but, owing to various circumstances, only 45 committees appear to have actually sat.

The necessity of considering so great a number of railway bills, in addition to other private bills, may certainly be expected to produce an unusual and inconvenient pressure upon the time of members of the house; but your committee trust, that as committees on railway bills may in this session begin to sit at an earlier period than in the last, it will not be found impracticable to constitute the requisite number of committees during the progress of the session.

Under these circumstances, your committee have not deemed it advisable to recommend to the house to make any selection from, or to place any limitation on, the number of railway schemes to be submitted to the consideration of Parliament during the present session.

As your committee, however, believe that much of the time of the select committees on railway bills is consumed, with little public benefit, in minute and detailed inquiries into the amount of traffic and the probable profit to the projectors, your committee are of opinion that the standing orders on these points should be altered, and that it should no longer be obligatory on committees on railway bills to make special reports on them.

At the same time, your committee have no wish to fetter the discretion of the select committees to make such inquiries as they may judge proper with regard to population, and to the extent of accommodation that would be afforded to the public, where they consider such information to be required.

Your committee beg further to suggest, that power be given to select committees to refer the consideration of any unopposed railway bill included in the group referred to them to the chairman of Ways and Means, and the members ordered to prepare and bring in the bill, to be dealt with as other unopposed bills.

STANDING ORDER, No. 87.

On Thursday, Feb. 19, in the House of Commons Nos. 7, 8, and 9, of the Standing Order; No. 87 were rescinded, this will get rid of a very expensive, tedious, and troublesome part of railway proceeding, as it will no now be compulsory to produce evidence relative to traffic.

DATUM LINE, Order No. 25.

A doubt arose in the minds of the committee respecting the London and Brighton (Dorking Branch) Railway, whether the *datum* line taken from the proposed junction with the London and Brighton Railway was taken from a sufficiently fixed point, and was in compliance with order No. 25. The committee accordingly postponed their decision, but subsequently decided that in this respect the standing orders had not been complied with.

The reception of the petition of the London and South Western (Romsey and Redbridge Junction) Railway, was objected to on several technical grounds. Among other objections, it was urged that the *datum line taken from the top-water* of the Andover and Reigate Canal was not sufficiently fixed. One engineer stated that the top-water was always nearly on the same level, it being regulated by a weir, but two other witnesses gave evidence of a very different nature on this point. One of the latter, who was employed on the canal itself, stated, that so far from the weir being sufficient to preserve the level, it was very small, and when there was much water he had to open a hatch to let it flow out. The sub-committee declared that the standing orders in this case had not been complied with.

It appeared that in the North Staffordshire (Churnet Valley Line) there were three fixed points given in the plans from which a *datum* line was to be drawn, one only of which, however, was the subject of controversy before the committee. The petition stated that one *datum* line depended on a point 418 feet below the "soffit" of the arch of Cockshott-bridge, and his agent contended that this point was not fixed, but variable and uncertain. The whole turned on the meaning of the "soffit." The opponents called several witnesses, among whom were Mr. Leather, a civil engineer of some years' practice, Professor Hosking, of King's College, London, and Mr. Tite, the architect of the Royal Exchange, who stated that by "soffit" they understood the whole of the interior surface of an arch from springing to springing, and not the top or crown. One of these witnesses said, that with such a point given to him he should consider himself at liberty to take the measurement for the *datum* line from any part of the interior surface of the arch, and that, therefore, this was a fluctuating and not a fixed point. On cross-examination, most of these witnesses admitted, that from this word being used in reference to a level, they might probably suppose it meant the top of the arch.

Mr. Burke, on behalf of the line, brought many experienced engineers, among them Mr. Vignoles, Mr. R. Stephenson (the engineer of this railway), and Mr. G. B. Bidder, who proved, that whatever schoolmen might understand by the word "soffit," no doubt could exist in the mind of a practical man as to its meaning, especially in a case like this, where height or depth was to be measured from it. These gentlemen distinctly stated, that none but a tyro in engineering could suppose it to mean any other portion than the top of the arch.

The Chairman announced that the committee (No. 1) considered the standing orders complied with in this case.

The *datum* line of the Lancashire and Yorkshire North Eastern Railway, was taken on a level with the topwater of the Leeds and Liverpool canal, which would be crossed by the proposed line. The Chairman doubted whether this could be allowed as the fixed point to which the *datum* should be referred. The engineer explained that there was a weir of stone work close to the point from which the level was taken, the water had not fallen below a certain point for the last 16 years.

This being considered satisfactory, the committee decided that this bill should be reported as having complied with the standing orders.

In the committee on the Great Grimsby and Sheffield Junction Extension Railway (No. 2) Bill was opposed, and the first allegation was that the 'datum' line shown upon the sections of the plans was not the same throughout the line, as two different 'datum' lines were shown in different lengths or parts of the line. Mr. Parkes objected to the allegation that it was not sufficiently stated, but was so vague that it was impossible to find out to what part it alluded. Mr. Dernfit said that it referred to the fact that one 'datum' line was taken from the High-street at Lincoln, and the other from Grimsby Dock. Mr. Fowler said the latter 'datum' line was in a branch not included in the present bill. Mr. Dernfit said the second allegation was that the point from which the 'datum' line was taken was the level of a stake driven into the ground at the point of junction with the Nottingham and Lincoln Railway, now in course of construction; but did not state whether it was the upper part of the stake or the lower part of it. He called a gardener of Lincoln, who stated that the stake was in his orchard, next to the wall, and was the "crown stake" of the Nottingham and Lincoln Railway. There was no stake in the street. The Chairman said that it appeared the stake was not on the west side of the High-street, but in the orchard, and therefore was incorrectly described. Mr. Parkes said the reference that it was at the point of junction with the Nottingham and Lincoln line, on the west side of the High-street, clearly described the point meant, and that the stake was correctly described as being on the west side of the High-street. He called Mr. Fowler, Mr. Joseph Gibbs, and Mr. Harrington, who all said that no engineer could mistake as to the point referred to, and that they should consider the stake a fixed point as it was protected by law, it being an offense to take any of them up. The 'datum' stakes were kept standing for a long time after a railway was completed, as it was from them that the levels were kept up along the line. The Chairman said, that the Committee were of opinion that the description was not accurate enough, besides having some doubts as to the sufficiency of a mere stake as a fixed point. They must, therefore, report the case to the select committee. The standing orders had not been complied with in this case.

Subscription Contract.

When the South-Eastern (from the Waterloo-road, near the Hungerford-Bridge, to the Greenwich Railway) Railway, had been gone through, the Chairman stated that the committee (No. 3) could not decide that the promoters in this instance had complied with the standing orders, inasmuch as a considerable doubt was raised in his mind, as well as in the minds of the other members of the committee, whether the subscription contract entered into was such a one as, consistently with the intentions of the house, they could consider sufficient. The contract presented to them was one which combined several different projects, for which separate and distinct estimates had been made—*i. e.*, there were several classes of works to be constructed, but only one subscription contract for the whole, and not a separate one for each of the estimates. The contract certainly provided in its pages for the parties binding themselves only for so much as would be applicable for the particular work or works, A, B, and C respectively, to which they might have subscribed. But, in order to prove the subscription contract for A, it appeared to them it was necessary to admit the proof of that for B and C, a course which he considered was not a strict nor such a compliance with the standing orders as was contemplated.

Mr. Burke, on the part of the promoters, urged that a precisely similar contract had been considered sufficient in one case last session.

The Chairman said, that was in the case of an unopposed petition, and might have been overlooked, and could not therefore form a precedent in this instance. The question, consequently, whether this project had complied with the standing orders must remain over until he had consulted the Speaker and the different chairmen of the other committees.

An objection was made to the Staines and Richmond Railway, an account of the deposit of 10 per cent. not having been paid by the subscribers according to the provisions of the Joint Stock Act. It was admitted however, that 10 per cent. had been paid into the Court of Chancery, in compliance with the standing orders of the House of Commons, but it was contended that the deed itself proved that 5 per cent. only had been paid by the subscribers themselves.—The Chairman, after hearing the objection, stated that this point had repeatedly been decided; and that if the amount required were actually deposited in the Court of Chancery, the committee could not inquire by whom it had been paid; whether it was by the subscribers or by some person for them was quite immaterial. The chairman accordingly decided that the standing orders had been in this case complied with.

An objection was made to the subscription contract of the Ayrshire and Galloway Railway, on the ground that Richard Hodgson and William Macdonald were parties to the deed in a double capacity, as trustees of the first part, and as subscribers (with others) of the second part, and thus covenanting with themselves for the performance of certain matters; which he contended was repugnant to the practice in England and to common sense, inasmuch as it placed the parties in a position in which they might be called upon to sue themselves for a breach of their covenant.

Mr. Connell, for the promoters, stated that the contract had been drawn up in conformity with the practice and the law which obtains in Scotland, where it was competent, in certain cases, for a man to sue himself under a deed. He apprehended also that, in the case of a debt due from one member of a firm to another, the firm might legally sue that member.

Mr. R. Mackay, Writer to the Signet, on the same side, said that a legal objection had never been stated in Scotland effectually against the power of any party to sue because he was a shareholder. Under the common law of Scotland a party could sue himself. It was of daily occurrence. He had taken the opinion of the Lord-Advocate on the point that morning who ridiculed the idea that a party could not sue himself by the law of Scotland.

The Chairman desired the room to be cleared for a division. On our re-admission, he stated that, in regard to the objection of Mr. Burke, the committee had decided that the standing orders had not been complied with, inasmuch as the subscription deed was invalid, in that it did not bind the subscribers, within the meaning of the standing order 40.

The committee on standing orders confirmed this decision of the sub-committee, but subsequently in the House the Attorney General declared that the contract was not illegal, consequently the report was referred back to the committee.

Notices.—Order, No. 17.

It was contended by Mr. Connel, on the part of Sir W. Napier, that the section of the proposed Ayrshire, Bridge of Weir and Port Glasgow Junction Railway, so far as it related to the parish of Kilbarton, was not in accordance with the standing orders, in that the notice which had been served on his client, Sir William Napier, did not inform him how a road in that parish which the petitioners intended to lower 15 feet would affect him, as they were required to show in the heading of the schedule (form referred to in standing order No. 17); secondly, that in respect to the position of the road, the level of the same, and the manner in which the railway would affect it, these particulars were all inaccurately described.

The committee, after minutely examining the sections on this point, and considering the order referred to, overruled the objections.

References.—It was contended by the opposition, that a narrow strip of ground in the parish of Port Glasgow, and described as vacant ground, was in the occupation of the Gourlock Ropeworks Company, and belonged to the Glasgow and Greenock Railway Company, and not to the parties named in the book of reference.

The petitioners' agent called a witness to prove that he had made diligent inquiries as to the ownership of the land in question, and that in prosecuting those inquiries he was referred to one of the servants of the Glasgow and Greenock Railway Company, at the station adjoining this piece of land; who informed him that he (the servant) had received instructions from head-quarters to withold information from parties concerned in the projected line.

The Committee were of opinion that the petitioners had used due diligence in ascertaining the ownership of the land, and that if parties refused to give such information whereby the promoters of a railway were led into error, the allegation of error came with bad grace from such parties. Therefore, in this case, the standing orders had been complied with.

Important Decision with regard to opposing a Bill before the Standing Order's Committee.

Mr. Burke, on behalf of a petitioner against the London, Newbury and Bath Railway, stated that he could prove that the books and plans deposited in the office of the House of Commons differed from those which had been deposited with the clerks of the peace. He contended that the petition was sufficiently in compliance with standing order No. 9 to entitle him to be heard, for as the plans and books of reference were incorrect, no landowner or occupier could know whether his land would be affected or not, and, therefore, was entitled to petition.

The Chairman said he had conferred, not only with other committees, but also with other persons, to whose opinion he was inclined to bow, and he had come to the conclusion that where the objection had reference to the subscription contract, or other matter affecting the public, then any one of the public might petition. *Where there was not any party affected, then the standing order No. 9, did not apply, but it was made for the protection of individuals, where there was a party affected,* then that party must be cognizant of an assent to such petition. He would not say the party affected must necessarily be a landowner or occupier. The committee might hold that under special circumstances some other person might be affected within the meaning of the order.

Mr. Burke expressed himself much pleased at the decision, which he was certain would affect some hundreds of petitions. He then withdrew the petition.

An important allegation was made by Mr. Coates against the Bill of the Berks and Hants, (Hungerford Extension) Railway, on behalf of a petitioner opposing the bill annexed to the promoters' petition, that power was sought by the Great Western Railway Company to raise the sum of 850,000*l.*, yet the said notices did not make mention of any application to Parliament for the amendment of the acts relating to the said company, nor had such notices been published in all the counties in which the works of the said company were situate.

Mr. Pritt read the notices from the *Gazette*, and contended that they were amply sufficient, and given in compliance with the standing orders.

The Chairman desired the room to be cleared; and on our re-admission, after an interval of upwards of half-an-hour, the Chairman intimated that with respect to this allegation, the committee had come to the following resolution, namely that the committee were of opinion that the standing orders had not been complied with, inasmuch as the notices of application to Parliament to make a railway did not state the intention of the Great Western Railway Company (though subsequently stated to be the owners of the said Berks and Hants Railway) to amend their acts for the purpose of raising a further sum of money, but a separate notice of the same dates respectively was given by the Great Western Railway Company to amend their acts, yet such last-mentioned notice did not contain the names of places through which the works were intended to be made.

ROYAL OBSERVATORY, PARIS.—A contemporary states that there is being constructed on the top of this building, a study cabinet, the walls of which, as well as the ceiling, are of pure crystal. It is in this chamber that M. Arago will work and watch the stars, planets, and comets, by the assistance of a monster telescope, which is now being made. It is expected that this new transparent observatory will be terminated by the month of July next.

The *Dauntless* and *Arrogant* frigates, on the designs respectively of Mr. White, of Cowes, and Mr. Fincham, master shipwright of this establishment, are progressing very rapidly towards readiness for launching; their timbering is finished, and their ceiling and planking. The Dauntless (Mr. Fincham's design) is intended as a steam frigate, but the Aorrgant will only have steam as an auxiliary to work a screw. The following are the principle dimensions of the Arrogant. Length between the perpendiculars 200 feet; Length of keel for tonnage, 175 feet; Breadth extreme, 45 feet, 4 in; Breadth moulded, 44 feet; Depth of hold, 23 feet; Burden in tons, 1,800; Horse-power for screw, 390. This fine ship is in the most forward state of the two, and presents a boldness of outline very much admired by all who have seen her since she has been planked. She presents a very handsome looking model, and is expected to prove a perfect man of war.

LIST OF NEW PATENTS.

GRANTED IN ENGLAND FROM JANUARY 29, 1846, TO FEBRUARY 25, 1846

Six Months allowed for Enrolment, unless otherwise expressed.

George Frederick Hall, of Norfolk-street, Fitzroy-square, in the county of Middlesex, pawnbroker, for "certain machinery or apparatus for writing and booking, numbering, cutting, checking, and expediting the delivery and receipt of pawnbrokers' duplicates, pass-tickets, and other like documents."—Sealed January 29.

James Brown, of Ball's-row, High fields, Coventry, for "certain Improvements in weaving."—January 29.

Augustus Turk Forder, of Leamington Priors, in the county of Warwick, solicitor, for "an Improved pump or engine for raising and impelling inelastic fluids, and producing motive power."—January 29.

Charles Cowan, of Valley-field mills, in the county of Edinburgh, paper manufacturer, for "Improvements in the manufacture of paper mill-board, and other similar substances."—January 29.

John Greenwood, of Church, in the county of Lancaster, manufacturing chemist, for "Improvements in dyeing Turkey-red, and other colours."—January 29.

George Howell, of Larkhall-lane, Clapham-common, Surrey, for "coating with a metal the surface of articles formed of copper, or copper alloys, or iron, whether wrought or cast." (Communication.)—January 29.

Michael Rimington, of No. 10, Rufford-row, Islington, in the county of Middlesex, gentleman, for "Improvements in obtaining and applying motive power." (Communication)—January 31.

George Hinton Bovill, of Millwall, in the county of Middlesex, engineer, for "Improvements in the manufacture of iron."—January 31.

Andrew Etienne, of Hatton-garden, in the city of London, gentleman, for "Improvements in the construction of railways, railway carriages, and in the means of preventing accidents on railways."—January 31.

James Pilbrow, of Tottenham, in the county of Middlesex, civil engineer, for "certain Improvements in propelling on land and water."—January 31.

Henry Highton, of Rugby, in the county of Warwick, master of arts, for "Improvements in electric telegraphs."—February 3.

Edwin Chesshire, of Birmingham, surgeon, for "Improvements in apparatus to be applied to railway carriages to reduce the prejudicial effects of collisions to passengers in railway carriages."—February 3.

Samual Brown, of Gravel-lane, in the county of Surrey, engineer, for "Improvements in gas engines, and in propelling carriages and vessels."—February 3.

Thomas Foxall Griffiths, of Wolverhampton, for "Improvements in stamping and shaping sheet metal."—February 3.

William Garnett Taylor, of Halliwell, in the county of Lancaster, cotton spinner, and William Taylor of Halliwell, aforesaid, labourer, for "Improvements in consuming smoke and economising fuel."—February 3.

William Malligan, of Bradford, in the county of York, manufacturer, for "certain Improvements in the power-loom."—February 4.

William Greener, of Birmingham, gun maker, and William Edwards State, of Peckham, Surrey, esquire, for "improved means of ignition and illumination."—February 7.

Thomas Clarke, of Hackney, Middlesex, engineer, Mark Freeman, of Sutton, in the county of Surrey, gentleman, and John Varley, of Poplar, in the county of Middlesex, for "certain Improvements in obtaining and applying motive power, parts of which are applicable to the regulating and controlling of fluids."—February 11.

James Palmer Budd, of Ystalyfera Iron Works, Swansea, merchant, for "Improvements in the manufacture of iron."—February 11.

John Keating, of North-mews, Fitzroy-square, in the county of Middlesex, scagliolist, for "certain Improvements in the manufacture of cement."—February 11.

Joseph Pierre Gillard, of Rue Martignac, in the city of Paris, professor of mathematics and philosophy, for "Improvements in the production of heat in general."—February 11.

Charles Tetley, of Bradford, in the West Riding of the county of York, stock and share broker, for "certain Improvements in machinery for raising and impelling water and other liquids, and also thereby to obtain mechanical power."—February 11.

William Edward Newton, of Chancery-lane, in the county of Middlesex, civil engineer, for "Improvements in the construction of instruments or apparatus for ascertaining, registering, and regulating the speed of carriages and machinery." (A communication.)—February 11.

Andrew Smith, of Prince's-street, in the county of Middlesex, engineer, for "Improvments in coating or covering metals for the purpose of preventing oxidation."—February 11.

Alfred Vincent Newton, of Chancery-lane, mechanical draughtsman, for "certain Improvements to be applied to the grinding of grain and other substances."—February 11

James Murdoch, of Staples-inn, in the county of Middlesex, mechanical draughtsman, for "an Improved process for preparing a certain material for the purpose of painting." (A communication.)—February 11.

George Stevenson, of Tapton-house, Chesterfield, in the county of Derby, engineer, and William Howe, of Newcastle-upon-Tyne, in the county of Northumberland, mechanic, for "an Improvement in locomotive steam-engines."—February 11.

William Wharton, superintendent at the Euston-square station of the London and Birmingham Railway, for Improvements in straps and bands."—February 11.

Charles Rowley, of Birmingham, button manufacturer, for "Improvements in buttons and other fastenings for wearing apparel, and in the machinery for manufacturing parts of the said fastenings."—February 18.

John William Stanbridge, of 38, Brudenell-place, New-road, Middlesex, gentleman, for "an Improvement in the manufacture of certain descriptions of silks and other fabrics."—February 18.

John Brocklehurst, of Holborn, in the county of Middlesex, lamp manufacturer, for "Improvements in the hanging and disconnecting of window sashes and frames."—February 11.

James Nasmyth, of Arundel-street, in the county of Middlesex, gentleman, for "certain Improvements in engines or machines for obtaining and applying motive power."—February 16.

William Edward Newton, of Chancery-lane, in the county of Middlesex, civil engineer for "Improvements in the preparation or manufacturing of thread or yarn." (A communication.)—February 17.

Jacque Cloet, of Manchester, in the county of Lancaster, gentleman for "a certain Improved combination of materials to be used as a substitute for leather or for waterproof cloth and other similar useful purposes."—February 17.

Juan Nepomuceno Adorno, of Mexico, in the republic of Mexico, gentleman, for "Improvements in manufacturing cigars and other similar substances."—February 17.

Edouard Auguste Desire Guichard, of Rue des Feuneurs, Paris, in the kingdom of France, for "Improvements in printing calico and other fabrics."—February 17.

Stephen Etievant, of Church-street, Soho, in the county of Middlesex, for "Improvements in stoves." (Communication.)—February 17.

Nicholas Francois Corbin Desboissierres, of Rue Saint Pierre, Montmartre, in the Kingdom of France, gentleman, for "Improvements in preparing and burning fuel."—February 17.

Joseph Clinton Robertson, of 166, Fleet-street, London, civil engineer, for "Improvements in nail making machinery." (Communication.)—February 18.

Robert Nisbet, of Lamden, in the county of Berwick, esquire, for "certain Improvements in locomotive engines and railways."—February 19.

Peter Claussen, of Leicester-square, Middlesex, esquire, for "certain Improvements in machinery for weaving, and in preparing materials for weaving." (Communication.)—February 20.

John Platt, of Oldham, in the county of Lancaster, machinist, for "certain Improvements in machinery or apparatus to be employed in the preparation and spinning of cotton and other fibrous substances."—February 25.

John Britten, of Liverpool, chemist, for "certain Improvements in the method of applying heat for the purposes of heating, cooking, and evaporating, and in the apparatus connected therewith."—February 25.

Peter Bancroft, of Liverpool, merchant, for "certain Improvements in the method or process of refining and purifying animal and vegetable oils and grease."—February 25.

John Harcourt Brown, of Brunswick-place, Barnsbury-road, gentleman, for "Improvements in securing letters, envelopes, covers, despatches, packets, and parcels."—February 25.

Thomas Murgatroyd Dean, of Stockport, in the county of Chester, engineer, for "certain improvements in machinery or apparatus applicable to to the furnaces or fire-places of steam-engines or other boilers."—February 25.

Moses Poole, of the Patent Office, London, gentleman, for "Improvements in cleaning and separating grain and other seeds." (A communication.)—February 25.

Antonio James Mayer, of Ashley-crescent, City-road, for "Improvements in certain wood-cutting machines."—February 25.

Josue Heilmann, of Mulhausen, in the Department Du Haut Rhin, France, machine maker, for "Improvements in certain machines used for preparing to be spun cotton, wool, and other fibrous materials."—February 25.

William James Cantelo, of Paris-street North, Lambeth, for "Improvments in apparatus for hatching eggs and raising the young, and for heating hot-houses and other buildings."—February 25.

Thomas Pemberton, junior, of Birmingham, manufacturer, for "a new or Improved method, or new and improved methods of ornamenting window-furniture and articles of upholstery in general."—February 25.

William Robertson, machine maker, of Gateside, Renfrewshire, for "certain improvements in the machinery for spinning and twisting cotton, silk, wool, flax, and other fibrous substances."—February 25.

George Alexander Thompson, of Connaught-terrace, Hyde-park, gentleman, and Joseph Wright, of Holborn-bars, mechanic, for "Improvements in propelling vessels."—February 25.

John Maddock, of Binstern, Stafford, earthenware manufacturer, for "a new and improved method of building and constructing kilns and ovens used by potters and manufacturers of china and eathenware."—February 25.

CORRESPONDENTS.

Mr. Foster's book on Book-keeping relates to subjects which do not fall within the scope of this Journal.

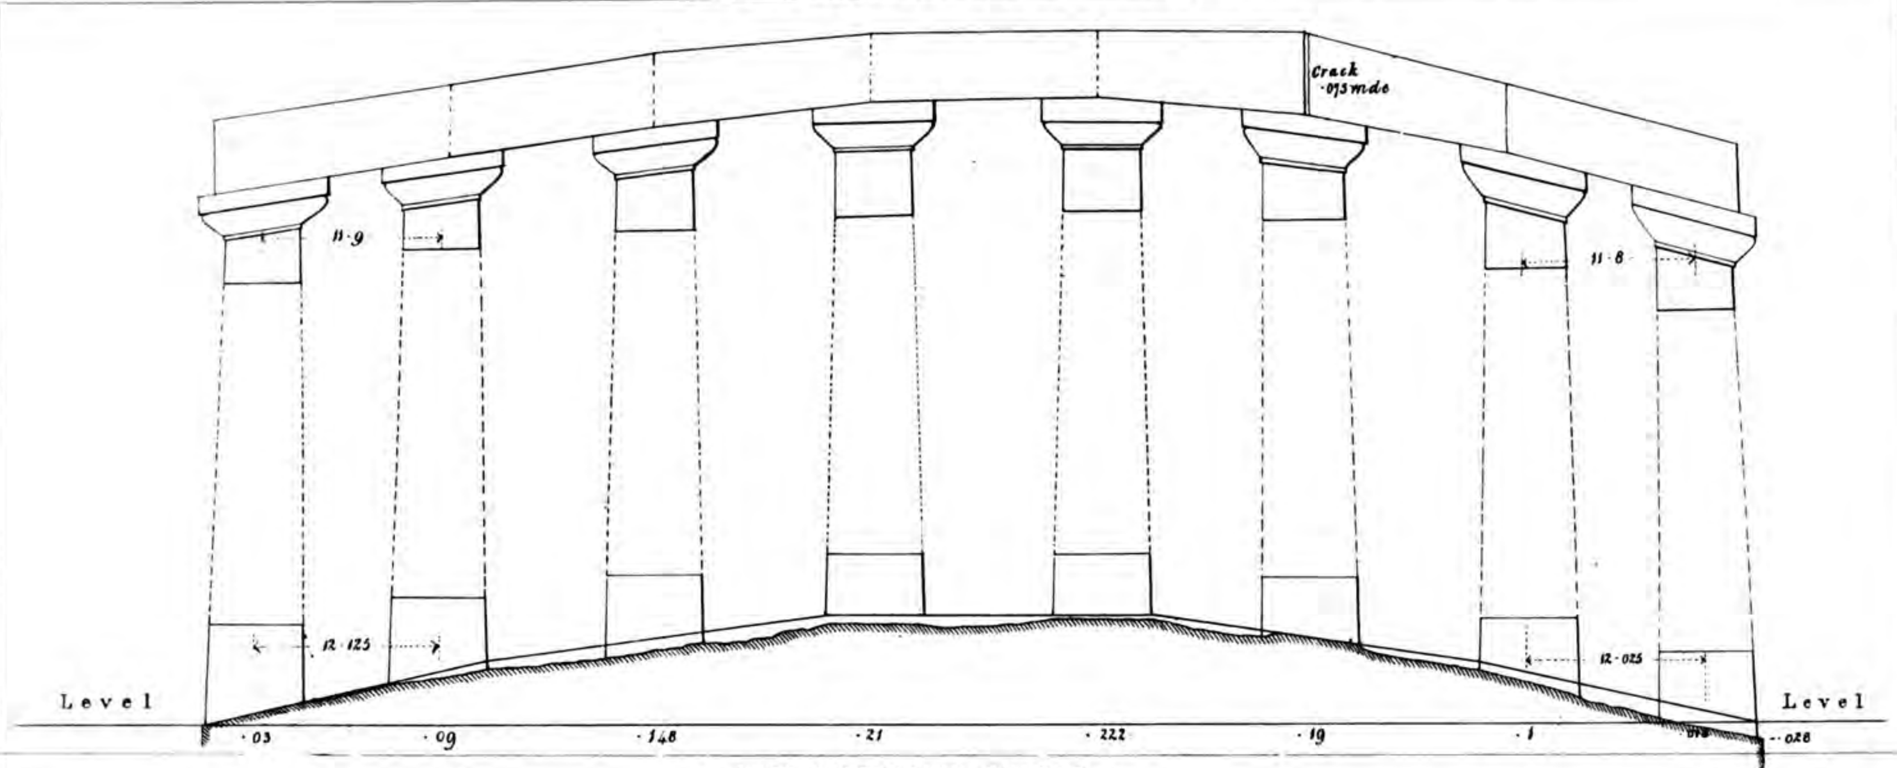
Received—Mr. Neville's paper "on the pressure to sustain banks of earth;" notice of this paper is in type, but is unavoidably postponed to next month.

The notices of new and restored churches in the present number are abridged from the Ecclesiologist.

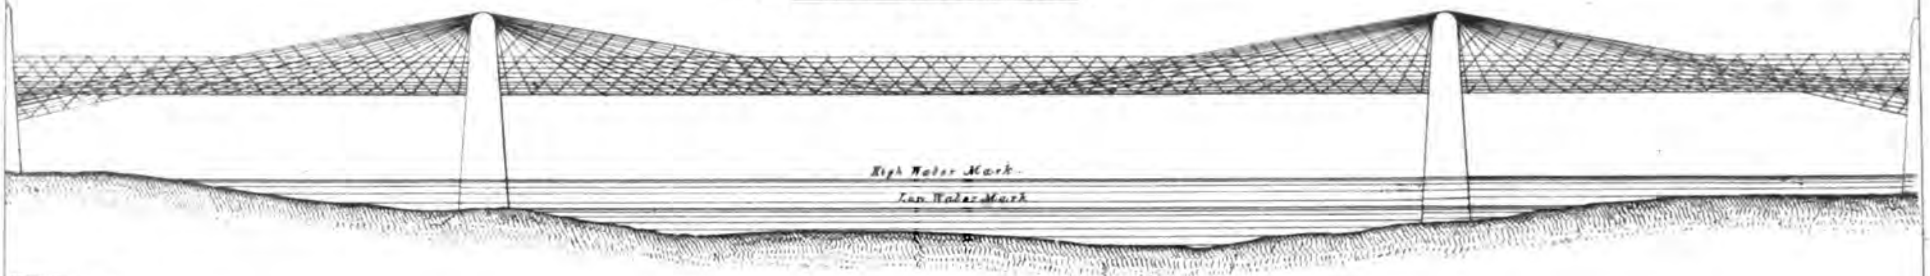
Can any of our readers refer us to books or documents containing the history of St. Margaret's Church, Westminster, and detailing the nature of the modern alterations.

M. The restorations of Notre Dâme at Paris are made at the expense of the French Government.

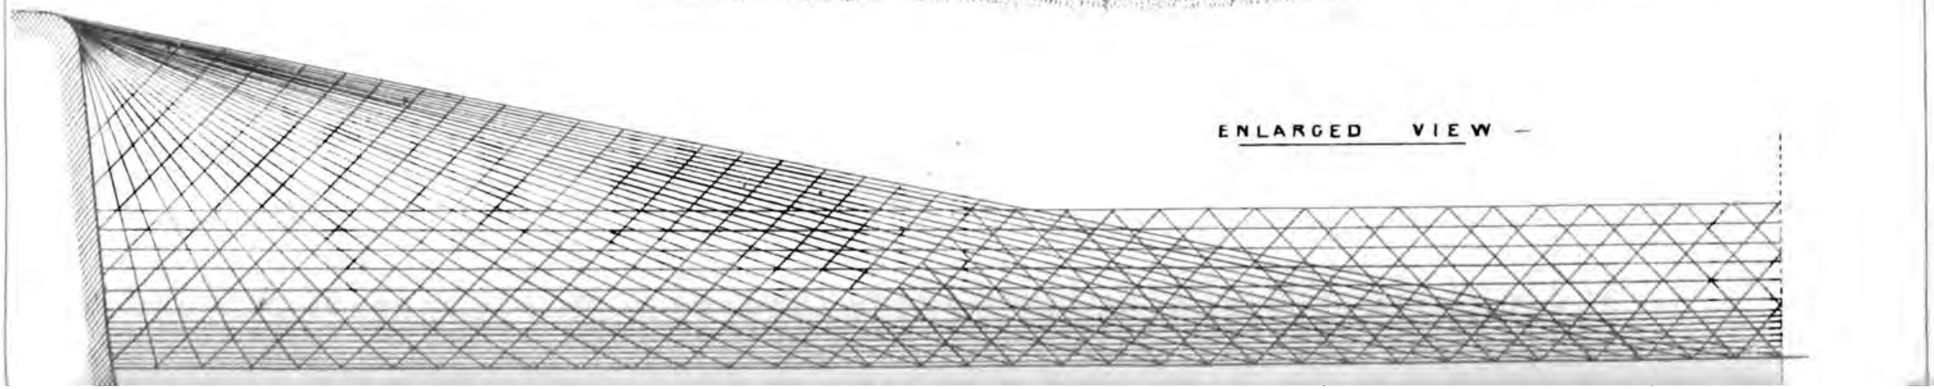
EAST FRONT OF THE PARTHENON –



AUST SUSPENSION BRIDGE –



ENLARGED VIEW –



ON THE ENTASIS AND OTHER CURVED LINES OF THE PARTHENON.*

By F. Penrose, M.A., Magd. Coll., Cambridge, Associate of the Institute.

Read at the Royal Institute of British Architects.

(*With an Engraving, Plate V.*)

It is an admirable principle of this Institution that it has for its object the bringing together of various points of information from its different members, inasmuch as no *one* can see or understand everything. It would be contrary to the spirit of this proposition, to expect that no one should get up here to speak who had not materials for an entire evening's lecture. In accordance with these views I shall only detain you a short time, to inform you of the results which I have arrived at, in a limited survey of the Parthenon; all the measurements I took having reference to its scientific, not its decorative construction.

It is a very convenient season for such discussion, after the very edifying and agreeable evening which we passed here on the last occasion of our meeting, when the zeal of Mr. Lucas and the remarks which he called forth from Mr. Donaldson, brought the subject so vividly into discussion.

However I will proceed at once to what I have to say—The first point to be considered is the curvature of the steps—it is obvious that the earlier investigators of the Parthenon had no opportunity of observing this as the ground was covered with rubbish, and it is so slight as to elude the eye unless brought down to the level of it.

Had Vitruvius however been in credit, the following passage would have sufficed to suggest it, "The stylobate or step should be so set out as to have in the middle an addition by means of unequal *footstools* (literally), *i. e.* unequal blocks. For if it be made level, it will appear to the eye sunk in the middle (literally channelled) to the eye." Again, "When the capitals are finished they must be arranged on the shafts of the columns, not level, but according to the same measurement as before, so that the symmetry of the architraves and upper members may correspond to the same addition as was made in the stylobate."

This was first observed in the Parthenon, I understand, by Mr. John Pennethorne. He unfortunately, however, allowed the Germans to have the credit of prior publication; it made its appearance in a Vienna architectural journal, four years ago. I have a drawing (see plate), made from my observations of the east front of the Parthenon. I levelled it, I believe, very correctly, as my instrument, on being taken to the opposite end, gave exactly the same line. I have drawn a black line along what I suppose to have been the original line; the shaded line marks that which I obtained from my measurements; these, in which I was assisted by Mr. G. Kennedy, were taken with the French metre, and I have reduced them to English feet and decimals of a foot, which, I think, is the best system we can use for scientific mensuration—it were much to be wished that it should become universal. A circumstance which would render this change less troublesome to workmen is, that the 100th of a foot is nearly the same as the eighth of an inch.

Now, observing that the sixth column from south-east angle is the highest for its situation of all the columns, and that the architrave above has a crack about ·06 feet in width, I infer that that point has been set most firmly in the foundation, and the rest have all settled more or less about it. This may perhaps have been all the result of earthquakes, as I found that the base of the central columns of the west front were ·08 feet higher than those at the east end, and the base of the south angle column of west front was ·09 feet higher than that at its north angle.

In the east front it will be seen by the drawing that the north-east angle of upper step is ·028 feet lower than south-east angle, showing a settlement in that part of the building, which is also attested by the aforesaid crack over the architrave of the sixth column. It will be seen that on the south half of the front the step runs very nearly straight, except that at the angular column there is a little more shoot, probably to throw off the water better. And the angular column is about ·02 feet longer than the others to compensate for this. The step, at this point, has a gradient of about $\frac{1}{130}$, afterwards $\frac{1}{350}$ nearly. The chief rise is ·022 feet, which is about the same as the amount which the columns lean from the perpendicular. The height above level of fourth column from the east on the south flank is ·28. It is quite clear that the step has been lowered a trifle by settlement, as the stones of the step immediately under the columns adhere so closely that they have actually grown together, as Stuart found to be the case; but lower down the joint is apparent enough.

An hyperbola may be drawn approximating very nearly with the line after allowing a very little for these settlements, which have unquestionably taken place, and as the conic sections have been applied constantly in the construction of this and the other temples at Athens, I think it not improbable that they were regulated in this matter by that curve.

Can any geometrical or optical considerations suggest the necessity for this addition in the middle of the step?

Vitruvius does not go so deep into this as he usually does on optical questions; he merely says that the step if level will look channelled. It occurs to me that it is in the pediment and not in the step that we are to look for the necessity of this correction.

It is a matter of constant experience that the presence of a curved line distorts any right line in its vicinity, as for instance, the tangent to a circle always looks bent contrary to the curvature of the circle, and the same thing is no less true of the chord. A small segment of a large circle may be made to look straight, or even bent contrary to its real direction, by the juxta-position of a curve of greater curvature.

The same thing obtains more or less in a pediment where the converging lines have ultimately exactly the same relative position as an arc and its chord. And any portico to which these corrections are not applied will give something of this feeling, if we look attentively at its angles. Another confirmation of this view of the matter is, that in the great temple at Pæstum, (undoubtedly built some time before the temple of Theseus,) the addition to the stylobate and entablature is applied only at the ends; the flanks are horizontal. At Segeste, whose greatness is probably posterior to the glorious days of Athens—and consequently their temple is to be referred to a later period—the addition is on all sides as at the temples of Athens. This adjustment could only be required in temples seen directly opposite. So in the Propylœa, we do not find any addition made to the stylobate.

We have heard something of a curvature of the entablature in an horizontal plane as well as the vertical. Mr Lucas stated last meeting that he understood from Mr. Pennethorne that such was the case. I admit that both the fronts of the Parthenon are bent inwards, but not that it was so originally.

In the east front of the Parthenon the four first architrave stones are in a continuous plane nearly vertical; the fourth is bent slightly inwards away from this, the rest are quite irregular. The entire deflexion in the east front is not more than ·09 feet.

I observed that the joints of masonry on the fronts are almost all crushed, so that it is clear that there has been a slight disturbance of the original plane of the building; indeed, the angular columns give less declination than the central ones.

I found that the fourth column from the south-east angle leant ·285 feet; (this is the same as that given in the supplement to Stuart.) From the north-east angular one I deduce ·225 after allowing for the amount of settlement due to the crack above the sixth column. I cannot admit that such horizontal curvature was ever intended. Vitruvius does not mention it, nor can any reason be assigned that I am aware of for the use of it. Constructive and optical advantages are obtained both by the leaning of the columns and the raising the stylobate and epistyle. It is evident that, in a country liable to earthquakes, a certain degree of pyramidal construction given to the building must be of statical advantage. The slight disturbance which has actually taken place has thrown the north-east angle column about ·07 feet to the right hand, and it would have leant away from the building in an unsightly manner had not there been an original declination three times as great inwards.

Still I do not compare my argument *a priori* with that drawn from marks of crushing and settlement on the building. As Wilkins fell into a sad mistake when commentating on these very subjects in Vitruvius, when he states his belief that it was only a fancy of Vitruvius, and did not enter into the works of the ancients. Vitruvius is very positive about the leaning of the columns, and states that their inner face should be parallel with the wall of the cella. The columns of the Parthenon have not nearly so much lean as this, however owing to the nature of the curve of their

* The curvature of the stylobate of the Parthenon is briefly noticed in the Seventh Volume of this Journal, p. 16.

entasis, they are so at their springing, which may perhaps be Vitruvius's meaning, as there is no instance, except, I believe, the temple at Tivoli, of so great a declination as he describes. It was well known generally among the ancients that such was the case. Cicero relates an amusing story, in his oration against Verres, how Verres was very anxious to do something in the building way, and restore a certain temple of Castor at Syracuse. He came into the temple, and on examining it, found every thing sound and in good repair. He turned about him, and asked his confidentials what he should do. One of them jokingly said, "Why, Verres, you have nothing to do here, unless, perhaps, you would like to set the columns perpendicular." That man (Verres), most ignorant on all subjects, asks, "What do you mean by perpendicular?" They answer him, that there was hardly any column which could be perpendicular. Then said he "By Hercules, let us do so, and put them perpendicular." Cicero thus holds up Verres for derision, for being ignorant on matters of taste.

It seems to me that the following consideration suggested the inclination given to the columns:—In consequence of the diminution of the columns, the upper spaces become larger than the lower, and as the eye measures the whole length of the architrave by the sum of the intercolumniations, it would appear longer than the step, and consequently the columns would appear to diverge from the ground, unless such inclination be given to the angular columns as shall correct this false impression.

Vitruvius states that all the members above the capitals should lean outwards $\frac{1}{12}$th of their height. This, I believe (and I have seen some very careful measurements of Mr. Scoles's, made with reference to this), does not obtain in any Greek building. The corona of the Parthenon, indeed, has an inclination outwards of 1 in 100, but all the rest of the members lean inwards in the direction of the columns; it is clear that $\frac{1}{12}$th would be too much, and especially at the angles would appear nearly $\frac{1}{8}$th, which would look preposterous. I have no doubt that the $\frac{1}{12}$th in the text of Vitruvius is corrupt, or else Vitruvius must have generalised too much; I should prefer the former hypothesis.

There is a small difference both in the west front and east front. In the outer intercolumniations of the Parthenon, that to the south is in both fronts about $\frac{1}{10}$th of a foot wider than the northern one. Can this have arisen from a desire to make the intercolumniations towards the south—which are more seen, both on account of sun and situation—more nearly equal to each other? In the temple of Theseus the same holds but *vicè versâ*. In both cases the addition is given at the side which from its position is most commanding.

The joint of the stone of the architraves next the angles is on both sides made to lie a little within the centre of the column (or towards the centre of portico), by means of which the two metopes next the angles are squares, and the next two differ, by a small quantity, from that figure. It must have been thought that it was more important to get the angular metopes exactly symmetrical on each face, than two contiguous ones on the same face. This adjustment, however, is not so apparent on the flanks and west front as it is in the east front; but the east was the principal front theoretically, though in the Parthenon the west front was seen more from the town.

There are some small and curious varieties in the abacus in different parts of the Parthenon. The more ordinary one on the east, west, and north sides is $\frac{1}{15}$th upper step. The abacus of the angular column is $1\frac{1}{4}$ Attic dactyli, or nearly $\frac{1}{80}$th greater. I divided $\frac{1}{100}$th of the upper step of the Parthenon (*i. e.* one Attic foot, according to the Greek fashion) into 16 dactylii, and have found these divisions to agree very well with the smaller dimensions, which were taken by myself as well as by others, and with fragments in the British Museum.

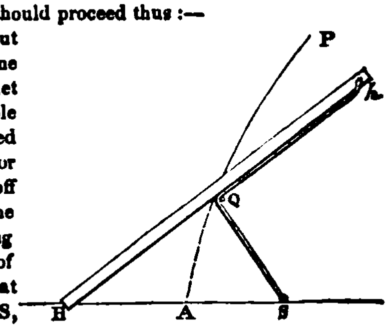
If the abacus be divided into 30 parts, 28 such parts will give the lower, and 22 parts the upper, diameter of the column. The angular abacus is $\frac{1}{5}$th the height of the column; the thickness of this abacus is $\frac{1}{4}$th of its breadth. On the south side every abacus is less by ·2 feet than those on the north side and fronts, and is equal to $6\frac{1}{4}$ Olympic or Attic feet, or $\frac{66}{1000}$ of upper step.

These capitals, being always seen either from the city below, or from the very narrow space between the temple and the wall, on the platform itself of the Acropolis, in quick perspective, a large portion of their under surface would be seen, which would give them a greater appearance of size than the others, which are not generally viewed from a similar situation, and which would, therefore, appear more as in elevation. The abacus in the British Museum is from the south side.

I now come to the entasis of the columns. In the Parthenon it is so slight as merely to correct the false impression which the eye always receives from columns whose sides are really straight lines, for the eye naturally fixes upon and measures the column at the neck, and the springing or base, but has nothing to compare it with in the middle, so it loses at that point in importance and requires compensation.

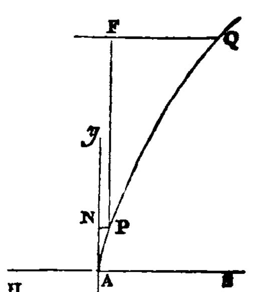
The entasis of the columns of the Parthenon is about that which would be given in an Ionic column of the same height, according to Vitruvius's rule, viz., the thickness of the fillet of one flute. I have found, from measurements taken at the edge of the flutes, that this curvature results from the columns being hyperboloids of revolution. The generating hyperbola has a principal axis equal to 1 Attic foot, a focal distance equal to 30 Attic feet; *i. e.*, the distance between foci is equal to 60 Attic feet, the line of the foci at a distance of twice the abacus below the upper step.

It is well known that the conic sections have been used very generally in these Greek buildings, but I am not aware that the exact nature of the entasis has been before demonstrated. In confirmation, I will only appeal to Mr. Scoles. Hearing that he had some accurate measurements of one of the columns, I asked him for his vertical measurements, and promised to bring him the horizontal diameters corresponding. On comparing these with his measurements the coincidence was so striking that I am morally certain that I have obtained the true nature of the curve. I have also consulted the dimensions of the columns of the Parthenon, given in the supplement to "Stuart's Athens," with a highly satisfactory result; I have also found the columns of the Theseus to be hyperbolic. A curve obtained geometrically with line and rule, owing to the unequal action of the elasticity of the string, gives a trifling deviation from the curve obtained by calculation, and approximates still nearer to the entasis of the columns. It is not to be supposed that, in forming their columns, the Athenian artists struck the hyperbola full size, for then they would have required a straight-edge about fifty feet long, which would have been very unmanageable; but any hyperbola, constructed with the same principal axis, viz., $a = 1{\cdot}013$ feet, will have its horizontal abscissa full size, and the vertical ordinates in some proportion, which can be easily determined. Consequently, to obtain any number of dimensions for constructing a column like those of the Parthenon we should proceed thus:—



Take a straight-edge H h, about five feet long; fix a string at one end of this straight-edge h, and let the other end traverse, upon a table or drawing-board, round a fixed point, H, by means of a pin or awl. Let the string be cut off exactly 2·025 feet shorter than the length, H h, of the rod. The string being fixed to the moveable end of the rod h, and to a fixed point S at some convenient distance H S, from H, viz., about three feet.

Now let the straight-edge revolve about H, and keep the string tight against it with a pencil, as at Q; thus will an hyperbola, P Q A, be traced on the board, having all its horizontal dimensions equal to the real size, and its vertical according to some scale which can be very easily determined:—



Draw A Y perpendicular to H S, and, at a distance, N P = $\frac{1}{11}$th of the axis we have been using, viz., $\frac{1{\cdot}013 \text{ feet}}{11} = {\cdot}092$ feet, draw P F parallel with A Y. Then set off F Q = ·696 feet, which is equal the entire diminution of the column, and the segment Q P will be proportional in height to the shaft of the column, and if it be divided so as to represent 31·4 feet, the scale so obtained will give the full size entasis at any point required.

A somewhat similar method may be used to obtain any desired entasis for any column that may be required, having first fixed upon the amount of the entasis and the diminution of the column by first drawing the curve as here described, with any convenient axis and foci, and then applying a straight-edge until we get exactly or approximately the amount of entasis and diminution required; dividing the length of the arc so obtained for a vertical scale of the column; but as this implies something of the loose nature of a tentative process, it would of course be more satisfactory to fix exactly the upper, lower, and middle points of the proposed curve, the distance below the springing of the focal line, and then obtain the curve by an analytical, or, when possible, by a rigid geometrical process; the first method, however, is very easily done and capable of great exactness.

The hyperbolic form is admirably adapted for Doric columns. The conchoid of Nicomedes, which is so very beautiful in Corinthian, has a point of contrary flexure near the neck, which is inconsistent with the solidity and dignity of Doric.

Before I leave this subject I will say that by slightly modifying the points, &c., and string in the geometrical drawing of the hyperbola, multitudes of beautiful curves are produced, some of which are very like those of the vases and amphoræ of antiquity. There can never be any need of drawing curves arbitrarily by eye, as there are an infinite variety of regular curves, suited to every possible want of art or science. I cannot help alluding to the exceeding beauty of the curves produced by Professor Willis by his epicycloidal chuck.

Are these isolated principles? Or are they not rather connected by some one beautiful connecting link?—I cannot yet attempt to decide: something must have been left to the eye and judgment. But it would be extraordinary that such wonderful adjustments—such subtle corrections, worked too with such precision and geometrical accuracy, should be in each case merely empirical. Without the most accurate measurements of these small differential quantities, taking into consideration every crack and movement among the blocks of marble, it must be hopeless to discover it. There is ample field for a work which shall be the standard of the scientific, as that of Stuart is of the decorative architecture of the Greeks.

Reference to the Engraving.

The engraving is a sketch showing the rise in the stylobate and the inclination of some of the columns in the East front of the Parthenon. The differences in the steps, &c. are drawn to a scale equal to one-fifth of the real size, and the remainder one 150th of the real size. The dimensions are given in feet and decimals of a foot; the figures under each column show the height of the steps above or below the level line. The irregular line at the foot of the columns shows the existing line of the steps, and the line above it the probable original form.

The upper and lower courses of the columns are the *scamilli impares* of Vitruvius; all the rest are symmetrical and perpendicular to the axis of the column. The left hand outer column leans to the right ·206, and the right hand one leans to the left ·15.

THE DECORATIONS OF THE OPERA HOUSE.

The example that is to be, of the New Palace of Westminster, and which is now only *in prospectu*, may be said to be operating by anticipation. All branches of decoration connected with architecture are, in city phrase, *looking up*, and even mural pictorial embellishment, in encaustic, if not yet in fresco, has begun to be introduced among us,—and that, perhaps, with more hurry than good speed. What was the first application of it is by no means a very prepossessing specimen, the decorations in the arcades of the Royal Exchange being almost ludicrously inconsistent with the purpose of the building,—so greatly at variance with all propriety of character, that were they very much better both as to execution and general effect, they would still be unsatisfactory. Strange to say, although *Decoration* would seem to hold out the fairest opportunities for the exercise of inventive talent and the indulgence of fancy, it seems to be shackled by and under the thraldom of "Precedent." Even in Ornamentation we either can, or else allow ourselves to do nothing without asking permission of Precedent. Our most approved novelties—our newest fashions in furniture and the fitting-up of rooms seldom amount to more than the re-introduction of obsolete and by-gone ideas,—not of ideas legitimately borrowed in order to be modified and so remodelled as to be made our own, but taken bodily, and copied with scrupulous exactness, on which very account what is intended for fidelity becomes no better than absurdity, and what was excellent in its own time—in accordance with the spirit and circumstances of that time, is rendered more or less ridiculous by misapplication. We hug and pique ourselves upon our wonderful talent—the only wonder being that it should be thought such—for imitating what has some time or other been done before. We plume ourselves upon being *plus arabe que l'Arabie*,—more Pompeian than Pompeii, more *à la Quatorze*, than the great Louis: All *à la grecque* and *à la Hope* one day, we are all Elizabethan the next; Renaissance, and Roman, by turns; Gothic or Grotesque, according just as fashion dictates.

The Opera House has just been embellished *à la Raffaellesque*, and by good luck—by sheer good luck it happens that that style—in reality the *à la* Titus is admirably well suited for the decorations of such a place, it being playful, poetical, and fantastic enough, for which very reason the application of it to a *pontifical* palace becomes somewhat questionable, not but that it would have been highly commendable in some of the successors of St. Peter had they emulated the noble example of Titus himself. By those who have spoken of them, great stress is laid upon all the decoration of that theatre being taken *verbatim* from accredited authorities. We are awed into admiration by the names of Raffaelle, Romano, De Udine; such piece of ornament, we are assured is from Genoa, another from Mantua. Then we have Guido's Aurora on the sofitte of the proscenium—which if not poignantly satirical, is admirably appropriate, twelve o'clock at night being the hour when the votaries of Fashion shout out

"Uprise ye then,
My merry merry men,
This is our opening day!"

Whether any of the miniature *subjects* in the panels on the fronts of the boxes be immediately taken from Raffaello and his contemporaries or not, is of very little moment, since as subjects they are utterly lost, and a few dabs of colour would show just as well, it is enough that the general effect is good,—light, sportive, fantastic, and not overloaded with meaning! This so to call it, unmeaning arabesque style of decoration may be allowed to be admirably in keeping with the lyric or musical drama, both being *outré*, and avowedly imitating nature only at a very great distance, and exceedingly conventionally: the nature of both is the nature of fairy-land, and only a formal blockhead would object to them that they are nature *à la lettre*. Arabesque may be regarded as the musical style of the pictorial art, and as distinct from subject painting as singing is from speaking. It is only the ultra-prudery of common sense that objects to such application of the pencil as nonsensical and absurd. In fact it is its vagueness and want of express meaning, together with its renunciation of any pretension to imitate natural objects *naturally*, that render this mode of painting preferable to *picture* in direct imitation of nature, for being allied with architecture so intimately as to assume somewhat of the nature of the latter art. Free and playfully fanciful, it is at the same time architectonic, accommodating itself spontaneously to linear and symmetrical arrangement.

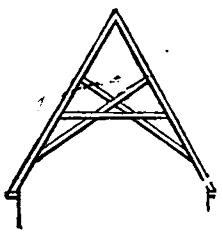
One very great thing in favour of the pictorial embellishments of the Opera House is that they are seen only by artificial light, which sheds over them a glow whose very warmth sobers them, whereas by day painting of the kind is apt to look garish if not tawdry. In a theatre it is in its proper element, the very atmosphere of the place being artificial; and where all is artificial, the artificial becomes the natural. Had there been even less of "picture" introduced—or we might say dragged in among the properly so-called pictorial decorations, better taste would, we think, have been shown. Besides Guido's Aurora over the proscenium there are four circular compartments in the ceiling containing copies of Albano's Seasons. In what respect they are at all significant we cannot divine:—there are not four, but only one Opera "Season" in the course of the year. Inapplicability of subject we could, however, wink at; but besides that we protest against the absurdity of sticking up "pictures" upon a ceiling where as "pictures" they can not possibly be properly seen,—and here they show only as mere spots,—even as panels in the ceiling, those compartments are quite at variance with sound architectural design and combination. Nor do we scruple to say this, although the ceiling is said to be taken from one in the celebrated Villa Madonna at Rome. We can only say, pity that instead of being *taken*, it was not left where it was found; and that Mr. Johnson, the commander-in-chief of the artistical forces employed, did not set his wits to work, and devise something better of his own.—As to the "*house*" itself, it is by no means a model for a theatre: all that it has of proscenium is confined to floor and ceiling between the orchestra and curtain, the boxes being continued quite up to the latter, so that the audience are almost mingled with the actors.

NEW CHURCHES.

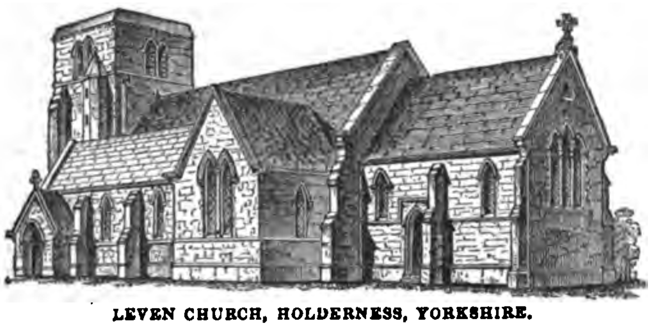
SIR—Will you allow me to notice the inaccuracy of the account of All Saints Church, Rise, Yorkshire, extracted from the *Ecclesiologist*, and given in your last number?

For that account, should be substituted,—That this church consists of a chancel (correctly proportioned) and nave, with a south porch, a massive tower, and broach spire, "in the first pointed style;" the nave will seat 220 persons; the cost is about £4,000. The exterior is wholly of Yorkshire (West Riding) grit stone, in regular courses, backed with brick; all the inside arches and splayed jambs of the windows and jambs of doors are dressed stone; the nave walls are plastered, but two lines of scrolls are cut out and filled in with Martin's cement, which is used to cover all the walls of the chancel. The east window is a triplet, plain outside, but inside, the arch is richly moulded and supported by detached pillars. The chancel pillars and arch are old, and were found in the old walls in so perfect a state as to be used with safety in the new building.

This church was built for Richard Bethell, Esq., upon the site of the old church, near his mansion. Hot-water pipes are laid under the middle aisle from a furnace and boiler, built externally; the pipes are covered by cast brass gratings. The whole of the chancel is paved with Messrs. Minton's encaustic tiles, and round the altar the wall is covered with figured tiles up to the window sills. All the seats, pulpit, lectern, stall ends, &c., of chancel, are of Norway oak. The roof has no *beams*, but is of the early form, found at Howden, Hemsworth, Fenton, Cottingham, the Augustines, London, and many others, which, when left open, are, after five centuries, found in a perfect state. Each rafter forms a perfect truss; the spaces between them are usually 18 to 22 inches; these fir trusses are *painted as oak*, all the boarding a pale azure, with gilt stars, *shaded*, taken from an old boarded ceiling in St. Mary's Church, Beverley. From authority of ancient decorations in England and on the continent, the walls are coloured drab or stone—the scrolls as parchment, rather lighter than the walls, margined with lines of scarlet —the texts in the characters preceding the Black letter (*novissima monachates*). All the pillar shafts are crimson; the lesser mouldings of the caps and bases are gilt, the hollows azure; the arches red and blue, with the under sides of the moulding covering them gilt. The stone reveals of the windows are coloured with water colour—pale blue; the light reflected from this pale blue is very considerable, and was shewn to great advantage during the execution of the work, as the stone absorbed the light. A cornice of wood covers the walls, which has the three primary colours introduced, the gilding, answering for the yellow, is narrow in proportion to its intensity, or rather, brilliancy. The painted glass windows, by Wailes, are good: the only fault being in the *imitation of old and defective glass* in some portions.



From the account in the *Ecclesiologist*, one should be led to suppose that this was a small extravagant building, filled with gaudy decorations and quackery: whereas it is a plain substantial edifice, the material coursed, as was the practise with the ancients, and it is founded on the true *masonic* principles, even to the mouldings—*nothing strictly copied, but composed.* No two buildings are to be found alike,—and why? Simply for this reason: that the principle, *on having the key*, is inexhaustible; and, by

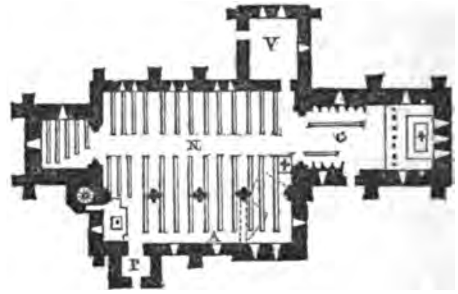


LEVEN CHURCH, HOLDERNESS, YORKSHIRE.

working upon that *key*, minutes will suffice to produce new subjects, where days may be expended in copying. Almost every ancient church, too, contains the diagram, upon which it has been composed.

I enclose you a sketch of a small village church, which is formed upon that diagram, built at Leven (four miles from Rise), and which is little more than a restoration of the old church of Leven—the old pillars, arches, font, piscina, and other portions are used in the new building; the church was dedicated to St. Faith. At the end of the south aisle was a chantry; part of the old rood was found and removed there.

As I am anxious to reform many of the errors into which modern architects have fallen, I will shortly send you some practical observations



PLAN OF LEVEN CHURCH.

N, Nave.—A, Aisle.—C, Chancel.—V, Vestry.—P, Porch.

which I have made on ancient ecclesiastical works during the last twenty-five years or more. I am, Sir,

Your very obedient servant,

London, March 10th, 1846. R. DENNIS CHANTRELL.

P.S. I have now some new churches in progress on this principle—first pointed," at Halifax; "second" (decorated), at Huddersfield and at Leeds; "third" or perpendicular, at Keighley, which latter, though perfect as a building, must be degraded by galleries, which I cannot acknowledge as in any way belonging to the building.

NOTES ON ENGINEERING,

IV.

ON THE STRENGTH AND FORM OF THE MENAI TUBULAR BRIDGE.

The plan devised by Mr. R. Stephenson for a railway bridge consisting of a wrought iron tube 450 feet long, is so bold in itself, and suggests such very important and instructive lessons respecting the theory of girders, that an investigation of the principles on which it is proposed to construct the Menai Bridge, and of the form which it will be necessary to give it, in order that its strength may be uniform in every part, cannot fail to be interesting.

Before entering, however, on the investigation of this particular case, it may be as well to notice briefly the views of those eminent philosophers who have undertaken to investigate theoretically the strength of beams. We find here as in every other branch of the physical sciences, that the labours of each succeeding investigator have tended to define and simplify the opinions of his predecessors; and it is not only very interesting, but very useful to trace historically these modifications, because by considering the difficulties that have had to be overcome before fixed principles could be established, we are led to see the essential nature of the principles themselves.

The first philosopher who endeavoured to determine the laws regulating the strength of bodies acted upon by transverse strains was Gallileo. The chief error of his theory was that he assumed that when a body was about to break by an excessive pressure, all the parts near the fracture are in a state of tension. Another of his suppositions was that the tension of all the parts of the section of fracture was the same. This second error was in part avoided by Leibnitz, the next writer on the subject; he assumed that the tension of the beam deflected by a pressure varies as the distance of the particles from the concave side of the beam; he however adopted the first mistake of Gallileo, namely, that the particles of the deflected beam were all in a state of tension. James Bernoulli seems to have been the first to whom it occurred that the particles of the beam exerted different kinds of action on different sides of it, that the convex side was extended and the concave compressed, and that consequently on the one side the strains were of the nature of *tensions*, and on the other of *pressures*. The simple deduction from this view of the case was that there is some place between the two sides of the beam where the extension of the particles ceases, and the compression begins,—that is, there is a line in the beam which is neither lengthened nor diminished in length by the deflection. To this line Bernoulli gave the name of the NEUTRAL LINE: his views are now exclusively adopted; the only difficulty still existing refers not to their accuracy, but the means of applying them.

A very simple illustration of the fact that a deflected beam is partly compressed and partly extended, may be obtained by bending a twig of hazel or willow; if the bark be tender and flexible, it will be found to have a corrugated appearance—to be gathered up in folds—on the concave side, and on the convex side to be tightly stretched or actually burst asunder.

The chief difficulty in the above familiar instance, and one which indeed Bernoulli's theory is generally subject to, is the determination of the precise place where the material is neither stretched or compressed. But there is also another objection which will frequently hold—Bernoulli adopted so much of Leibnitz's theory as assumed that the tension of any part of the beam varied as the distance of a fixed line—that line being according to Leibnitz in the upper or lower surface—according to Bernoulli the *neutral line* between the two surfaces. Bernouilli's law of the molecular forces was in fact this, that if at any part of the beam, a plane be drawn perpendicular to the neutral lines, the elastic forces perpendicular to that plane (whether of the nature of pressures or tensions) are proportional to the distances of the molecules from the neutral line. This law was founded on Hooke's principle that the restitutive forces of a body are proportional to the amount by which its natural length is increased or diminished. But it is found in practice that it is possible to apply so great a strain to a body that Hooke's law ceases to be true; in other words, that there is a degree beyond which if the extension or compression of a body be carried, its restitutive powers will no longer continue to increase with the strain, but will actually diminish. The point is called the "elastic limit;" the nature of it may be illustrated by bending a flexible strip of metal or wood to such an extent that the restitutive forces are no longer able to restore the original form of the body, which remains permanently bent.

The difficulty certainly is often opposed to the application of Bernoulli's laws, because it is a matter of common experience that beams may be so much strained and bent as to permanently retain their deflection when the load is removed.

The most celebrated of the modern writers on the theory of the strength of girders are M. Poncelet and Prof. Moseley. The elaborate researches of the latter contained in the fifth part of the *Mechanical Principles of Engineering*, are well known to the English reader. In these researches however, the weight of the girder itself is neglected as small compared with the load to be supported: but as in the case of the Menai bridge, a great proportion of the strength of the material is required to support its own weight, a separate investigation seem to be required.

Distinctions between girders, arches, and suspension bridges.

It is very necessary that the effect on girders by which the molecular action on their upper and lower sides have opposite tendencies should be clearly conceived in the mind: for it is this opposite tendency which constitutes the essential strength of girders. It is also their *characteristic*, by which they are distinguished from the other structures for supporting loads between piers or abutments. In the *arch* the material is entirely in a state of compression, in the *suspension bridge*, of tension—in the *girder* alone part of the material resists compression, and part resists extension. Did not this property exist, the girder must, like the arch, and the suspension chain be more and more stretched, the more nearly it was horizontal. It is known that no finite tension will make a suspension chain quite horizontal, and that when the deflection is small the strain and tendency to rupture is very great. In the arch also it is known that where the curvature is small, the lateral thrust is greatly increased, and that when the height of the arch is very great compared with its span, the strain on the material is not much more than that of the superincumbent mass. In the girder, however, it is found that no advantage is gained by giving the surfaces a great curvature; the strongest and most useful form which can be devised is that for which the girder is equally strong in every part, and for the attainment of this object, the curvilinear surfaces of the girder may be made very much flatter than would be the curves of an arch or suspension chain, subjected to equal strain under similar circumstances.

Another important characteristic of the girder, due to the opposite tendency of the molecular action on its upper and lower sides, is that unless it be positively bent by its load, it exerts no lateral force on its abutments. A beam supported on two props will exert upon them a vertical pressure only, and however much it may be loaded will exert no horizontal force at its extremities unless the load be sufficient to alter its geometrical form. In an arch or suspension-chain, however, the smallest load requires a corresponding lateral force, this force being in the former of the nature of a thrust, in the latter of a tension. The distinguishing property of a girder in this respect is due as has been said to the *antagonism* of its molecular actions, for it is demonstrable that whatever lateral forces its particles exert on the lower side are counterbalanced by equal and opposite forces on the upper side, so that ultimately the resultant horizontal force is zero.

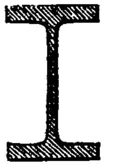
Form of section of greatest strength.

Before proceeding to determine the amount of the strains actually exerted in the proposed Menai tubular bridge, it is necessary to consider what form of the *transverse section* of the girder gives the greatest strength. These considerations cannot be expressed more clearly than in the following quotation from the fifth part of Professor Moseley's work already referred to. The extract deserves careful perusal, as the correct comprehension of it will clear up all difficulties as to the means by which the strength of girders is obtained:—

"Since the extension and the compression of the material are the greatest at those points which are most distant from the neutral axes of the section, it is evident that the material cannot be in the state bordering upon rupture at every point of the section at the same instant, unless all the material of the compressed side be collected at the *same distance* from the neutral axis, and likewise all the material of the extended side, or unless the material of the extended side and the material of the compressed side be respectively collected into two geometrical lines parallel to the neutral axis; a distribution manifestly impossible, since it would produce an entire separation of the two sides of the beam.

"The nearest practicable approach to this form of section is that represented in the accompanying figure (fig. 1), where the material is shown collected in two thin but wide flanges, but united by a narrow rib.

Fig. 1.



That which constitutes the strength of the beam being the resistance of its material to compression on the one side of its neutral axis, and its resistance to extension on the other side, it is evidently a second condition of the strongest form of any given section that when the beam is about to break across that section by extension on the one side, it may be about to break by compression on the other. So long, therefore, as the distribution of the material is not such as that the compressed and extended sides would yield together, the strongest form of section is not attained. Hence it is apparent that the strongest form of the section collects the greater quantity of the material on the compressed or the extended side of the beam, according as the resistance of the material to compression or to extension is the less. Where the material of the beam is cast iron, whose resistance to extension is greatly less than its resistance to compression, it is evident that the greater portion of the material must be collected on the extended side.

"Thus then it follows, from the preceding condition and this, that the strongest form of section in a cast iron beam is that by which the material is collected into two unequal flanges joined by a rib, the greater flange being on the extended side; and the proportion of this inequality of the flange being just such as to make up for the inequality of the resistances of the material to rupture by extension and compression respectively.

"Mr. Hodgkinson, to whom this suggestion is due, has directed a series of experiments to the determination of that proportion of the flanges by which the strongest form of section is obtained."

Effect of the vertical ribs.

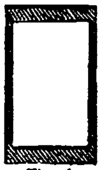


Fig. 2.

Now it will be seen from the representation of the transverse section (fig. 2) of the Tubular Bridge that it is in fact a girder of the required form, except in that it has two lateral ribs instead of one central rib. These ribs, it will be seen from the quotation, contribute to the strength of the girder, not so much *directly* by their own strength, as *indirectly* (1) by separating the upper and lower flanges, and (2) by establishing that rigid connection by which the opposite tendency of the molecular action already spoken of is maintained. These two offices of the vertical ribs ought to be rightly understood. Respecting the first, it may be observed that for a given quantity of material, the strength of the beam increases with the distance by which the upper and lower flanges are separated. This increase of strength does not arise from the increased mass of the rib, so much as from the circumstance that the further the flanges are apart, the further are they from the neutral line within the girder, and, consequently, the *greater is the leverage of the molecular forces*. The advantages of making the molecular forces act at a great distance from the neutral is illustrated in a very striking way in the floor-joists of a house, which are uniformly laid on their thinnest edges, in order that their upper and lower surfaces may be separated by the greatest possible interval. Again, if a flat slip of wood, such as a flat drawing rule, be pressed on its broad side, there is no difficulty in bending it; if, however, it be pressed on its thin edge it will be almost impossible to produce a deflection. Now, it is carefully to be noted that in both experiments the nature of the forces called into action are precisely the same; the material remaining unchanged, of course the cohesion or elastic force is unchanged also; the only difference is that, in the second case it acts with much greater advantage than in the first, simply because its leverage is increased.

It is but a very slight extension of this idea to conclude, that the form of the greatest possible strength is that in which all the elastic force acts at the greatest possible distance from the neutral line, or in which all the material is collected in the upper and lower flanges, except what is absolutely necessary for the due connection of them by the rib or ribs.

This brings us to consider the second office of the rib—the establishing a rigid connection between the flanges. It is not sufficient that the flanges should merely be *kept asunder*: for this purpose an open railing of vertical bars would be sufficient. But it is easy to see that if such a contrivance were substituted for the solid rib, the "antagonism" of the molecular forces would not be maintained. It is absolutely necessary that the upper and lower flanges should be in opposite states of elasticity and that they should mutually *counteract* each other. These requisites cannot be answered unless the web be rigid—not only vertically, to prevent the flanges approaching each other, but also laterally, so as to act in every part as a *rigid lever*, of which the fulcrum is in the neutral line, the molecular actions of the flanges constitute the balanced forces.

Before concluding these preliminary remarks, it may be as well to notice one passage from Mr. Stephenson's Report, published in the last number of this Journal. He says—

"Another instructive lesson which the experiments have disclosed is, that the rectangular tube is by far the strongest: that the circular and elliptical should be discarded altogether."

It may, however, be fairly asked, whether it were necessary to make that a matter of *experiment* which might be unhesitatingly predicted by the ordinary laws of mechanics? It is clear that, comparing a curvilinear and a rectangular tube of given depth and containing a given quantity of material, the latter is that in which the greatest proportion of the material has the maximum leverage, and consequently that the rectangular form is that of the greatest strength.

1. *Practical Limits to the length of the Girder.*

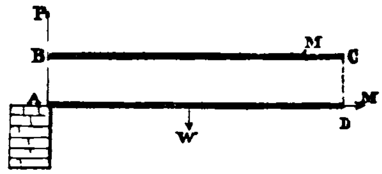
It will be found in the following methods of calculation that the particular form of the transverse section adopted by Mr. Stephenson, affords peculiar facilities for the determination of each problem without incurring the difficulties which are usually opposed to the application of the theory adopted by Bernoulli. It will be assumed in all that follows that the ribs are only sufficiently strong to bear their own weight, and to maintain the necessary rigid connection between the upper and lower flanges—that is that the whole of the available strength of the material is applied where it may have the most useful effect. It will remain to show hereafter how the flanges may be made to satisfy this assumption, or how far they will modify it.

It is proposed for the Menai Bridge that the plates of iron shall be one inch thick; this construction very nearly satisfies the conditions of the greatest strength as laid down in the extract from Moseley's Engineering given above. The first problem which will be the determination of the greatest possible length of a girder of the depth proposed (30 feet) so that it may bear its own weight.

It is found by experiment that wrought iron will bear with safety a strain of nine tons to the square inch, and if that amount be much exceeded, the material begins to stretch. Now as the beam cannot be deflected without some part of its material stretching, the point to be determined is this—what is the length of the beam when by its own weight a strain of nine tons to the square inch, is applied to the metal. It is obvious that if the beam be of uniform depth, the longitudinal strains will be greatest in the middle.

Let A B C D, fig. 3, represent a longitudinal section of one-half the girder, which is supposed to be cut in half by a vertical plane at C D. If we suppose the half beam to be acted upon at C D, by forces similar to the

Fig. 3.



molecular actions which actually exist at C D in the undivided beam, it is clear that the conditions of equilibrium will not be affected.

The forces acting on A B C D are—1st, P the upward pressure of the abutment (the beam being supposed uniform P = ½ the weight of the beam, by the ordinary conditions of equilibrium). 2nd, a downward force W equal to the weight of A B C D, and acting at the centre of gravity half way between A and D. 3rd, the molecular actions at C D.

Respecting these molecular actions it is to be observed that they are wholly horizontal; for P and W being both equal to half the weight of the beam P = W, and therefore if a third vertical force were introduced the equation of vertical forces could not hold. The molecular forces are therefore horizontal; they are also equal and opposite, for otherwise the equation of horizontal forces could not hold. As therefore we have supposed the plates A C, B D to be of comparatively small thickness, we may suppose the molecular actions to be represented by two forces M, M, in the directions indicated by the arrow heads. The only effect of representing all the forces of compression by one single force, and all the forces of tension by another single force, is the assumption of that which is practically true, that all parts of the section C exert equal pressures, and all parts of the section D equal tension, and that all the forces at C and at D, act so near each other that they may in each case be represented by a single force.

Taking moments about B, W ½ A D = M. A B. (1.)

Now we suppose the tension at D to be 9 tons or 20,160 lb. to the square inch; consequently if we call the area of the section D, a inches, M = 20,160 a.

W is the weight of the plates B C and A D: if the length of each of them be l inches, its solid content is $a\,l$ cubic inches, and since the weight of a cubic inch of wrought iron is about ·28 of a lb. the weight of each plate is $a\,l \times {\cdot}28$, and W is double this or $2\,a\,l \times {\cdot}28$. Substituting in (1.)

$$a\,l\,\text{A D} \times {\cdot}28 = 20{,}160\,a\,\text{A B} \qquad (2.)$$

$$l^2 = \frac{20160}{{\cdot}28}\,\text{A B} = 72{,}000\ \text{A B}.$$

A B the depth of the girder is in the proposed bridge 30 feet or 360 inches. Therefore multiplying 360 by 72,000, and extracting the square root, we get the value of l in inches: this value will be found equivalent to 424·26 feet. Hence we arrive at the following conclusion, l being half the length of the girder;

The greatest length of a girder 30 feet deep, which will support its own weight safely is 848 feet.

It will be observed that this conclusion is independent of the arch of the cross sections C and D, or of the width of the girder. This circumstance arises from the tension and weight being both proportional to the cross section.

2. *Tension at the centre of a Girder 450 feet long.*

The length proposed by Mr. Stephenson falls far within the limits of length determined by the last proposition. The next point to determine is the actual tension per square inch when the length is that of the Menai Bridge—namely, 450 feet.

Using the figure and notation of the last proposition we have putting in 2), the value of l or A C = 225 feet (= 2700 inches), and the value of A B = 360 inches; and putting also t for the tension per inch at D.

$$a \times (2700)^2 \times {\cdot}28 = t\,a\,360,$$

$$t = \frac{7{,}290{,}000 \times {\cdot}28}{360}$$

Effecting the operations indicated by this equation, we find the value of t to be 5670 lb., or 2·53 tons. Hence we come to this conclusion—

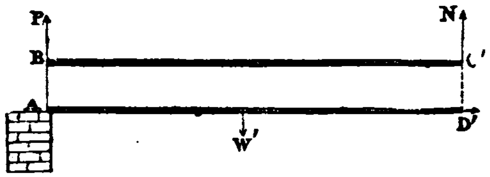
When the girder is 450 feet long the tension produced at its centre by its weight is rather more than 2½ tons to the square inch.

This conclusion like the last is independent of the area of the section C or D.

3. *Vertical strain on any part of the Girder.*

It has been demonstrated in the first proposition that the molecular actions are entirely horizontal at the *centre* of the girder; this however is not the case at any other part of it. We shall find that if a section be supposed to be made at any point but the centre, that the molecular actions have to be replaced by a vertical strain in addition to the horizontal couple of tension and pressure, and it will be found also that this vertical strain increases continuously from the centre to the extremities of the girder, while the horizontal couple on the contrary is greatest at the centre and zero at the extremities. The effect of this vertical strain, if it were sufficient to produce rupture, would be—not to tear the material *asunder*—but to make the particles at the surfaces of the section *glide* upon each other. It may be shown however that the vertical strain is so small that this effect need not be apprehended, and in fact may be neglected without appreciable error.

Fig. 4.



Let A B C' D', fig. 4, represent the longitudinal section of a larger portion than half the beam, the vertical line C' D' being now beyond the middle point. Let W' be the weight of A B C' D', and let N be the sum of the vertical strains acting at C' and D'. Then we have for the equation of vertical forces—

$$W' = P + N.$$

But the value of P is the same as in fig. 3, and is of course unaltered by the vertical section being removed to C' D'; that is, the value of P is, as before, W or half the weight of the girder. Hence

$$N = W' - W.$$

That is, the vertical strain is the difference between the weight of the portion of the beam on which it acts and the weight of half the beam. From the last equation it is clear that N increases as W' increases, and if the section be taken close to the further extremity of the beam where W' is nearly equal to the weight of the whole beam, N will be equal to 2 W – W, or half the weight of the beam. Giving N this its greatest value we may readily ascertain the strain which it produces per square inch of the vertical section. Taking as before the area of the section C' or D' to be a inches, and therefore of the two together $2a$, and putting v for the vertical strain per square inch, $N = 2\,a\,v$. Also the solid content of the two plates together is $2a$ multiplied by the length 5400 in. (450 feet), and since the weight of the cubic inch of iron is ·28 lb., the total weight of the two plates is $2\,a \times 5400 \times \cdot28$. Hence since N equals half this weight;

$$2\,a\,v = a \times 5400 \times \cdot28.$$

It will be found from this equation that the value of v is 756 lb., or *the greatest vertical strain per square inch is rather more than one-third of a ton.*

It is clear that this strain would have so small an effect to produce rupture that it may safely be neglected.

4. *Tension produced in the Girder by a given load.*

It has been shown that the greatest strain produced in the girder by its weight merely is rather more than 2½ tons to the square inch: so that if 9 tons to the square inch be taken to be the degree of strain which may safely be applied to the material, we have rather less than 6½ tons to the square inch, which may be produced by the railway train or other load upon the bridge. It is clear that when the load is at the centre it has the greatest effect or moment about the points of support at the extremities. Let us now examine what strain a given load would of itself produce at the centre neglecting the weight of the girder. Recurring to fig. 3, let us suppose the force marked W no longer to exist, and that at the point D a force w, equal to weight of the given load is applied. Let the force marked M now represent the strain produced by w. Also let P instead of its former value take the value now required, namely, $\frac{1}{2}w$: then it will be clear by reasoning similar to that in Prop. 1, that no *vertical* force but w acts at D. Taking moments about C, and putting $P = \frac{1}{2}w$,

$$\tfrac{1}{2}w \,.\, A\,D = M \,.\, C\,D.$$

A D and C B are in the proportion of 225 feet : 30 feet, or 15 : 2, so that we may substitute for the above equation;

$$M = \tfrac{15}{4}\,w.$$

Hence whatever number of tons w may weigh, the strain produced by w will be 3¾ times as many tons. To find the number of tons strain per *square inch of the vertical section*, we observe that the width of the plate is supposed to be 15 feet or 180 inches, and its thickness one inch, so that the area of the section is 180 square inches, and consequently the strain per inch is the 180th part of M. Consequently the strain per inch is equal to

$$\frac{15}{4 \times 180}\,w = \frac{15}{720}\,w = \frac{1}{48}\,w \qquad (3.)$$

From this equation we get the following simple rule—

For every 48 tons load acting at the centre of the bridge a strain of 1 *ton per square is produced on the metal plates.*

It follows from this that since after deducting the strain produced by the weight of the bridge an additional strain of rather less than 6½ tons per inch may safely be produced by the load, *the load which could safely be applied at the centre of the bridge is rather less than three hundred and twelve tons.*

In Mr. Stephenson's report it is calculated that the bridge can bear a load of 747 tons at its centre. But this discrepancy may easily be accounted for, by supposing that Mr. Hodgkinson's experiments had reference to the *breaking weight*, whereas here the load calculated is that which with the weight of the bridge would produce a strain of 9 tons to the square inch. It is to be observed also that in the present calculation the amount of the extreme load is somewhat underrated, because it is supposed to act at a single point, whereas in the case of a railway train it would be distributed over a considerable portion of the length of the bridge, and consequently when the train was at the centre of the bridge, the part of the load cut off by the vertical section C D, and resting on A D, would not act wholly at D, but the centre of gravity of this portion of the train would be applied at a point somewhat nearer the extremity, and the moment of the load would be proportionably smaller.

This however does not make a material difference. Mr. Stephenson says in his report that for practical purposes a strength equivalent to 747 tons in the centre would be insufficient; it is clear therefore that as 312 tons (which is less than half this load) causes a strain of 9 tons to the inch when the dimensions of the bridge are those here assumed, it is necessary to determine other dimensions by which the strength may be increased. There are two ways of effecting this object—1st, by increasing the depth of the girder; 2nd, by increasing the area of the transverse section of the plates, (that is, by giving the plates greater width, or greater thickness, or both). There is indeed a third method of increasing the strength, namely, by increasing the dimensions of the vertical ribs beyond the degree of strength necessary for the rigid connection of the upper and lower plates, but this method is so unphilosophical and involves such a waste of material that it may fairly be excluded.

The examination of the means of obtaining the requisite degree of strength by increasing the thickness of the plates, and the depth of the tube shall be given in the next number of this Journal. It is proposed also to examine how the dimensions of the tube may be varied in different parts of it so that the strength may be uniform throughout, to examine the effects of expansion and contraction of the material by variations of temperature, the form of the vertical ribs so that they may be sufficiently strong to perform their office without adding to the strain on the flanges, and lastly, the effects of imbedding the ends of the tube in solid masonry.

It may be as well to say one or two words to prevent the purpose of these suggestions being misinterpreted. They are certainly not intended for the guidance or direction of the distinguished engineer who has planned the Menai tubular bridge, and whose scientific knowledge is fully adequate for the calculation of its dimensions; but to those who have not fully considered the principles of the strength of girders the present investigations may offer an instructive lesson, especially as the conclusions are derived not from gratuitous and dangerous hypotheses, but from the common fundamental principles of statical equilibrium.

H. C.

The syndicate of the Fitzwilliam Museum, Cambridge, have received from Mr. Cockerell designs for completing the hall and staircase of the new building, for parts of which Mr. Basevi had not left any settled designs. Working drawings and estimates were ordered to be prepared forthwith.

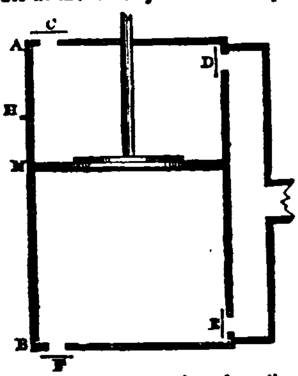
ON ATMOSPHERIC RAILWAYS.

Resistance from the Heat developed in the Air Pump.

By F. Bashforth, B.A., Fellow of St. John's College, Cambridge.

There are considerable differences between the mean theoretical and experimental resistances to the air pump piston, for given heights of the barometer, as stated in Mr. Stephenson's Report on the Atmospheric System. The discrepancies, for low heights of the barometer, are easily explained by a reference to the diagrams from which the numerical results were deduced. It here appears that the exit valve by its flapping through a very considerable space, caused an increased and useless resistance. In addition to this, it will be seen that at the very commencement of the stroke, the indicator frequently gave a pressure of nearly 1 lb. per square inch greater than the pressure in the tube. This no doubt was caused by the stream of air rushing into the cylinder in the same manner as water into the hydraulic ram. Thus the mass of air enclosed and expelled was greater than what was supposed by theory.

When the barometer rose to about 19 inches, although the above two disturbing causes diminish with the increased rarefaction in the tube, the differences of the theoretical and experimental results increased. This was so considerable that Mr. Stephenson was driven to suppose that in addition to the heat developed, a considerable leakage in the air pump existed. It appears, however, that the first cause is quite sufficient, and that the connecting tube must have admitted 206 cubic feet of air per minute at the density of the atmosphere. Let



$a = AB$ = length of stroke of air pump piston.

k = area of air pump piston.

Π = pressure of the atmosphere on a unit of surface.

$P_1 P_2 \ldots P_n$ the pressure of the air in the tube after $1, 2, \ldots n$ strokes.

$\rho_1 \rho_2 \ldots \rho_n$ the density of the air in the tube after $1, 2, \ldots n$ strokes.

V = volume of the receiver.

v = volume of the pump cylinder.

Suppose that at the nth stroke when the pump piston has described a space $BM = a - x$, that the density of the air is ρ and pressure P. Then

$$\frac{P}{P_{n-1}} = \left(\frac{\rho}{\rho_{n-1}}\right)^K \text{ (Miller's Hydrostatics (28.))}$$

Also $\rho V = \rho_1 (V+v)$.

$\rho_1 V = \rho_2 (V+v)$.

&c. = &c.

$\rho_{n-1} V = \rho_n (V+v)$.

$\rho V^n = \rho_n (V+v)^n$.

$\rho_n = \rho\left(\frac{V}{V+v}\right)^n = \rho R^n$, suppose

Also $P^n = \Pi R_n$, for the rarefaction of the air goes on slowly, and it is in contact with so large a surface of metal, that we may consider the temperature to be uniform, and $\therefore$ the pressure and density. The tendency however would be in favour of the atmospheric traction. $k a \rho_{n-1}$ = mass of air inclosed at the commencement of nth stroke $= k x \rho$.

$$\therefore \frac{a}{x} = \frac{\rho}{\rho_{n-1}}. \text{ Also } P = P_{n-1}\left(\frac{\rho}{\rho_{n-1}}\right)^K = \Pi R^{n-1}\left(\frac{a}{x}\right)^K,$$

when the exit valve opens $P = \Pi$, and suppose $x = \alpha$,

$$\text{then } 1 = R^{n-1}\left(\frac{a}{\alpha}\right)^K \text{ and } \frac{\alpha}{a} = \left(\frac{1}{R}\right)^{\frac{n-1}{K}}.$$

Work done in compressing the air =

$$\int_a^\alpha k P\, dx = \Pi R^{n-1} k \int_a^\alpha \left(\frac{a}{x}\right)^K dx = \frac{\Pi R^{n-1} \left(\frac{a}{\alpha} - 1\right)}{K-1}$$

$$= \frac{\Pi a k}{K-1}\left(R^{\frac{n-1}{x}} - R^{n-1}\right)$$

Work done in expelling the air $= \Pi k x = \Pi R^{\frac{n-1}{K}} a k$.

Work done by the assistance of the air in the tube

$$= \Pi R^{n-1} k \int_o^a \frac{V\, dx}{V + (a-x)\frac{v}{a}} = -\Pi R^{n-1} \frac{V}{v} a k \log_e R$$

Hence work done during the nth stroke,

$$= w_n = \Pi a k \left\{ R^{n-1} \frac{V}{v} \log_e R + \frac{1}{K-1}\left(K R^{\frac{n-1}{K}} - R^{n-1}\right)\right\}$$

Work done at the end of n strokes.

$$= W_n = \Pi \left\{ \frac{1-R^n}{1-R} \frac{V}{v} \log_e R + \frac{1}{K-1}\left(K \frac{1-R^{\frac{n}{K}}}{1-R^{\frac{1}{K}}} - \frac{1-R^n}{1-R}\right)\right\}$$

If w_n = a maximum, $\frac{d w_n}{d n} = o$.

This gives $n = 100$ nearly corresponding to a rarefaction of between 21 and 22 inches, which agrees exactly with experiment. If we do not allow for the heat developed, theory gives 19 inches.

STEPHENSON'S REPORT, TABLE NO. V.

Height of barometer.	Theory.	Difference.	Experiments.	Theory with heat.	Difference of Theory and Experimen
6	2·6	0·8	3·4	2·6	0·8
7	3·0	0·8	3·8	3·0	0·9
8	3·4	0·7	4·1	3·4	0·7
9	3·7	0·8	4·5	3·8	0·7
10	4·0	0·8	4·8	4·1	0·7
11	4·3	0·8	5·1	4·5	0·6
12	4·6	0·8	5·4	4·8	0·6
13	4·8	0·8	5.6	5·1	0·5
14	5·0	0·8	5·8	5·4	0·4
15	5·2	0·7	5·9	5·6	0·3
16	5·3	0·7	6·0	5·7	0·3
17	5·4	0 7	6·1	6·1	0·0
18	5·5	0·8	6·3	6·2	0·1
19	5·5	1·1	6·6	6·3	0·3
20	5·5	1·2	6·7	6·4	0·3
21	5·4	1·4	6·8	6·4	0·4
22	5·3	1·5	6·8	6·4	0·4
23	5·1	1·4	6·5	6·3	0·2
24	4 8	1·4	6·2	6·1	0·1
25	4·5	1·2	5·7	5·9	—0·2
26	4·0	0·9	4·9	5·5	—0·6
27	3·4	0·9	4·3	4·9	—0·6

The numbers found in Table V. of Mr. Stephenson's Report correspond to the valves of $\left(\frac{w_n}{ak}\right)$ for every inch of the barometer from 5 to 27 inches, where $\Pi = 15$ lb. and $K = 1·416$. The value found by comparing the theoretical and experimental velocities of sound. The accompanying table exhibits the theoretical and experimental values of the mean resistance to the piston.

In addition to the above test we may construct theoretical diagrams, and compare them with those found by experiment.

The equations to the part described before the exit valve opens

$$\text{is } y = h'\left(\frac{a'}{x}\right) \text{ when heat is neglected} \qquad (\alpha.)$$

$$\text{and } y = h\left(\frac{a'}{x}\right)^K \text{ in the other case} \qquad (\beta.)$$

where h' denotes the length of the line between 0 lb. and the dotted line in the figures representing the pressure of the air in the tube, and a' the length of the diagram. (α') evidently represents a series of rectangular hyperbolas referred to the same axes as asymptotes.

The curves (β) are found to agree very nearly with experiments, whilst (α, are very different when the height of the barometer is about 20 inches.

Both theories have their use. It has been seen that when heat is neglected the work done by the engine, and the useful effect may be considered equal. The other by its close agreement with experiment enables us to estimate the necessary loss of different arrangements on the supposition that the machinery is perfect.

Between 19 and 25 inches the loss arising from this source is 15 or 24 per cent. of the useful effect, and is another reason why the rarefaction in common instances ought not to be pushed beyond 18 or 19 inches.

UNFAITHFULNESS IN ARCHITECTURE.

By unfaithfulness in architecture we mean—the employment of forms or materials in such a manner that the true character of the architecture is disguised. This definition includes the use of materials deceptively, the application of architectural members to wrong purposes, the introduction of them when not used constructively, and lastly the decoration of the conspicuous parts of a building in such a manner that the eye is deceived as to the architectural character of the parts unseen.

A curious instance of unfaithfulness in architecture has recently been exhibited in some buildings connected with the Croydon Atmospheric Railway, in the employment of structures, resembling in form the turrets of Pointed Architecture, as *chimneys*. From these turrets may be seen issuing day by day dark volumes of smoke, and consequently all the upper portions of the ornamental work are blackened with soot. This begrimed specimen of mock architecture is of course so ridiculous that the most superficial observer can detect the absurdity of it: but it must be carefully noted that though in this case the accident of the discolouration has rendered the architectural error palpable, it is not that accident which *constitutes* the error—the principles of pure taste would have been quite as much violated even if the ridiculous appearance of the soot-covered mouldings had not rendered the violation manifest. At the same time we ought always to feel satisfaction when these accidents occur, because they render obvious to the most uneducated observers, the defects which otherwise would be condemned by those only who had studiously examined the principles of architectural taste. Though in fact we shall usually find that in all instances like these of the Gothic chimneys, some attendant disaster is sure to follow, which by a kind of architectural retribution—punishes the error by a signal publication of it.

To return however to the general subject, we may remark that one of the necessary consequences of architectural unfaithfulness is the neglect of what has been aptly termed *apparent construction*. This term (first introduced by Prof. Willis, we believe), signifies that development of the construction of a building by which it is made manifest how each part is supported, and in what manner each member contributes to the stability of the whole. It is not of course to be argued that wherever apparent construction is uniformly observed, the architecture is necessarily beautiful; because in that case we must be prepared to find beauty in a hut, a sty, or a stable; for in these structures the principles of apparent construction are generally observed for the sake of economy. But still the converse proposition may be safely asserted, namely, that where apparent construction is violated one of the sources of the beautiful is neglected; and it also seems an unavoidable conclusion that where forms which are individually beautiful are combined faithfully, the resultant must necessarily be beautiful also.

It is necessary that the exact value of faithfulness as an element of beauty should be thus clearly ascertained, because it is not uncommon to hear those who argue most zealously for the necessity making architecture faithful, speaking as if they thought that by securing to it this single merit, perfection was attained. For instance we find one of our contemporaries pronouncing the architecture of the Parthenon, faithful and *therefore* beautiful, whereas it is clear from the common instances which we have adduced, that faithfulness is separable from beauty—that it is but one element (though an essential one) of beauty, for we may readily conceive the possibility of architecture being faithful which is not beautiful, though it be quite impossible to imagine perfectly beautiful architecture which is not faithful.

We will take an instance, and perhaps our selection may appear a bold one, to illustrate our meaning. The dome of St. Paul's, notwithstanding the astonishing constructive skill which it displays is distinctly an example of neglect of the rules of apparent construction. The exterior dome instead of being supported entirely by the substructure, *as it appears to be*, is in fact carried by a timber framing resting on a cone of brickwork concealed between the inner and outer cupolas. On this cone of brickwork also rests the lanthern, which *apparently* is supported by the outer dome. Moreover the lateral thrust to the cone is resisted not by buttresses or other supports openly displayed, but by a hidden iron chain, which by its tenacity preserves the stability of the masonry.

If it appear very bold heterodoxy to adduce such an instance as this, we will bring the architect himself as a witness to corroborate our opinion. It will be remembered that the original design submitted by Sir Christopher Wren, for St. Paul's, was rejected. In this first design, of which a model exists in the present cathedral, "he endeavoured to gratify the taste of the connoisseurs and criticks with something coloss and beautiful, with a design antique and well studied, conformable to the best style of Greek and Roman architecture." Respecting this second design however—that ultimately adopted, we are told in the *Parentalia*, that he "then turned his thoughts to a cathedral form so altered as *to reconcile as near as possible the Gothic to a better manner of architecture*."—That is, he attempted an impossibility.

The character of St. Paul's, as has been recently stated by Professor Cockerell in his lectures, is (independently of the individual members) that of a Mediæval Cathedral. A cruciform building with a lofty central dome, it is obviously as different in form as it possibly can be, from the ancient classic models. And consequently in reconciling classic architecture to forms which it never contemplated, and for which it was not designed, it was necessary to import numerous contrivances which never belonged to the original style, and which therefore of necessity involved the violation of the principles of apparent construction.

To take another instance, and perhaps the most flagrant one in the same building,—who would imagine by inspection from the exterior, that the whole of the upper order round the church is nothing but a mask to conceal the flying buttresses behind it which are similar in purpose to those which in the ancient cathedrals are not only displayed openly, but are among the most beautiful features of the architecture. Of the hundreds who pass St. Paul's daily, how few are aware that the whole masonry which appears above the lower range of columns is an isolated mask, that it has nothing to do with the interior of the building, that it might be removed without producing the slightest change in the interior, that in fact it is merely an appendent excrescence answering no purpose whatever except that of concealment.*

It can scarcely be denied that the adaptation of classic architecture to the mediæval form involves incongruities and necessitates unfaithfulness of construction. The mere consideration that the characteristic of the one style is verticality, and of the other horizontality, seems sufficient proof that the two can never be successfully reconciled. In these particulars, namely—the predominance in the one of vertical, and in the other of horizontal lines—the two styles are not merely different but are diametrically opposed to each other. And it is clear that this antagonism is so direct, that it can never be avoided except by the violation of the principles of one or both kinds of architecture.

This truth has been laid down with sufficient distinctness by others than ourselves; but there is another great distinction between Christian and Classic Architecture, which though generally neglected is a most frequent cause of architectural unfaithfulness—Classic Architecture is characterized by UNITY—Christian Architecture by MULTIPLICITY. In the most perfect specimen of the Classic style, the Parthenon, the ground plan is the simplest possible, a rectangle, and all the details are combined so as to represent to the mind one single uncomplicated idea. In the most perfect specimen of the Mediæval style,—Cologne Cathedral, perhaps—the effects of awe and astonishment are produced by the combination of an infinite number of the most varied forms: the effects therefore in these two cases depend on entirely different principles. We endeavoured to explain this distinction in a former paper, by designating the one style as *statuesque*, that is, resembling a statue or sculptural group, in which every part contributes to the development of one single thought or action, and the other as *picturesque*, because it derives its beauty from the same various and complicated groupings which characterise the highest kind of painting.

If it be once admitted that Grecian and Christian Architecture are respectively distinguished by *unity* and *multiplicity*, it follows as a necessary consequence that an edifice in which the design as a whole is Mediæval, and the individual members Classic, must be incongruous. It would, we think, be scarcely denied that, were it necessary at the present day to build a new metropolitan church of the same importance as St. Paul's, notwithstanding the general admiration of the architecture of Sir Christopher Wren, the attempt to combine the cathedral form with the elements of Corinthian architecture would not be renewed.

Architectural criticism has frequently been censured for deficiency in fixed leading principles. Those whose office it is to pronounce on the

* That we may not appear singular in this criticism, we quote the following from the description of this church in Gwilt's Encyclopedia of Architecture. "We must here mention one of the most unpardonable defects or rather abuses which this church exhibits..... The enormous expense of the second or upper order all around the church was incurred for no other purpose than that of concealing the flying buttresses that are used to counteract the thrusts of the vaults of the nave, choir, and transepts—an abuse that admits of no apology. It is an architectural fraud."—B. I. ch. III. sect. 7.

merits of modern buildings are accused of forming their judgment on circumstances peculiar to each individual case, and not on broad general rules. The criterion however which we here advocate, that of faithfulness is certainly sufficiently general and definite. It were difficult to overrate the advance which modern architecture might make, were the necessity of using forms and materials faithfully once fully established in the minds of architects and critics. Even if such an obvious truth as this could be once firmly established—that a column when not used as a support, is simply a deformity—that the hoisting of a column on the first floor of a building, or the sticking it against the face of a wall, where instead of supporting the building it is supported by it—if only such plain lessons as these could be learned, we should have made a bold step towards the attainment of purity of taste.

Those who really love the art, and feel a generous zeal for its advancement, should devote their best energies to the development, and establishment of philosophical principles in it. It is a painful but unavoidable reflection, that while in most other professions the ability of the practitioner outruns the desires of the people, modern architecture scarcely ever satisfies their expectations. There is no difficulty however in assigning a sufficient reason for these deficiencies. Almost all other branches of modern skill exhibit a spirit of a philosophical accuracy which exactly accords with the intellectual genius of the age; in architecture alone we are still trammelled by obsolete forms, and instead of adopting the principles and emulating the excellence of the purest ancient architecture, continually reproduce the barbarous incongruities invented by our more immediate ancestors.

CHURCH ARCHITECTURE, AND CHRIST CHURCH, PLYMOUTH.

Only by the encounter of opinion with opinion is it that prejudice can be overcome, and truth elicited in matters of opinion, criticism and taste. Such encounter, however, cannot take place unless contrary, and conflicting opinions are brought forward in the same quarter, so that the same readers may learn what is said on both sides of the question; otherwise they get only one—perhaps the weaker half of the argument, which passes for being unanswerable, merely because it is unanswered, or not allowed to be answered, all that would make against the side which has been taken up, being studiously suppressed. Such convenient one-sidedness generally takes the plausible name of consistency, and it certainly flatters the indolence of those who having made up their minds upon any subject of inquiry, once for all, do not like to be disturbed and put to the trouble of reconsidering what they would fain believe to be incontrovertible. Yet even sound opinions are apt to grow rusty by time, and the advocacy of them to degenerate into mere dogmatism, if they be not occasionally stirred up and turned over afresh. This has been decidedly the case with regard to architectural opinion and criticism, in which browbeating assertion founded chiefly upon previous authorative *dicta*, has been substituted for convincement, whether in confirmation of or in opposition to such authorities; for nearly the same superstitious reverence for *precedent* which prevails in regard to architectural styles, prevails also in regard to architectural doctrines. Nevertheless, even doctrines that are sound in the main, require sometimes to be further explained, to be illustrated by positive example, and to be set in a fuller and clearer light; and it is owing to this act being done, that so far from being able to defend the traditional opinions and arguments which they have adopted at the outset of their studies, people feel bewildered when they find them impugned, and unable to defend them, though they may be obstinately determined not to give them up, or even admit any qualification of them.

Wherefore should not architectural criticism, instead of being confined to the narrow and beaten track in which it is now made to move—or rather hobble along just at the heels of precedent—a sort of *laquais de place* to it, and sometimes a Will-o'-the-Wisp,—why, I ask, should it not be allowed to range freely and exercise itself as it lists? It is time for us now to turn our attention to something more than the consideration of styles alone, and the mere settling of dates and matters of that kind, to which the study of the art as a branch of literature and criticism has hitherto been almost exclusively limited, the merely historical and antiquarian quite overwhelming the *æsthetic*; whereby such study has been rendered one that chiefly exercises the faculty of memory, leaving that of taste inactive, and inert. If in addition to the historical and non-architectural we obtain tolerably full matter-of-fact description, it is nearly the utmost that we ever do. Take our English Cathedrals—for they have been more frequently and more minutely spoken of than any other structures of the kind; which among them all has been made the subject of a complete critical and æsthetic examination, noticing every peculiarity in it? In other words, have we any *artistical* descriptions of them?—that sort of description which not only illustrates but *illuminates*, kindling up into beauty, irradiating and making clearly perceptible what is also hardly discernible to ordinary eyes?

No wonder, therefore, that persons in general hold architecture to be a dry study, and find it to be a distasteful one, encumbered with grave and learned pedantry on the one hand, and a dully plodding, and mere mechanical pursuit on the other; while as to the vaunted mystic excellence of 'proportions,' thanks to those who have systematized them, they are to be got at ready-made—for the matter of that so is criticism too, and the essence of it consists not in judging of buildings according to their intrinsic and individual merit as productions of architecture, but in *prejudging* them according to certain conventionalities, and wherever those are broken through, in condemning without further inquiry. Nearly the same one-sidedness which once scouted Gothic architecture altogether, as barbarous, prevails now, the difference being that it is in contrary direction, pushing veneration for it to superstition.

Cumbersome tediousness, amounting to nothing as architectural information, and bewildering unreadableness are the prevailing faults of most of the recent publications which profess to speak at length of our ancient architecture as exemplified in particular buildings. As to modern churches, though they obtain more frequent and a far greater share of notice than almost all the other classes of buildings put together, they are criticised only *Ecclesiologically*, or else cried up as wonders in newspaper paragraphs that read very much like paid-for newspaper puffs. Mr. Wightwick may, therefore, consider himself singularly fortunate, and his Christ Church at Plymouth especially favoured by the latter having been made the subject of remarks partaking of controversy; and as I myself think think it has been captiously censured for what I am inclined to look upon as an improvement rather than the contrary, in modern church architecture,—at least where galleries are introduced, I avail myself of the opportunity arising out of what has been said to offer some further observations. Besides that, I honour Mr. Wightwick for being one of the few of the profession who think for themselves, without waiting to be prompted by precedent on every occasion. Candidus owes him some reparation for having published, some time ago, a paper in one of the leading periodicals, entitled "Wightwickism," intended to be commendatory, but which some dull matter-of-fact blockhead in a Plymouth newspaper pronounced to be nothing less than a complete cut-up!—whereas, had that been my object, I should have exhibited my ability in cutting-up after a very different fashion. Perhaps, for the benefit of the country gentlemen, that is, country newspaper editors, I ought to give warning that I am not going to cut-up Wightwick now; *tout au contraire*, to give him my good word—and it may go for just as much as that of many others.

In his reply to the strictures upon his church at Plymouth, Mr. Wightwick asks if it be "quite fair to call the only front that shows a *show front*." Most certainly not, if that term is to be taken, as was evidently meant in an injurious and reproachful sense; and if not so intended, it is only an Anglicised version of the Italian '*faciata*,' and our naturalized Anglo-Italian word '*façade*.' As a term of a reproach in contradistinction to 'façade,' that of 'show-front' applies only where the other sides of a building are seen, yet are quite out of keeping with the display affected in the principal one. The British Museum, for instance, will have a veritable show-front, and even that front will be in some measure disfigured by the paltry buildings which are allowed to come into sight between the main body of the edifice and the west wing. It will be said by some that a church *ought* to stand quite apart from other buildings, so as to show more than a mere façade towards the street: yet such 'ought' is not very evident, it depending in a great measure upon circumstances, and even where there is nothing to prevent a church from being quite insulated; that may be rather a disadvantage than not in regard to architectural design, because if the funds are limited, either architectural finish will be confined almost exclusively to the west or entrance end of the building, which therefore becomes a mere show-front, or such inconsistency is avoided only by impoverishing that and making the whole exterior equally poor and insipid throughout. One or other of these flagrant defects is exemplified in most of our modern structures, whatever merit some of them may possess in other respects; and one of the latest of those erected in the metropolis, which shows very well from one point of view, looks almost ludicrously mean, owing to the body of the church being fully exposed to view on the north side, it being a mere pigmy in comparison with the tower and spire, at the foot of which it seems to have squatted down.

After all, 'show front,' perhaps, might pass, were it not for something much worse, the unpardonable *peché mortel* of Mr. Wightwick's church being that it is lighted on the sides only by clerestory windows, there being none in the aisles. This is found fault with as *unchurch-like*,—and if by 'unchurch-like' were meant nothing more than that it differs from what we are accustomed to see in churches, the epithet would be suitable enough; but it implies a very great deal more—nothing less than something unbecoming to, and what ought on no account to be adopted for churches. Yet why not?—more especially if situation requires it, when such mode of obtaining sufficiency of light in spite of the external obstructions occasioned by surrounding buildings, ought to be prized as a great advantage in itself and one immediately derived from the Gothic style, and in effect characteristic of ecclesiastical examples of it. Were it found that an interior having no other side windows than clerestory ones, can be but imperfectly lighted, the objection might be considered tolerably valid; but such certainly does not appear to be the case in regard to Christ Church, because in the extract given from the Plymouth Journal it is spoken of as being "cheerful as the day," though that may be only a flourish of newspaper rhetoric. Be that as it may, we need not travel to Plymouth to ascertain whether it be possible for a church so circumstanced in regard to windows to be adequately lighted, because there happens to be one now erecting, and fast advancing to completion, near Fitzroy-square, which instances every one of the points that are deemed architectural heresies and deviations from orthodox ecclesiology in Mr. Wightwick's structure, it being built in between houses, consequently having only a show-front, and being lighted on its sides by clerestory windows only. In regard to the Plymouth structure, it has been assumed somewhat confidently that it must be either insufficiently lighted, or the clerestory windows so enlarged as to become "very prominent features"—of course disadvantageously so. Excess of size in its clerestory windows is certainly not the fault of the other church just alluded to, for there they consist of very small apertures put in pairs over each arch of the aisles; yet so far from there being any deficiency of light, there seems to be rather too much, and that it requires to be moderated by diapered glass, notwithstanding that at present one of the end windows is covered up by temporary boarding before it. Little, indeed, can be said in favour of the interior itself, since it is bare and poor, but its unsatisfactoriness is certainly not occasioned by there being no windows in the aisles, since were there any, the effect would be rather for the worse than the contrary.

"We never should expect," it is urged in argument against Mr. Wightwick's building, "to meet with an ordinary *skylight* in an ancient church," which remark, as far as it has any drift at all, seems to imply that such is, nevertheless, the case in his modern one, although to answer to the name of skylight at all, his clerestory must be a very *extraordinary* skylight indeed. That the exclusive employment of clerestory windows, or in other words, of windows placed aloft, so that light streams down into the building, is contrary to the spirit of pointed architecture, is more easily asserted than to be borne out by proof. The effect so produced is certainly a peculiar and unusual one, but it has generally been prized accordingly as of rare merit. This it is which if it does not constitute, contributes so greatly to the peculiar and charming effect of the octagon in Ely Cathedral. To say that and similar instances do not answer to the title of "clerestory would be only cavilling about words, because the point for actual consideration is, not whether such term can be correctly applied to instances of the kind, but whether such mode of lighting a Gothic interior principally, if not entirely, from the upper part of its sides, be contrary to the spirit of the style itself or not; or if not exactly that, be "un-church-like." That it must inevitably be the latter, and that the character of an interior so lighted must partake of that of an exhibition-room or picture-gallery has been decisively taken for granted, else why should the National Gallery be referred to as proving most convincingly that the effect attending light admitted from above must be "essentially secular." Why! except that single circumstance, there is not a single particular of resemblance, and even in regard to that there is a difference, the rooms alluded to being lighted by *sky-lights* or lanterns in the ceilings. Undoubtedly the light is there generally diffused, because it was intended to be so, neither is there any decided architectural expression or any play of light and shade, there being nothing whatever to produce either the one or the other. Does it follow that every other interior into which the light is admitted at all after the same manner as in a picture-gallery or museum, must on that account resemble an apartment of the kind? Can no differences as to style, as to design, as to arrangement, as to fitting up, as to quantity of light, &c., overcome such fatal resemblance to a secular building?

Had it been intended to judge fairly what striking architectural expression and effect may be achieved almost entirely by admitting light from above, a very secular building indeed—namely the Bank of England, might have been referred to as exhibiting a variety of modes and ideas of the kind, all of them attended with differences of effect. There might even have been policy in especially pointing to the halls and offices in the Bank, as that would have furnished a very plausible protest against the unseemliness, if not actual profaneness, of adopting for religious buildings an arrangement in regard to lighting, that could by any possibility be likened to one desecrated by having been made use of in a temple of mammon.

It is amusing to observe how readily people allow themselves to be scared by bugbear words and mere names, 'secularity' is one of them, as if everything in and about a church ought to be totally distinct from, and bear no sort of resemblance whatever to anything else of the same kind employed in buildings of a different character. If such ought to be the case, we ought to be informed *how* it is to be accomplished. Some of the leaven of secularity is freely enough tolerated in churches without scandalizing even the most scrupulous,—coats of arms, for instance, monuments with fulsome epitaphs, and other mundane varieties. Rooms with either lantern lights, or with windows only overhead in the upper part of their walls, are not so exceedingly common that such mode of lighting can be regarded as secular and unchurchlike on that account. And if there be anything at all in symbolism, *light from above*, proceeding immediately as it were from heaven, while all external objects reminding us of this every-day world are excluded from view, might surely be thought equally appropriate and significant in a church. It is not denied that side windows in the aisles are characteristic of our ancient churches, and if in modern ones they are made worthy features in themselves, and the character established by precedent can be fully kept up in all other respects, well and good; but where aisles serve only as recesses for seats and galleries, windows in them chiefly render the deviation from ancient precedent all the more offensive—in fact, a positive solecism, exactness being profusedly aimed at under circumstances which render it unattainable. If we can imitate with perfect consistency, with such thorough observance of former architectural *costume*, and with such *deceptive* fidelity that a modern structure can perfectly counterfeit an ancient one, correctness, though after all it amounts to no more than copying, may pass for a merit; but when altered circumstances require a different mode of treatment, it is for the architect to comply with the exigencies of circumstances without forfeiting any of the spirit of the style he adopts, but on the contrary to engraft upon it fresh ideas that may serve as precedent hereafter. Truly, it is not every one or any one that can do this; otherwise architecture would not deserve the name of ART. All the more honour therefore be to those who can.

CANDIDUS.

PARSEY'S AIR ENGINE.

The facility with which unprofessional observers are deceived respecting the value of mechanical inventions is really lamentable. The locomotive air engine is a case in point. This contrivance was described with an engraving in our last volume, p. 298, and we should have contented ourselves with the notice then given, without again alluding to the subject, but that we find this invention lauded in newspaper paragraphs as calculated to produce a revolution in the system of locomotion. To the scientific man the language of the paragraphs alluded to will suffice to prove that they are written by incompetent persons, but the general reader has not the same means of ascertaining the value of these encomiums. We wish to call attention to a notice which has been forwarded to us by a Dublin Correspondent. The object is briefly to show that for a journey of thirty miles there would be required 37,200 cylinders full of air, or as many *cubic feet*, if each cylinder full be a cubic foot, (a very low estimate); and that supposing this air ten times as much compressed in the reservoir as in the cylinder the capacity of the reservoir must be equal to one-tenth of the 37,200 cubic feet; that is, the magazine if eight feet diameter, would be required to be 75 feet long. Of course it would be preposterous to carry with the engine a vessel of this magnitude.

In the first place, no power is *gained* by using compressed air, because as much force must be employed in condensing the air into the receivers, as the condensed air can exert when brought into action. Next let us see what size of magazines or cases would be required for a railway locomotive worked with compressed air, for a thirty mile stage.

"The cylinders of a modern locomotive are about 14 inches diameter, that is, the pistons have each an area of about one foot; the stroke is usually about 16 to 18 inches, and the circumference of the driving wheels is about 17 feet; they will consequently make about 310 revolutions in a mile; the pressure in the pistons is about 50lb. on the inch. Then, assuming that the air is compressed to a pressure of about 5000 lb. on the inch, we have the elements for calculating what size of magazines or cases would be required."

"As the wheels would make $310 \times 30 = 9300$ revolutions in 30 miles, and as the two cylinders would each be filled twice during each revolution, there would be $9300 \times 4 = 37,200$ cylinders full of compressed air required to carry on a locomotive 30 miles! Assume that the air was worked expansively in the cylinders, and that only a cubic foot was admitted at each half stroke, the quantity of air compressed to 50 lb. on the inch, would be 37,200 cubic feet; but as the air is supposed to be compressed to 500 lb. on the inch in the portable magazine, its cubic contents would still require to be 3,720 cubic feet! To hold this would require a cylindrical magazine of about 8 feet diameter, and 75 feet long! Rather a bulky case to move about, or carry along a line."*

We have only one remark to make in support of these conclusions, and that is, that not only would there be no gain of power by the above arrangement, but many sources of absolute loss. In the first place there would be the friction of the engine pumping the air into the magazine, and in addition the friction of the locomotive engine worked by the compressed air. So that comparing Mr. Parsey's system with the present locomotive system, there would be for every journey the friction of two engines instead of one. Another source of loss would arise from the fact that all elastic fluids when compressed develop their latent heat. Now as the elasticity of air is greatly increased by an increase of heat, it is clear that the development of latent heat would in the present case greatly increase the labour of pumping. This increased elasticity by the generation of heat would however be all *lost*, for the magazine would be rapidly cooled by the radiation of its metallic surface. Another loss would arise from the *refrigeration* of the air by its dilation when passing from the magazine to the cylinder.

It may be said that air could be pumped into the magazine so slowly that the development of heat would not be apparent to the senses. But this is only concealing the evil instead of removing it. It is true that the heat might be generated so slowly that the radiation of the cylinder would carry it off as fast as it was produced, but this would simply render the evil *non apparent*.

Contrasted with the previous quotation which avoids all difficulties arising from the variation of the pressure in the reservoir, we have a letter addressed to the *Mining Journal* in favour of the new invention. We wish to draw attention to one error in it, because it is one very likely to be committed by a person not familiar with the theory of pneumatics, and as it entirely vitiates the calculations. The writer calculates "that to draw a train 60 miles with a tractive force of 3000 lb. the work done must be 1,188,000,000 lb. moved through one foot," and the letter concludes in the following manner.

"Let it be proposed, to compress the air to 1000 lb. pressure, which will give a medium working pressure of 500 lb. per square inch; 1000 lb. pressure per square inch is equal to 66 atmospheres—consequently, a column of air compressed into 66 times its density—*one* foot high, and 1 inch square at the base—will lift 500 lb. 66 feet high, or 33,000 lb. 1 foot high; consequently, a column of compressed air of 66 atmospheres, being 1 foot high, and 1 foot square at the base, will lift $33,000 \times 144$ lb. 1 foot high, or 4,752,000 lb. 1 foot high. Then, as 4,752,000 lb. will require one cubic foot, what will 1,118,000,000 lb. require?—Answer, 237 cubic feet. In like manner, if the air were compressed to 2000 lb., the contents of the magazine required would be 60 feet. A magazine of 3 feet diameter, 9 feet long, and 1 inch thick, would, therefore, be amply sufficient; the weight of such a magazine would be 4000 lb.—An Engineer: *London, Feb.* 18."

The chief error in the above paragraph is the assumption with which it starts, that if the air be at 1000 lb. pressure at the first, and at 15 lb. pressure at the last, the average pressure will be about half way between these two pressures, or equal to 500 lb. Now we want to show that the average will not be nearly so much as this, and the explanation is worth attending to, because it shows the danger of "jumping" at conclusions.

Suppose, for simplicity, the case taken in the extract, of the air in a tube 66 feet long, and of uniform diameter, being compressed so as to occupy only one foot of the tube at its end: what we want to find is the work done by this compressed air (or the number of pounds moved one foot by it), while being dilated back to its ordinary density. Tracing its progress foot by foot from the first foot to the sixty-sixth, we find that at the second foot it occupies twice as much space as at first, at the fourth foot, four times as much space, at the eighth, eight times as much, &c. Consequently the pressures at the 1st, 2nd, 4th, 8th, &c., feet are respectively 1000, 500, 250, 125, &c. Now the mere consideration that at the second foot the density is reduced to 500, shows how terribly the average has been overrated in the above extract, where the rapid decrease of pressure is neglected, and the air is supposed to act with the same average force throughout the 66 feet, which in fact it exerts only from the first to the second foot.

We could not without a few mathematical symbols calculate the exact amount of work done in the present case, still we can give an approximate method readily intelligible to any one acquainted with the first four rules of arithmetic. Let us consider what would be the pressure of the air at the first, second, fourth, eighth, &c. feet, and let us suppose that it passes from each one of these stages to the next without a diminution in pressure. This supposition of course exaggerates the amount of work done. Then from the first foot to the second it moves 1000 lb. through one foot; from the second foot to the fourth it moves the half of 1000 lb. through two feet (= 1000 lb. through one foot); from the fourth foot to the eighth it moves the fourth of 1000 lb. through four feet (= 1000 lb. through one foot, &c.) Arranging the results in the form of a table, we have—

			Work done or number of lb. moved one foot.
1st to 2nd foot,	1000 lb. through 1 foot	=	1000
2nd to 4th, half of	1000 lb. through 2 feet	=	1000
4th to 8th, quarter of	1000 lb. through 4 feet	=	1000
8th to 16th, one-eighth of	1000 lb. through 8 feet	=	1000
16th to 32nd, one-sixteenth of	1000 lb. through 16 feet	=	1000
32nd to 64th, one-thirty-second of	1000 lb. through 32 feet	=	1000

This gives the total work up to the 64th foot; for the remaining two feet add two sixty-fourths of 1000 lb. (about 31 lb.), and we find finally for the total work done, that according to the above calculation (which is a very favourable one) the number of lb. moved one foot is 6031. The "Engineer" makes the number 33,000, or more than five times as much!

The following method gives the true result much more accurately. If the pressure at a distance of 1 foot from the end of the tube be 1000 lb., at any increased distance x the pressure will be $\frac{1000}{x}$, and $\frac{100}{x}\,dx$ will be the work done through a short distance dx, $\therefore$ the whole work done will be $1000\int\frac{dx}{x}$ between limits 65 feet and 1 foot $= 1000 \times \log_e 66$ $= 1000 \times 4{\cdot}1896 = 4189{\cdot}6$.

The amount of work then really done is equivalent to 4189 lb. moved through one foot. Comparing this with the quantity calculated by the "Engineer," (namely, 33,000 lb.), we find that he has made it between *seven and eight times what it ought to be.*

It is really lamentable to see people deluding themselves and others in this manner. The newspapers state that Prince Albert saw the model of the air engine, and expressed his approval. It is not however stated that he made any calculations, or that his royal power extended to a suspension of the laws of elastic fluids.

We had almost forgotten to mention that the pressure in the reservoir supposed to be 1000 lb. to the square inch, is more than ten times as much as the very extreme pressure which is considered safe in the boiler of a locomotive engine.

Dredging Machinery for Egypt.—M. Cavé, of Paris, who contracted for the building of the Chaptal, iron steamer, with all her machinery complete, which is about leaving France, is now busily engaged at Rouen, in shipping off to Alexandria, in Egypt, the different materials to complete the large dredging machine, for which he has contracted with the Pacha, Mehemet-Ali, for the purpose of dredging the Nile, so as to render it perfectly navigable. This is only a preliminary step towards the cutting of a navigable ship canal across the Isthmus of Suez, to join the Red Sea with the Mediterranean—one of the grand projects of the Emperor Napoleon.

* Of course if the pressure be 1000 lb. to the inch in the reservoir, the size of it will be reduced one-half.

PRESSURE ON RETAINING WALLS.

In the first volume of the Transactions of the Institution of Civil Engineers, Ireland, is published a paper by Mr. Neville, on the horizontal resistance required to sustain banks of earth. The *formulæ* arrived at in this paper were printed at p. 242 of the last volume of our journal; and a letter having appeared at p. 359 of the same volume, subscribed "A Young Engineer," asking for a demonstration of the results given, Mr. Neville has been good enough to send us in reply a copy of his printed paper. Before, however, making any extracts from it, we wish to state an objection which appears to us to apply generally to the mechanical considerations on which the mathematical investigations are based. If, however, we mistake Mr. Neville's views, he will, of course, have the opportunity of replying.

The earth behind a revetement wall of a railway cutting pressing on every part of the masonry, the equations given by Mr. Neville determine *the resultant of all the* horizontal pressures, but the *moment* of this resultant the application are left undetermined. Now, the determination of the value of the resultant pressure, is not sufficient of itself for ascertaining the necessary strength of the retaining walls, or rather, that value, if it *alone* be determined, does not afford the slightest assistance whatever in examining the conditions of equilibrium. The case contemplated by Mr. Neville appears to be one which seldom if ever occurs in practice—namely, the moving of the revetement wall bodily forward without overturning. Whereas, in reality, the real points to be ascertained are the necessary thicknesses of masonry, to prevent, 1st, the slipping of the courses of bricks on each other; 2nd, the overturning the structure about its base.

In order to the ascertaining these two points, two sets of equations are required. The first set of equations must exhibit the variations in the degree of pressure on the revetement at different heights from the ground. It is manifest that the pressure will not be uniform, that it will generally be greater near the base than the top of the wall. Consequently, to prevent the courses of masonry slipping on each other, the "wall of equal strength" (that is, the wall in which the strength is everywhere proportionate to the pressure) will be of the greatest thickness at the base and diminish upwards. To ascertain the varying form of the wall the *law* of variation of the different pressures must be ascertained. Mr. Neville has, however, considered only one single pressure to be acting on the wall—namely, the resultant of all the pressures, which, in reality, exist.

The next point to be ascertained is the tendency to overthrow the wall by turning it about its base, to this end we must have equations exhibiting not the *value* of the pressures merely, but their *moment or leverage*. For it is clear that of two equal pressures acting on a wall, that which is applied at the greatest distance from the base will have the greatest *purchase* or effect to throw down the structure. To find therefore how strong the wall must be built to prevent its being overturned, it will be necessary either to ascertain the resultant force and *also* its point of application; or (if it be possible) we may determine the sum of the moments of the pressures on every point of the wall. In analytical language if p be the pressure on a unit of the area of the wall at a height x from the base, the quantity to be determined is $\int p\, x\, dx$.

The calculations of the paper before us would be perfectly satisfactory, if it were possible so to build the retaining wall that by means of it a pressure equal, and exactly opposite to the resultant of the pressures from the earth could act at the same point of application. This, however, is obviously impossible, for the horizontal resisting force exerted by the wall is applied at the base, since all the strength of the structure is derived ultimately from its connection or cohesion with its foundations. The resultant pressure of the earthwork is however applied at some point above the base; the two forces, that which sustains the wall, and that tending to overthrow it, cannot therefore be supposed to be applied at the same point. The determination of the value of the latter force, therefore, is not of itself of any value, for it may happen for instance to be applied at a distance of two feet from the base, or at a distance of four feet, and in the latter case its effect will be twice as great as in the former. It is not the pressure, but the momentum of it which is to be sought for, and without this be determined, no useful result can be deduced from the mathematical investigations.

Mr. Neville quotes in a note the concluding remarks of a paper on the resistance to banks of earth, by Tredgold, in the 51st volume of the "Philosophical Magazine," and adds "It is, however, evident that Tredgold was mistaken in this conclusion." If Mr. Neville will again refer to the original, he will, perhaps, see that the mistake is his own, and arises from a misapprehension of the sense intended to be conveyed. He might, by-the-bye, have taken a hint for his own investigation from Tredgold, who is careful to determine not the pressure only, but the moment of it.

OCEAN WAVES.

(We have slightly abridged this interesting paper from the "Nautical Magazine.")

Oceanic waves, from whatever source they may arise, have always been regarded as objects of interest to command our attention, yet very little is known of the laws whereby they are raised, augmented, or transferred. Landsmen, when actually embarked in stormy weather, are generally so deranged by sea-sickness and the ship's motion, as to be rendered unfit for observation or philosophical research. On the other hand, practical seamen, accustomed to the sea from an early age, although not altogether disqualified, become so familiar with all kinds of waves, that the subject is a matter of indifference to them.

It is, however, very certain that erroneous notions are entertained about waves, for we read in works of acknowledged merit, that the height of waves above the mean sea level, seldom exceeds six or eight feet, yet the language of poetry and metaphor raises them into aqueous mountains.

Some sense, and a good deal of nonsense about waves, was published by a section of the British Association for the advancement of Science. Being smitten with the mania of making *observations* on waves, and leaving Daddy Neptune to make the actual *experiments*, I seriously set to work at my official residence, which is within thirty feet of the Atlantic, and 3,800 miles from the nearest land on the north-east coast of South America; the waves, therefore, coming from the south-west have "a pretty considerable fetch." I had, perhaps, the best opportunity, and much inclination to collect as many facts as possible about the waves, that are almost constantly commanding my attention. I now send those I made at Plymouth, believing they may be useful; as nothing of the kind has ever been published, they afford data for mathematical research. The observations are arranged in a tabular form, with very brief remarks of my own, extracted from a paper of mine, where the subject is more fully discussed.

Observations made on Waves reaching Bovisand, east-end of Plymouth Breakwater.

Remarks on the Observations.

No. 1.—San Carlos to Bovisand Rocks.
2.—This evening only ten waves over space.
3.—Distance traversed from San Carlos Buoy to Pier.
4.—Waves become crowded near the Pier.
5.—The east wind has probably diminished the velocity of the waves.
6.

* On this day, the height of the waves, unbroken, was measured, by means of many observations. The mean level of smooth water on the tide gauge was noted, and the eye of the observer being 32 feet above the sea level, his visible horizon was 39,520 feet. The buoy on the Tinker Shoal was distant 6,180 feet, and as the waves reached this buoy and raised it, the summit of the wave was in a line with the observer's eye and his visible horizon. Since the distance of the visible horizon and height of the eye are given, and the distance of the Tinker Buoy also given, the height of the waves at the buoy may be found, because, 39,520 : 32 feet :: 39,520—6,180 : 27 feet, the height of the wave above the mean level, and as the sea was breaking in a depth of five fathoms, the depressions were equal to the elevations ∴ the height between the two extremities, or rather hollow, would be 54 feet.

7.—Cranes being washed down on the breakwater.
8.—Tide ebbing, barometer rising, and sea breaking in five fathoms.
9.—Small waves have run into large ones.
10.—High water.
11.—Swell subsiding.
12.—These waves raised by the south-west wind of yesterday.
13 and 14.—These waves indicate an approaching south-west wind as they subside.

These results were noted with the greatest care, and may be taken as pretty correct. Without going into a discussion of the very many results that may be obtained by analyzing the table, I may state two or three facts, viz:—

1st.—The velocity of waves is retarded as they advance into shoaler water. I have actually seen a wave overtaken and emerge into another, No. 1.

2nd.—The velocity of waves is not dependent on their height, No. 8 and No. 10.

3rd.—These experiments on a large scale appear to prove a *result* obtained by Mr. Scott Russell on a *small* scale, viz., that when the depth of the water equals the height of a wave, it breaks, and becomes a wave of translation. (See No. 8, *remarks.*)

4th.—Deep water facilitates the undulations of waves, (September 28th, No. 6 and 7), the tide rose eight feet, and the increase in velocity of the waves was one-and-a-half feet per second.

Leaving your readers to make comparisons or draw conclusions, I may briefly assert that the hydrostatic and hydrodynamic force that water exerts is far from being so well understood as it should be by those who assume the duties or appellation of "civil engineer." The man who contrived the huge iron tank, which burst the other day at Liverpool, when only two-thirds full, destroying much property, and drowning several persons, knew nothing of the *pressure* that his tank would have to sustain when filled with water. The hydrostatic pressure at any depth, is as the square of the depth = the sum of all the pressures above it.* In computing the force that a wave is capable of exerting upon a solid immersed in the sea, we have to take into consideration the rate at which the water moves or impinges against the solid, in addition to the hydrostatic pressure upon it. There are many gentlemen who add C.E. to their names, and who believe that the impulse of a volume of water in motion upon a solid structure opposing it, will be as the volume into the velocity, as is the case when one solid impinges upon another, as a mass of ice upon a stone. But a little reflection will convince us that the force which a volume of water moving exerts upon a solid obstacle, is not proportional to the velocity of water, but to the *square* of its velocity. The velocity with which a wave is thrown forward is equal to the velocity with which the *undulation* was previously moving, and although a very high wave is always dangerous, it is not always the very highest waves that are the most destructive.

If reference be made to the table of observations, it will be seen that No. 7 had waves moving at the rate of forty-six feet per second; these waves were far apart, and of middling height. They were, however washing the huge blocks of marble about on the breakwater, and knocking down the cranes upon it, whilst much higher and more crowded waves moving at the rate of 41·8 feet per second, were less destructive to the works, (*see* No. 8.)

The effect being, (ceteris paribus), as the square of the velocity, we may estimate what the height of the waves, moving at the rate of 46 feet, shou'd be, to equal the impulse of the waves 27 feet high, and travelling at the rate of 41·8 feet per second.

Put x = the required height.

Then $41{\cdot}8^2 \times 27 = 46^2\,x$. Now by this equation the value of $x = 22$ feet. Hence it would appear the height of the waves on the 28th of September must have been greater than twenty-two feet to produce the results upon the breakwater, although their height was certainly less than the height of those measured on the following day.

William Walker.

---

* There is a slight ambiguity here. It is the total amount of pressure on the vertical sides of the tank which varies as the square of the depth—the pressure on any one point varies as the depth simply.

We are told further on, in the text, that the resistance of the wave does not follow the laws of impact of solids, but varies as the square of the velocity. Views so vague as these ought not to be expressed by a writer who takes upon him to condemn the philosophy of others. It is indeed usually assumed that the resistance of fluids varies as the extent of surface and the square of the velocity conjointly. But this law is only approximate, and "a little reflection will" not "convince us" of its truth, as that can only be ascertained by direct experiment, and cannot be proved by independent reasoning.—[Ed. C. E. & A. Journal.]

ON THE TEMPERATURE OF THE EARTH AND SEA.

A Lecture on this subject was delivered at the Royal Institution, by Mr. S. A. Taylor. He observed, that the atmosphere is an ærial film surrounding the earth, but, although of almost inappreciable thinness when compared with the earth's diameter, it forms a non-conducting investment resisting the radiation of terrestrial heat into space. The mean density of the earth, according to Baily, is 5·66, or about twice 2·8, the density of rocks and strata constituting its surface. We infer from hence that the mass of the earth, must be formed of materials lighter than the common metals, as iron, tin, lead, &c. Its specific gravity falls between that of titanium and tellurium. From careful inquiry it appears that the temperature of the *surface* of this planet depends entirely on heat acquired from the sun. Part of the heat thus received is conducted to a certain depth below the earth's surface; and part radiates into space. The greatest natural cold on the surface was observed by Erman at Yakutsk, the capital of Eastern Siberia, where the thermometer stood at 72 deg. below the zero of Fahrenheit. The temperature of space beyond the limits of the atmosphere must therefore be much colder—too cold to admit of the maintenance of life under its present conditions. The heat of the sun penetrates the earth to but a very small depth. Diurnal variations of temperature are not perceived below two or three feet, while the annual variations do not affect the earth's crust below 1-400,000th of the diameter of this planet. On the alternate heating and cooling of this film of depth depend the vicissitudes of climates, seasons, and cycles of years.

Mr. Taylor then stated, that, at a certain depth below the earth's surface, there is a stratum at which the thermometer is almost stationary. This stratum is consequently termed *the stratum of invariable temperature*. The depth of this stratum depends—1st, on the directness with which the sun's rays fall; and, 2nd, on the conducting power of the superficial strata. It must, therefore, be different at different localities. At Paris the depth of this stratum has been accurately ascertained to be 90 feet below the surface, at which depth the temperature has, for 50 years, remained constant at 53 deg. Fah. In other different parts of the world, this stratum varies in depth from reasons already assigned. In the tropics it is three or four feet, in the temperate regions from 55 to 60 feet below the surface, while in the regions of extreme cold, solar influence does not extend beyond three or four feet, the ground below this depth being found always frozen, to the extent of 400 feet. Generally, however, the temperature of this invariable stratum differs but little from the mean temperature of the place. Mr. Taylor then directed attention to the important and universal truth, that, when carried below this stratum of invariable temperature, the thermometer rises. The rise is not, however, the same at all depths in all places. As there are *iso-thermal* lines *on* the earth's surface, so there are *iso-geothermal* lines *beneath* it. Many localities, as five of the principal mines in Cornwall, the well of Grenelle at Paris, the Monkwearmouth mine of Sunderland, Joseph's Well at Cairo, &c., were noticed as indicating the great curvature of the iso-geothermal line.

The theory of the existence of internal heat was then established from—

1. This progressive rise of the thermometer in descending into mines and other excavations.
2. The high temperature of the water of artesian wells.
3. The high temperature of natural thermal baths or springs.
4. The phenomena of volcanic eruptions and earthquakes.

From accurate examination of these sources of inquiry, there has been found that the thermometer rises in mines one degree for about every 50 feet of depth; a result confirmed by the fact that the temperature of water in artesian wells increases in about the same proportion to their depth. The heat of thermal springs has been found equal to that of boiling water, and the perfectly fused condition of substances ejected from volcanoes indicates a temperature of 1000 deg. The opinions of various philosophers respecting the cause of the central heat of the world were reviewed. Buffon held that the earth was a vitrified ball in the act of cooling; Leslie and Halley that it was a hollow sphere, made up of stories like a house; others, that the interior of the earth is in a perfectly molten state, the heat at twenty miles below the surface being sufficient to melt granite. Having pointed out the objections to these various hypotheses, Mr. Taylor affirmed, as an apparently certain fact, that this internal heat does not affect the temperature of the earth's surface. He particularly dwelt on a calculation made by Arago, that if in the period of 2000 years the earth had cooled only 1-300th of a degree, the fact would have been indicated by a difference in the length of the day, in consequence of that contraction of its diameter which any diminished temperature of that planet would have occasioned. Mr. Taylor quoted also records which proved that the climate of Tuscany has undergone no change during the last 200 years. With respect to the temperature of the sea, many difficulties are offered to accurate observation. The uncertainty as to the depth to which thermometers can be sunk, the influence of cold and warm currents, the laws regarding the circulation of heat in liquids, and the effects of heat on the density of water, present serious obstacles to accurate results. The most careful observations and calculations give an oceanic temperature of from 34 deg. to 44 deg. It is probable that the submarine strata are sufficiently thick to prevent the free conduction of central heat, while the effects of heat on the density of water, together with its rapid diffusion throughout the mass of the ocean, would render a high temperature imperceptible at any one point. On the other hand, the abundance of insular volcanoes sufficiently testifies the existence of igneous matter beneath.

From these considerations, Mr. Taylor concluded—

1. That, at a certain depth below the surface of the earth, there is a source of heat which increases as we descend.

2. That this heat cannot be derived either from the sun or from chemical changes.

3. That this heat neither perceptibly affects climates or seasons, nor influences the temperature of the surface of the earth, nor of the depths of the ocean, nor of the atmosphere.

4. That the vicissitudes of climates and seasons are entirely referrible to solar influence.

5. That this influence, even at its maximum, does not penetrate below 1-400,000th of the earth's diameter.

6. That, although we have positive evidence that subterranean heat exists, we can neither measure its intensity, nor determine the exact ratio of its increase towards the centre of the earth.

7. That there is no evidence to show that the earth is gradually cooling from a high temperature.

EXPLOSION IN A SEWER AT IXELLES.

A report has recently been published in a Brussels Journal on the causes of an explosion which occurred on the 2nd of January last, at Ixelles. The following account is taken from this report, which however we have not translated very faithfully, as in several places we have made omissions for the sake of brevity. The report is signed by M.M. Nollet, Dieudonné and Spaak; their principal object seems to be to remove all apprehension as to the possibility of explosive gases being generated in sewers.

It is stated that the street gas pipe under the Etterbeek road was broken, and that in consequence there was an abundant escape of gas which penetrated the sewer in which the explosion took place. Another main gas pipe under the Ixelles road was also broken; but this second accident might have resulted from the explosion, which caused a great deal of damage in the neighbourhood. The sewer in which the explosion took place had been in use only twelve days. The commissioners on entering the sewer in which there was room to stand upright, found in it water slightly blackened; but the flame of a candle burned in it as brightly as in the external air, respiration was not impeded, and there was but very little odour.

The water from the Ixelles road after passing through trapped gratings falls into a brick cistern, from which the overflow, after leaving the heavier deposits in the cistern, passes into a conduit from which the liquid deprived of the insoluble matter* passes into the sewer.

Much rain had previously fallen. The water was consequently constantly renewed; the temperature of it was also below zero (centigrade), and there was little vegetable matter present.

Two questions presented themselves. Was it possible, as had been suggested, that carbonated hydrogen could have been generated in the sewer itself, and there formed an explosive mixture? Again, in what manner could this mixture have been produced?

The reply to the first question is, that carbonated hydrogen could not have been formed either in the sewer or the branch pipes; that neither the nature of the substances, nor their stagnation, nor the degree of temperature, nor the length of time, four conditions requisite for the supposed decomposition, permitted this hypothesis.

If it be true that in the Pontine Marshes and other marshy places where there is a large quantity of mud, composed principally of the detritus of vegetable matter, and constantly covered by water heated by the sun, bubbles of carbonated hydrogen escape, especially when the mud is stirred, it is when the four conditions determined above concur to produce the phenomenon.

But it may be said that sewers contain fæces and other animal substances. The examination of the nature of the gas emanating from these substances has been undertaken by a commission appointed in Paris to superintend the purifying of ancient sewers. The average of 21 experiments gives the following result:—

Oxygen	18·10
Azote	78·70
Carbonic acid gas	2·80
Sulphuretted hydrogen	·90
	100·00

In no instance was the gas inflamed during the visits: on the contrary it was remarked that the flame of a candle burned feebly and sometimes was extinguished. This was a necessary consequence of the composition of a gaseous mixture in the sewer of Rue du Chemin Vert at Paris, of which the following is the analysis.

Oxygen	13·79
Azote	81·21
Carbonic acid gas	2·01
Sulphuretted hydrogen	2·99
	100·00

This gas was asphyxiant; it instantly extinguished the flame of a taper.

In one instance only M Serpette, Inspector-General of Sewers, at Paris, found a gas which inflamed on the introduction of a lamp; the flame of the gas went out and again caught fire, but this phenomenon which never occurred, but in this one instance, took place in a sewer of the Rue du Ponceau, where the mud was very deep and had long been undisturbed, and the gas burned without explosion. All the facts are detailed in the work published by Parent du Chatelet on the sewers of Paris, and in his treatise on public health published in 1836.

One more instance is known of fire occurring in a sewer at the approach of a flame, but this occurred from the passage into this sewer of a liquid refuse containing a large quantity of tar produced at some neighbouring gas works.

With respect to the explosion in the main sewer at Ixelles, it is ascertained that the main gas pipe was broken before the explosion near the drain of the Etterbeek road took place. Several days before the accident occurred a strong odour of street gas was perceived in the neighbourhood. This odour is easily distinguished from that of drains, and it was so strong that notice of the escape of gas had been given at the gas works. It is to the mixture of this gas with the air of the drain that the explosion must be attributed.

To prevent the recurrence of so serious an accident, it is proposed to make the gas tubes of increased thickness where they traverse cross streets, and to imbed them in brickwork. It is also proposed to replace the existing close covers of the drains by openings which will facilitate the renewal of the air. The inside of the drains also has been carefully coated with plaster, so that there is no cause to apprehend that a detonating mixture can be again formed under circumstances resembling those which led to this disastrous explosion.

* On the other hand it is stated in a memoir, by Dupuytren, on the mephitic air of cesspools (Journal de Medecine, Vol. XI.) that on analysing the air in one of these places there were—

Azote	94
Oxygen	2
Carbonate of ammonia	4
	100

In another case there were—

Azote	89
Oxygen	6
Carbonic acid gas	5
	100

Height of Vesuvius.—According to the latest observations of the scientific men charged with the geodetical works of the kingdom of Naples, the height of Vesuvius, at its most elevated point—a point which has undergone no change for many years—the *punta del Palo*, is 1203¼ mètres (3948 feet) above the mean level of the sea.

STYLES AND METHODS OF PAINTING SUITED TO THE DECORATION OF PUBLIC BUILDINGS.

By C. L. Eastlake, R.A.

Secretary to the Commissioners on the Fine Arts.

External Conditions of Works of Art.

The materials and dimensions of works of Art, and the situations and lights for which they may be intended, are termed *external conditions;* as distinguished from the character of subjects, the aims of individual artists, the tendencies of general taste, and similar influences. The former class only, as affording definite grounds for investigating and as suggesting practical inferences, can here be considered.[1]

Whatever be the external conditions, it is essential that the visible impression of the work should, under the circumstances, be as complete as possible. To insure this, not only the executive means, but the qualities to be represented still require to be adapted or selected accordingly as conditions vary. Such methods and resources constitute in each case a specific and appropriate *style;* the criterion of which is, that the amount of excellence resulting from it is unattainable in the same degree by any other means.

The question respecting the relation of painting to external conditions is not unimportant in considering the tendencies and claims of different schools. In general, the great masters seem to have inquired what the outward resources at their command could best effect. Such a habit, instead of confining, was rather calculated to enlarge their invention and to vary its forms. The result of their labours is the sufficient ground of the world's admiration; but their docility cannot be duly appreciated without a reference to the local circumstances under which they worked.

An inquiry into the principles which may regulate such varieties of style appears to be especially requisite when painting is employed in the permanent decoration of public buildings, and may now be resumed with a more direct object, as particular localities in the new Houses of Parliament approach their completion. In such further investigation it may sometimes be necessary to advert to the statements and illustrations that have been before submitted.

The conditions now proposed to be considered are—

Dimensions, Situation, Light, and the Means of Representation.

Large dimensions (in respect to the size of the entire painting), requiring a corresponding point of view; the height at which the work may be placed, requiring a distant point of view independently of dimensions; imperfect light; and a method of painting possessing limited technical resources, are all to be considered as *causes of indistinctness,*[2] requiring to be counteracted by such means as the method of art adopted can command; by such means as may appear preferable on general grounds, and which, supposing its practical difficulties overcome, may render that method the fittest.

The relation between the longest dimension of a picture, and the distance from which the work requires to be viewed, may here require to be again remembered. Once and a half the extent of the longest dimension (whether in width or height is immaterial) is the minimum of distance to which the spectator can retire in order to see the entire surface. A circle cannot be embraced by the eye till the spectator retire to a distance equal to once and a half its diameter.

The law relating to the next condition is a necessary consequence of this. In some cases, the situation of a picture, independently of its dimensions, may require that the work should be viewed at a considerable distance. A painting placed opposite the eye, and measuring 14 feet high (such being assumed to be its longest dimension), would require, according to the foregoing law, to be seen at a distance of 21 feet. But if the lower edge of that painting be 26 feet from the ground, the spectator must retire to the distance of at least 60 feet before the eye can embrace it; for a painting equal to the whole height (40 feet) would require that distance.

This is the state of the case with regard to the compartments to be painted in the House of Lords. They are 26 feet from the floor, and may be reckoned to be about 14 feet high.[3]

At the end opposite the throne, the compartments are in recesses, and will be less fully lighted. At this end, therefore, all the causes of indistinctness above enumerated are combined, and may suggest a counteracting treatment in the paintings accordingly.

If, on the one hand, these considerations may furnish an answer to those who look for finish and minuteness of detail in specimens of fresco-painting that have reference to such a situation; it will be acknowledged, on the other, that the general treatment which may be calculated to correct the consequences of such conditions is a problem requiring some experience to solve. Fortunately, a reference is possible to the example of great artists under similar circumstances.

Dimensions.

The instances are not frequent in which the size of the objects represented on a large surface is too small for the distance which the size of the entire painting requires. Raphael's first work in the Vatican, called 'The Dispute of the Sacrament,' would be such an instance if the room in which it is painted were large enough for the spectator to retire to the requisite distance. This is not possible; the whole of the painting cannot be embraced by the eye at once. The experiment can, however, easily be made with the engraving; the small size of the figures, as compared with that of the entire work, is then apparent. This imperfection, as is well known, was rectified by the artist in his subsequent works in the Vatican.

Situation.[4]

The next condition—situation, without reference to dimensions, presents greater difficulty. Michael Angelo, after having painted the second compartment in the ceiling of the Sistine Chapel—about 60 feet high—appears to have found (as is, in fact, the case) that the size of the figures was inadequate to the distance at which they were to be seen. Condivi relates that the artist was on the point of abandoning the work because of some supposed defect in the lime; but the real cause of his temporary dissatisfaction is apparent in the subsequent change in his style; the figures in the compartments last executed being more than thrice the size of those in the first paintings.[5] Thus, whatever may be the dimensions of the picture (and in ceilings the compartments are commonly smaller than the distance would require), the size of the figures must always have reference to the place of the spectator.[6]

In this instance, therefore, although the space was scanned by an experienced eye, the means employed to counteract the effect of the existing conditions were miscalculated. The example shows the necessity of simplicity, magnitude, and distinctness for works requiring to be seen at a distance, and is also valuable as affording encouragement to our artists, should they think that their first efforts are in any respects not altogether adapted to the place for which they were intended.

Light.

It will appear from the practice of another great painter, that imperfect light required, in like manner, magnitude and simplicity of parts; while, at the same time, large masses of deep shade were avoided. The frescoes of Correggio, in the tribune of the church of S. Giovanni in Parma, were remarkable for these qualities. An idea may be formed of their general style by the portion which remains (now in the library at Parma, representing the 'Coronation of the Virgin'). Pungileoni remarks[7] that the figures generally were considerably larger than life, not so much in this instance on account of their distance from the spectator as because they were seen by a subdued, reflected light. The result was probably satisfactory; for objects require to be magnified, even when seen near, to counteract the indistinctness arising from want of light.

Means of Representation.

A fourth case is that in which the indistinctness to be guarded against arises from the means of representation. Fresco, with its limited scale of colour, cannot produce such varied effects as oil-painting; but a much stronger instance of defective means and of the excellencies which the necessity of counteracting them may induce, is to be found in the Cartoons of Raphael. The ultimate works for which the Cartoons served were copies wrought in tapestry—a mode of representation which, in the early part of the sixteenth century, was far from exhibiting even the comparative force of colour, and light and shade which it afterwards attained.[8] With a view to such faint transcripts, however, the great artist worked; he knew that his drawings would be transferred to them, and that in the tapestries alone, possibly, his designs might live.[9] Distinctness was nevertheless attained, without any sacrifice of such of the proper attributes of painting as was compatible with the means employed; and without any violation of probability. When we consider the great qualities which were combined

1 It has not been thought necessary again to consider the question of the adaptation of style in painting to that of the architecture of the new Houses of Parliament. It may be sufficient to repeat that the Tudor style in England is coeval with the best examples of Italian art, and that if Raphael had accepted the invitation of Henry VIII. to visit this country, edifices erected during or before the reign of that monarch might have been adorned with the great artist's works. Second Report, p. 65. Compare First Report, p. 19.

2 It is necessary to separate the causes from the remedies of indistinctness. A distant point of view, whether the consequence of the size of the work or of its situation, is in itself a cause of indistinctness; the size of the objects represented, if calculated to counteract this, is among the remedies, but, it will appear, may sometimes be overlooked.

3 The height of the compartments to the point of the (Gothic) arch is 16 feet; but the picture, properly so called, may be considered to terminate two feet lower.

4 In pictures of processions or unconnected incidents, the treatment here referred to cannot be considered a defect.

5 The figures in the third compartment correspond in size with those in the first (either for the sake of uniformity or because the scaffolding immediately under the ceiling prevented the artist from making his observations earlier); the great change begins in the fourth. It is scarcely necessary to observe that large foreground figures are quite compatible with subjects requiring numerous actors. Michael Angelo's treatment of the subject of Haman is an example. The figures in the subject of Noah (the first ceiling compartment) might, even with the present composition, have been as large as those in the Creation of Eve. The circumstance of the ceiling subjects last executed requiring fewer figures is therefore not to be considered the only cause of the change in the artist's style. See Condivi, Vita di Michelagnolo Buonarotti, Firenze, 1746, p. 27. The first edition of this work was published in Rome, 1553, in Michael Angelo's lifetime.

6 The subjects in the small gold-coloured medallions in the ceiling of the Sistine chapel must have been, even at first, almost invisible from below. They are, however, to be regarded as mere decorations.

7 Memorie Istoriche di Antonio Allegri, Parma, 1817, vol. i., p. 134.

8 The admiration of Italian contemporaries is excusable, from the novelty of the manufacture at that period. The praises of Paris de Grassis, Vasari, and others may be compared with the juster remarks of Gunn, Cartonensia, London, 1832, p. 85; and Cattermole, The Book of the Cartoons, London, 1840, p. 21.

9 Such designs were treated as mere working drawings; they were cut into slips for the execution of the tapestries, and were then thrown aside till again wanted for the same purpose. It was in this mutilated state that the cartoons at Hampton Court were first brought from Flanders. See Quatremere de Quincy and Longhena, Istoria, &c., di Raffaello Sanzio, Milan, 1829, p. 586; and Trull, Raphael Vindicated, London, 1840, p. 8.

with these requisites—when we find that such apparently unpromising conditions had the effect of raising even Raphael above himself, we can hardly refuse to admit that a due employment of limited means of representation may, at least, invite attention to the most important attributes of art.

In cases like those that have been adduced it is probable that the qualities which might fit the works for the circumstances of place, light, or materials for which they had been calculated, would be looked upon as defects on near inspection. The critics on art who have had the best right to exercise an unrestricted judgment, have ever dwelt on the necessity of inquiring what qualities are to be chiefly looked for in the subjects of our observation.[10] It may be sometimes requisite even for persons of cultivated judgment to bear in mind that the excellencies on which the highest reputation of great artists is founded, are to be sought, not so much in the beauty of parts as in the grand or tasteful arrangement of the combined work, in the harmonious relation of entire masses, and the grace of entire forms. These qualities, which suppose the labour of the mind because they have reference to a whole, have ever constituted the worthiest criterions of merit, in the practice of the arts.

The influence of conditions, similar to those in question, on every department of painting, may be traced in the works of great artists; for, from whatever cause the sense of vision is imperfectly addressed, the selection both of qualities in nature and of the technical means fitted to represent them, will be influenced accordingly. But, before pursuing the inquiry, it may be desirable to state the elementary facts connected with visible distinctness, since these, though familiar in reference to nature, are more complex in relation to works of art when seen under particular circumstances.

Causes of Distinctness in Nature.

They have been defined as follows: an object in Nature can only be apparent, by differing in its visible attributes from what surrounds it. The chief causes of this distinctness are—difference of position; of mere magnitude; of light and shade; of form, and of colour.

Accordingly these attributes constitute the general resources of the artist; but it will be for him to inquire which of those means are more especially calculated, under any extraordinary conditions, to produce a result which shall satisfy the eye. The nature of the resources themselves will require to be first considered.

Position.

The differences of Position exist either superficially or in depth. In basso-rilievo, for instance, they are (either in the horizontal or perpendicular sense) superficial. In painting, on the other hand, although they are superficial as regards the actual plane, they are chiefly sought and expressed in (apparent) depth; one of the great aims of this art being to conceal the flat surface and to represent space. Various practical and other considerations, presently to be noticed, tend, however, to limit this attribute in works executed under the conditions before supposed.

Magnitude.

The differences of Magnitude are either real, [12] as at one and the same distance; or may be only apparent, as the result of perspective. The subdivisions of the remaining causes of distinctness above enumerated will be referred to hereafter.

It must be evident that gradations in magnitude will be more full and varied when they comprehend, if only in a limited degree, the perspective diminution of forms. The great Italian artists seem to have considered this essential to distinguish painting, however severe in style, from basso-rilievo, in which the varieties of magnitude are real.[13] But in the works before referred to by Michael Angelo and Raphael, this perspective diminution of figures is confined to narrow limits; partly because the technical means may have been wanting to mark the relative distances of objects when the work was seen under the conditions required; but chiefly because figures much reduced in size cannot be consistently rendered expressive as actors or spectators. In the second compartment of the ceiling in the Sistine Chapel before mentioned, the effects of the perspective are expressed without restraint; but the indistinctness which was the consequence was probably among the causes that induced Michael Angelo to reduce the space in depth in the other compartments (as regards the figures) almost to the conditions of sculpture. In Raphael's Transfiguration the figures on the Mount are supposed to be distant with reference to those below; but, had they been so represented, they would have been devoid of meaning and importance: they are, therefore, by a judicious liberty, brought within that range of vision where expression, actoin, and form are cognizable.

On great exception is, however, not to be overlooked. Correggio, who was devoted to picturesque gradation under all circumstances, and sometimes at any sacrifice, adopted a different course. The perspective diminution in the cupolas at Parma (to say nothing of the objects being represented as if above the eye) is extreme; so that even the principal figures are altogether subservient to the expression of space. This was the chief object; but the grandeur of form and character which the nearer figures exhibit has been justly considered to place these works far above subsequent efforts of the kind, which, in the hands of the "machinists," soon degenerated to mere decoration.

If the criticisms which the frescoes in the Duomo at Parma called forth on their completion had any foundation, it may be inferred that the great distance at which the figures were seen rendered it impossible, in some cases, to discern the nicer gradations of light and shade which are essential to make perspective appearances intelligible. Such considerations must, at all events, operate to restrict foreshortening under similar circumstances. But here, again, it is to be remembered that painting is still distinguished from basso-rilievo. Examples of foreshortening are accordingly to be met with in works intended to be seen at a considerable distance, and in which the technical resources were very limited; for instance, in the Cartoons of Raphael. The amount of foreshortening which is introduced in them may be considered to be the just medium. Its effect in rounding and connecting the groups, and in giving a due impression of depth, is in accordance with the truth of those works in other respects, and (even in the tapestries, while in their unfaded state,) may have been quite compatible with distinctness.

The transition from this picturesque treatment, and still more from the unlimited depth of Correggio's compositions, to the flatness of a style resembling that of the early mosaics, is violent indeed.[14] In cases where a gold ground is introduced behind the figures, painting really approximates to basso-rilievo, and to the conditions of the Greek monochroms, without even the advantage of the figures and the ground being of the same quality. Under such circumstances, neither perspective nor foreshortening can be introduced to any extent. The varieties of "Position" are almost confined to one and the same plane, and consequently the relations of Magnitude are real. The splendour of the gilt field, though subdued by being roughened (for this is absolutely necessary), betrays the comparative dulness of the painted surface, and the final outlines on the ground (even making allowance for the gradation of real light on a large resplendent surface) are in danger of being too uniformly distinct, unless a darkening colour be partially added to the gold.

The union of absolute reality with imitation is rarely, if ever, satisfactory, as it is essential that the most important qualities should exhibit the nearest approach to nature. As an accompaniment to painting, there is, therefore, no defence for the gilt ground, when it appears as such. For the rest, it cannot be admitted, on the one hand, that art need be reduced to mediæval penury in order to agree with this hard condition, if adopted; nor on the other, that even the extreme restrictions in representation which it actually involves, considered in themselves, necessarily suppose incompleteness. An analogous style springs from those restrictions which, in adhering to its own resources, may still have its characteristic perfection. Wherever there is gradation, wherever a greater quality becomes conspicuous by comparison with the lesser (even if abstract lines alone be the means of representation), we recognize an important principle of art.

Light and Shade.

The influence of the general conditions before mentioned may next be considered with reference to Light and Shade. The varieties of this source of distinctness, though infinite, are, like those of Magnitude, merely differences of degree. The circumstances best calculated to display it will be again considered in examining its relation to colour.

The example of Correggio, which was adduced with reference to perspective and foreshortening, may also appear to recommend the employment of chiaro-scuro without restriction, under any circumstances; but this, his favourite attribute, was confined, in the instances of the cupolas at Parma as compared with his oil pictures, to a light scale, especially in the upper portions of those cupolas. It is evident that a dark effect would have ill suited both the places and the subjects.

The instances are rare, and not always successful, in which extensive surfaces, whether on canvas or on walls, have been covered with masses of low half light and deep shade. Such masses, as is well known, are especially ill adapted for fresco, on account of its tendency to reflect light only from its surface.[15] Among larger works of the kind, one of the best specimens is perhaps Raphael's fresco of the Deliverance of Peter from Prison. But, although successful in this instance (as far as the material permitted), the great artist did not resort to the same style on other occasions; on the contrary, in a subsequent work, the Incendio del Borgo, in which the subject might have justified a free use of chiaro-scuro, he did not employ it to any great extent. The reasons for employing it in the first instance appear to have been accidental.[16]

---

[10] See Reynolds, Fourth Discourse, and the Idler, No. 79.

[11] Position is added by Professor Whewell (Bridgewater Treatise, p. 130). Abstract magnitude may be allowed to form a separate class, as spheres (for example) of different sizes may be said to differ rather in magnitude than in form.

[12] The term 'real magnitude,' in painting, is restricted to such superficial dimensions as have a permanent relation to each other. Under this category may be classed proportion or symmetry.

[13] The style of basso-rilievo, as generally practised by the Italians, was not strictly in conformity with this definition, as they injudiciously endeavoured to represent in it the effects of perspective.

[14] The general predilection for all the modes of decoration which belong to the "renaissance" may be an excuse for here briefly reconsidering the claims of the gilt ground in itself, and with reference to peculiar conditions in representation.

[15] It may at first appear that all pictures reflect light from their mere surface, but this is not, strictly speaking, the case. One great charm of oil-painting is its power to reflect light from an internal surface, through superposed substances more or less diaphanous.

[16] Among the painters whose frescoes, previously executed on the walls of the same apartment, were destroyed to make room for the superior works of Raphael, Vasari mentions Pietro della Francesca. This artist was remarkable for his study of chiaro-scuro, and in that department of art had probably considerable influence on his contemporaries and successors. The subject of his work here referred to is unknown, but supposing it to have exhibited a striking effect of light (like his Vision of Constantine), it is quite conceivable that Raphael should aim at similar qualities in substituting for it a work of his own.—See Vasari, Vita di Piero della Francesca, and Vita di Raffaello, and Passavant,

Other examples, with all their excellence and even with the advantages of the richer method of oil painting, are more or less unsatisfactory, from causes independent of the materials. The night scene of the Martyrdom of S. Lorenzo, by Titian, is heavy in its effect.[17] Of Tintoret's darker works it would be unfair to speak, as the shadows have too often become black, either by time or by some mischievous technical process.[18] The celebrated Nightwatch, as it is called, by Rembrandt, is generally acknowledged to be overloaded with shade;[19] and the Santa Petronilla of Guercino is a monument of great, but in that instance, misdirected powers. These are the most remarkable examples of dark pictures on a colossal scale. The Last Judgment, by Michael Angelo, now obscured by time and the smoke of candles, must always have had a solemn effect from the depth of the flesh colour (a treatment which may be traced to the influence of Sebastiao del Piombo), but there are no masses of deep shade. As the work is in fresco, mere blackness would have been the result had such been introduced.

The unfitness of masses of extreme shade in paintings of considerable dimensions (without reference to the material) is explained by the fact that the distance at which the work requires to be viewed tends to obliterate the fainter lights and reflections in such masses, thus changing depth to flat obscurity.[20] In subjects which require gloom, it is still essential that the indistinctness should be felt to be intentional, and not to be the result of such distance. The size of the work should admit of the spectator being so placed as to see all that the artist intended to be seen. The 'Notte' of Correggio can be thus perfectly seen at the distance which its size requires; but, in looking at the 'Night-watch' of Rembrandt, under like conditions, the spectator is presently compelled to draw nearer. The conclusion is, that the amount of darkness in the latter is too great for its size, and on the other hand, that moderate dimensions may render such a treatment, if suitable on other accounts, not only unobjectionable, but desirable. The finer gradations of low tones can be appreciated only on near inspection. Subjects, the intended place of a work, or other circumstances, independently of dimensions,[21] may interfere with this consideration, but it is not the less true that the scarcity of light which would be inappropriate in a collossal picture is quite compatible with the physical conditions here referred to, in regard to works of smaller size.

The Venetian painters, as compared with those of the schools of Lombardy and the Netherlands, appear with few exceptions, to have systematically avoided a preponderance of deep shade.[22] This must be understood as meaning no more than that their treatment of light and shade was calculated for works of large dimensions. From the first, the great Venetian colourists were accustomed to execute frescoes in the open air, and sometimes in situations where the distance at which the paintings could be viewed was far greater than their size required.[23] The elements of distinctness and breadth were thus familiar to them, and, it must be confessed, were sometimes transferred to works which, admitting of near inspection, might have suggested a different treatment.

"Venetian shade," which, notwithstanding the occasional darings of Tintoret in more capricious directions, is characteristic of the school, and which the praise of Agostino Carracci has rendered proverbial, is the worthy auxiliary of composition on an extensive scale, and is fitted, by combining distinctness with breadth, to correct the uncertainty which arises from distance or want of light; it is calculated to give place and meaning to form, to display the remembered attributes of colour, and, while it renders force of local hues indispensable, to combine solidity with clearness. The view which the Venetian artists took of nature was consistent with the ordinary destination of their works.

They appear, in most cases, to have assumed that the objects to be represented were seen by the diffused light of the atmosphere, as opposed to the case where the light is derived from a particular source. The practical result of this is that intense shadow is smaller in quantity, and that the picture is chiefly composed of gradations of half and reflected light; brightness thus marking projection[24] and obscurity, depth. It has often been said that in Venetian pictures (more constantly than in those of other schools) the foreground objects are, relatively to their hues, the lightest; the retiring ones being lower in tone. The diminution of the force of shade in remoter masses, the introduction of accidental cast shadows, of dark hues near, and bright objects, buildings, or sky in the background and distance, may conceal without altering the artifice. This system of effect in Venetian pictures corresponds with that of general nature, and, like that, is too familiar to be remarked;[25] but its apparent simplicity conceals a scale of gradation the fulness of which may be more difficult to compass than the pronounced effects of confined light. Hence the unaffected character of "Venetian shade; and hence, at the same time, its powers in marking the essentials of form, while it leaves the general idea of colour unimpaired.[26]

If the artists of the northern schools may be accused of sometimes employing the effects of a confined light for scenes supposed to take place under the broad atmosphere, the Italian painters (for the practice was not confined to the Venetians) must be acknowledged to have as often adopted the opposite course; viz., that of representing scenes in interiors as if seen under a diffused light. They appear to have thought that objects so illumined are more intelligible in pictures requiring to be seen at a distance (as was the case with altar-pieces), and that such effects are in themselves more large and beautiful.

The effects themselves, though derived from the observation of nature in the open air, were produced by various artifices in Italian painting-rooms. The most common (still in use) was that of employing oiled paper instead of, or before, the glass of the window. A Madonna of Raphael's takes its name (dell' Impannata) from the oiled paper window, probably that of the painter's studio, in the background. Leonardo da Vinci, who is careful to distinguish between *ombra*, "the diminution of light," and *tenebre*, "the privation of light,"[27] frequently recommends attention to the effects above described, and speaks of the modes (probably then common) of producing them. He remarks that objects seen in a diffused light are more beautiful than when lighted from a confined source, and that when represented in pictures they are more intelligible at a distance.[28] He recommends the mitigated light of evening, or of cloudy weather, in preference to the direct light of the sun, in order that shadows may have due gradation.[29] He observes, that not only the equal force but the hardness of the boundaries of such shadows, if imitated in pictures, tends to render objects confused when seen at a distance.[30] The latter appearances (hard-edged shadows), he adds, "are especially condemned by painters." His contrivance for securing the larger effects which he recommends, is to stretch a linen awning across an open court. In one instance he suggests that the walls should be blackened; in another, that they should be painted flesh colour, and be altogether open to the sky. Elsewhere he mentions the "Impannata" (for ordinary lights);[31] and again proposes an expedient, similar in its results, for softening the edges and varying the strength of shadows by lamp light.

Neither Leonardo nor the Venetians were ever deficient in force; but the latter in making the fullest use of the principle thus dwelt on by the Florentine compensated for their comparatively small amount of '*tenebre*,' as nature compensates for it, viz., by intense local colours. This resource never led them to neglect the study of chiaro-scuro on their own large, and, it may be added, difficult principles, but only served to conceal its artifice. So intent were they on securing relief, as well as breadth of general effect by means of light and shade, that they frequently defined the perspective balance of light and shade. The expression is, however, usual and allowable, and the Venetians themselves were not more accurate; their technical term for 'lighting up' with the brush, was 'colmizare,' from colmo, summit, most prominent point. See Boschini, la Carta del Navegar Pitoresco, Ven. 1660, p. 288.—Light in hollows, or rather slight concavities (called by the French artists 'sillons lumineux'), is hardly an exception. In some cases, for example in plaster casts, the appearance is assisted by a difference of tint.

Rafael von Urbino, Leipzig, 1839, vol. i., pp. 192, 434-5. Of Raphael's fresco Wilkie observes, "the St. Peter in Prison, finely as it is arranged, is black and colourless." See Thoughts on the Relative Value of Fresco and Oil-painting, by B. R. Haydon, London, 1842, p. 31.

17 Compare Burnet, Practical Hints on Light and Shade in Painting, London, 1838, p. 4

18 This is the case even with some of the fine works in the Scuola di S. Rocco, in Venice.

19 See Reynolds, Journey to Flanders and Holland; and Kugler, Handbuch der Geschichte der Malerei, vol. ii., p. 178.

20 It has been before observed that although an object may be increased in magnitude to any extent, in proportion to its distance, and in order to accommodate the spectator, yet its force of light and shade cannot be increased beyond a certain point, and that point is supposed to be already attained in pictures requiring to be seen near. Not only is force not to be increased in proportion as distance increases, it is unavoidably diminished by it, in consequence of interposed air.

21 In modern exhibitions where no space is lost, and where, consequently, the eye is influenced by the effect of the mass, an entire wall approaches the conditions of a large picture. Hence the amount of light in the component parts of this decoration is required to be great. A subdued window light may also have its influence.

22 The relative amount of light, shade, and half-light, in the works of the colourists, as given by Reynolds, is well known, and it will be remembered that he made his observations chiefly from large pictures. See notes to Du Fresnoy.

23 The circumstance of Titian and Giorgione painting on the façade of the Fondaco de' Tedeschi is well known. (The remains of some of the figures there painted by them, now quite obliterated, were etched by Zanetti in the last century: two were engraved by Giacomo Piccino at an earlier period.) Examples of a similar kind by Pordenone and other artists still exist in Venice and in various towns of Friuli.

24 The "central light of a globe" (Fuseli, Second Lecture) would not be the most favourable, with reference to the spectator, for displaying the object, or for ensuring a

25 Thus in some of the vast compositions of Paul Veronese, although every figure keeps its place, the artifice of the gradations of light escapes observation, as it does in nature. The Venetians seem to have considered that the office of light is rather to exhibit the qualities of material objects than to display itself. Effects of light are generally confined in their works to the distance, where, as regards figures, form and colour are no longer important.

26 Zanetti (Della Pittura Veneziana. Ven. 1771, p. 99) justly observes, that in the heads of Titian the broader shades do not approach the force of the shadows under the features. Compare Barry, Works, vol. ii., pp. 45, 49, 51.

27 Trattato della Pittura. Roma, 1817, p. 274.

28 Ib., p. 357. "Distinctness of local colour and precision of outline, are the peculiar character of objects placed out of the effect of strong (sun) light." Burnet, Practical Hints on Colour in Painting, London, 1843, p. 18.

29 Ib., p. 336. When Reynolds, speaking of Vandyck's St. Sebastian, now at Munich, observes, that it is painted in his first manner (when he imitated Rubens and Titian), which "supposes the sun in the room," he can only mean the reflected or diffused rays, not the direct light, of the sun. The picture which he describes, sufficiently proves that the latter effect is not imitated. In some of Rubens's works, however, the effect approaches that of the direct sun-light.

30 Ib., p. 71. He elsewhere observes that objects represented with masses of intense shade, instead of appearing distinct at a distance, appear 'tinted.' Dark shades under such circumstances, (having no longer the quality of depth,) assume the effect of neutral colours. Ib. 248.—The equal force of shade in many of Guercino's pictures might exemplify the justness of Leonardo's remarks on that point, but the works of Paul Veronese often exhibit a modified and agreeable use of cast shadows. In preserving their comparative sharpness he reduces their force, so as to give the impression of a mitigated sunlight.

31 Ib, p. 70. The Impannata may mean cloth as well as oiled paper. Most of these contrivances, although not without interest as connected with the Italian practice of art, are obviously fit only for a bright climate; but the observation of nature and the technical expedients which were then habitual to the artists had also relation to the due effect of works in vast localities. It was the more essential to preserve the general appearances of nature in colour and light and shade, because the forms in votive altar-pieces were often individual.

depth of their compositions and the place of each figure by means of chiaro-scuro alone. Tintoret was in the habit of placing large paintings thus studied, but before any colour was added, in the situation which they were ultimately to occupy, in order to judge of their effect and keeping.[32] The habits of the Venetian and other colourists in thus occasionally preparing their pictures may be adverted to hereafter in an inquiry into the early methods of oil painting.

Form.

The treatment of form[33] which is applicable to pictures intended to be seen at some distance, has been already partly considered in reference to certain works by the great Italian masters. It is further to be observed that the means employed to insure distinctness in this department of painting may, without due caution, tend to confound its style with that of sculpture. It is obvious that forms are most intelligible when they are freest from peculiarities; therefore when in any extreme case it may be necessary to counteract indistinctness, it would appear that a generalized treatment is indispensable. But in sculpture this intelligible appearance can only be produced by means of form; whereas in painting, colour (which in like manner admits of a generalized treatment) can powerfully contribute to such a result. The representation of figures of unusually colossal dimensions need not be supposed.[34]

The grandest examples of painted figures on a colossal scale—the Prophets and Sibyls, by Michael Angelo, in the ceiling of the Sistine Chapel—do not exceed 15 feet. In such representations, as those celebrated works prove, painting can still maintain its complete independence as compared with the sister art. The figures in question though, strictly speaking, abstract conceptions, have the force of character of real beings. It is also to be observed that in the subjects by Raphael in the Vatican, the treatment of form does not approach the conditions of sculpture; as a proof of this it is to be remarked that the portraits introduced in those compositions do not appear incongruous. Thus, although it may be admitted that the most intelligible forms are those which are freest from accident, and that such forms must be best calculated for works intended to be viewed at some distance, yet it appears that, even in the most limited styles of painting, the degree of generalization which is necessary, with a view merely to distinctness, need not be confounded with the more abstract beauty of sculpture. If, again, the subject should require an approximation to the latter, the full display of the proper attributes of painting, which may be compatible with the existing external conditions, is indispensable. Thus colour enables painting to vary its forms and characters consistently with the intelligible effect at present assumed to be requisite, and is, therefore, the department of this art in which an abstract treatment can be best adopted consistently with its independence of sculpture. In general, the region of the 'ideal' (the largest view of nature) is more safely approached by means of attributes which are exclusively characteristic of the art; the poetic impressions of each mode of representation are then of a distinct order.

But to whatever extent characteristic details in living forms would be admissible in the higher styles of painting, the causes referred to would unquestionably operate to limit the introduction of inanimate objects and accessories, and would influence their treatment.

It is unnecessary to repeat what has been before observed on this subject; a consideration in connection with it is however not to be overlooked. Next to the great requisite that each mode of representation should rest chiefly on its own resources, the works of great artists teach the principle that the noblest object of imitation should always be the nearest to nature. In sculpture, and in painting when employed to represent human actors, this noblest object is life, with its attributes of action and thought. When the field for displaying this quality is even confined to a head, it is still required that no circumstance represented should surpass it in completeness of imitation. Rarely in the works of the best Greek sculptors or in those of the excellent modern painters does an inanimate object exceed in truth the representation of the living surface. The contrivances with a view to insure this insubordination are, necessarily, most daring in sculpture, in which certain qualities are in danger of being confounded with reality. It will generally be found that the employment of conventional methods (as opposed to the more direct truth of representation) increases in proportion as objects are easily imitable, and, consequently, in danger of interfering with the higher aim. Thus, to take an extreme case, rocks, which in marble are sometimes made identical with nature (thereby betraying the incompleteness of the art), are generally conventional in fine sculpture. Witness the basso-rilievo of Perseus and Andromeda, and various examples in statues where rocks form the support of the figure. In order to reduce what would easily amount to literal reality to the conditions of art, the substance in this instance is, so to speak, uncharacterized.[35]

In painting, the instances are rare in which such absolute identity with nature is possible.[36] The representation of a flat surface, of coloured patterns, and painted objects, are almost the only cases; and far less artifice is sufficient to reduce them to the conditions of imitation. But as regards the necessity of superior truth in the living surface, compared with all other objects, the principle is the same as in sculpture. The contrivances to insure this superiority, without violating nature or betraying the artifice, are among the distinguishing merits of fine pictures. Inanimate objects may often form a considerable part of a composition, and therefore cannot be neglected; the colourists, as has been often observed, have contrived to give interest to such subordinate materials, by dwelling on a portion only of the qualities of the substance, and selecting such qualities, with a view to give value to the flesh, as if they were merely forced into notice by the existing comparison. In the instances in sculpture where absolute identity with nature is to be guarded against, it appears that the substance requires to be in a great measure uncharacterized; in the cases now referred to, the objects are only partially characterized. The principle is, however, the same in both methods; art is permitted, or rather required, to be apparent, in proportion as nature is in danger of being too nearly approached.

Colour.

The general treatment of colour which is calculated to assist distinctness, cannot be better exemplified than by the practice of the Venetian school. It may be first necessary to recur to the elementary facts before noticed.

It was observed, that an object in nature can only be apparent by differing in its visible attributes from what surrounds it; its distinctness in a word, supposes the presence of some or more qualities which are wanting elsewhere. Thus, the imitation of the appearances of nature is especially conversant with differences; it is opposed to (absolute) equality, and is founded on Gradation and Contrast.

The first, a difference of degree, comprehends Magnitude and Light-and-shade. By means of their varieties,—perspective, depth, relief, and roundness, in other words, substance and space are represented.[37]

The second, a difference of kind, comprehends Form and Colour; by means of which physical and even moral characteristics are expressed. Position, as an incommunicable attribute, belongs to the same category.

The possible interchange of these two sources of variety (as regards their effects), is constantly exemplified in nature and in art. An abrupt difference of degree amounts, practically, to contrast; the full scale of differences of kind involves gradation. Contrast itself is imperfect without the auxiliary element, by means of which equality even of antagonism is prevented and one impression predominates.

The great office of colour is then to distinguish. Each object in nature has its own hue as well as its own form, and hence the origin of the painters' term 'local colour.' This characteristic difference becomes more strikingly conspicuous at a moderate distance, when objects are seen as wholes, and in their largest relations and oppositions; for in a nearer view, the eye is necessarily more confined to their component varieties.

On the contrary, light and shade, being common to all substances, and presenting differences of degree only, is less powerful at a distance as a means of distinguishing objects from each other; but in a nearer view, when its infinite gradations are appreciable, it is sufficient, without the addition of colour, to express the relative position even of contiguous objects, as well as of their component parts.

Accordingly, while chiaro-scuro in all its richness and delicacy is indispensable in pictures that are to be viewed near, colour is no less desirable in colossal works, or in such as can only be seen at a distance.

When employed under such circumstances by the Venetians, its larger appearance, above described, was selected in preference. The 'local hue,' displayed and influenced as it must be by what surrounds it, was especially dwelt on by them as a means of insuring distinctness. The union of due variety (a union which, in all cases, taste alone can define), with this integrity of local tint, has been considered to be one of the great excellencies of Titian, who, nevertheless, changed his style—accordingly as his works were to be seen in vast halls and churches, or in ordinary apartments—from the most daring force of local colour to the fuller har-

32 See the introductory "Breve Instruzione" in Boschini's Ricche Minere della Pittura Veneziana. Ven. 1674. Tintoret and Bassan, the darkest of the Venetian painters, are still examples, in their main aim, of the principles of the school. Their study of chiaro-scuro was, however, more derived from interior and even from nocturnal effects. Both were in the habit of using small models illumined artificially; less (in Bassan's case) for the sake of noting accidents of light than for the purpose of observing its gradation on objects more or less removed from its source. Boschini remarks that, with the Venetian painters, "every room answered the purpose of the open air;" meaning that they could give the effects of open light, either from contrivances like those above mentioned, or from observation and practice, wherever they might be placed while painting. See La Carta del Navegar, &c., pp. 72, 137, &c.; and Ridolfi, Delle Maraviglie dell' Arte. Ven. 1648, vol. 2, p. 65.

33 The 'differences of form' (almost another word for the visible world) can only be classed in their abstract elements, viz., as mere lines. These may vary in position, direction, and extent. Lines are said to be massed by extension; they may be contrasted in their direction, and are repeated by parallelism.

34 It is remarkable that the only ancient example on record of painting thus employed (by command of Nero) was a portrait. The figure, painted on cloth, measured more than 100 feet. The extreme modern instance, a consequence of the folly of the artist rather than of his employers, is the cupola of the cathedral at Florence, begun by Vasari, and finished by Zuccaro. One of the figures, if erect, would be about 50 feet. See Pliny, l. 35, c. 7, and Kugler, ib., p. 385.

35 The same liberty is observable in sculptured armour as treated by the ancients; sharpness is avoided, and the polish does not surpass, sometimes does not equal, that of the flesh. In like manner steps, or any portions of architecture, are irregular. On a similar principle, probably, the inscriptions on the finest antique medals are rudely formed; for it cannot be supposed that the artists who could treat the figures and heads so exquisitely could have been at a loss to execute mechanical details with precision.

36 Mere form is, or may be such an instance; but as, in painting, the imitation of substance and space is more or less incomplete, the literal truth of the mere outline, when present, is in no danger of confounding the work with nature.

37 The differences of degree which all visible qualities and their 'forms' may exhibit, are perhaps to be resolved into modifications or abstractions of Magnitude and Light, the representatives of mere gradation. Position comprehends augmenting or diminishing intervals. Colour, degrees of warmth and coldness, transparency and opacity, purity and commixture, intensity and lightness. The boundaries of substance, degrees of sharpness and softness in their relief. Mere lines, degrees of extent.

mony of broken tints observable in near objects. The abstract treatment is more exclusively the style of Giorgione;[88] by him it was first carried to its utmost limits, and was sometimes, perhaps, too indiscriminately employed, without reference to dimensions and distance.

The general style in question has been well defined (making some allowance for the stress on its leading attribute), by Mengs, whose observations on this subject are adopted by Fuseli. These writers observe, that "the breadth of local tint" referred to was attained by taking the predominant quality in a colour for the only quality; by painting a complexion, for instance, "which abounded in low tones, entirely in such tones, and by generalizing, in the opposite sense, another near it, of a lighter character; by painting a carnation, abounding in ruddier tints, entirely in such tints, and by depriving of all such tints its neighbour that had few." The aim being distinctness, qualities that were common to several objects were exaggerated in the one that had most, and comparatively suppressed in the others. The same principle, derived from the observation of nature in her largest aspects, was extended to every visible 'difference of kind.' The soft elasticity of flesh (ever a great object of the colourists) was, if possible, more than usually dwelt on in the neighbourhood of substances which, either from their general nature, or from the character which they were made to assume, were calculated to give it value; for not only inflexible and sharp substances, but sometimes drapery was made to serve this end, independently of colour, by abrupt folds, and crisply-painted lights. The shine on the surface of skin was omitted generally, but most so when polished surfaces were near it; while these were allowed to reflect light like mirrors. Gradation supported the comprehensive system; colours were varied not merely in their hues, but in their mass, degrees of brilliancy, and other qualities. Vivid colours were therefore few, and thus the end even of distinctness was harmony. Lastly, the same breadth which obliterated differences in detail, obliterated them also, to a certain extent, and according to the scheme of effect, in opposing masses; thus was insured, yet without the appearance of artifice, that plenitude of impression which the eye requires.

It must be apparent that not all the contrivances above adverted to would be applicable in works intended for a near view. The emphasis on local colours, for example, is in them no longer necessary to insure distinctness, and, moreover, might supersede peculiar beauties; yet the example of the colourists may show how much of this greatness of style may be sometimes infused with effect, even into narrow dimensions.

The system of the Venetians comprehended other methods, which may be considered, in a great measure, peculiar to the school, and which were equally calculated to counteract indistinctness. Among the means adopted by them for securing such a result, their treatment of certain colours, as affected by light and shade, merits attention. The artifice was, as usual, derived from the observation of nature in the open air. At that distance where the entire object acquires full force of local hue by the opposition of what surrounds it, the focus (if the expression may be allowed) of its colour will vary, according to the real depth or lightness of its tone. That focus will sometimes be in the illumined parts, sometimes in the 'diminished light,' which we call shadow, accordingly as the particular hue requires more or less light to display it. All forcible colours are most apparent in their brightest parts, even when the light is powerful. All delicate colours are impaired, and sometimes nearly effaced, in strong light, and are then most apparent in their shadowed portions, where they become deepened by means of reflection. But, let the same object be transferred from the open air to a confined or less vivid light, and the effect is reversed; the shadows become dark and, generally, neutral, and the colour is displayed in the light only. The larger system, though adopted by the Venetian painters from habit and predilection almost indiscriminately, was especially employed by them in works intended to be seen at some distance. Fulness and breadth were in such cases indispensable; and by a judicious use of the effects in question, they increased colour without sensibly diminishing light. The extreme and exaggerated instances of this treatment were generally in situations which admitted only of a distant view. The abuse of the style was indeed sufficiently guarded against by the principle, seldom forgotten in pictures of the school, that colours require in all cases te be more or less subdued and broken, for the sake of general harmony. This object was even partly attained by the practice referred to: the ordinary (and most commonly applicable) principle is, that colours should be neutralized in shade; but, in the excepted cases above described, where they are most displayed in reflection, they require to be, and are in nature, in a great measure suppressed and neutralized in their illumined parts. This is assisted by the colour of the light, which, although assumed to be nearly white, appears comparatively warm on cold light colours, and the contrary on warm ones. Harmony, therefore, was also promoted by this method.

The influence of certain conditions on the leading departments of painting has now been considered. In this examination, the effects of distance on objects in nature, and also on their painted representations, have been adverted to. The two are not to be confounded; but the question respecting their relation presents no difficulty in a practical view. It is quite certain that the most distinct and easily recognized appearances are best adapted for pictures requiring to be viewed at some distance. The machinery of art is selected accordingly. The point, or degree of remoteness in nature, where colour is most distinct (that is, most large and powerful), is not the point where form is so; for figures must, even at such a moderate distance, be considerably reduced by perspective. It is not the point where outline is so; for, in ordinary cases, outlines are soon blunted by distance. The artificial combination of the breadth of general appearances with due distinctness of form is not dictated merely by the necessities of particular conditions, nor is it confined to particular schools; it is a liberty which all have taken, and is one great source of what is called ideal beauty; for the "enchantment" which "distance lends" is thus combined with precision.

Such are among the expedients adopted by the great painters, in order to counteract indistinctness. The considerations which weighed with them may not only be applicable in similar cases, but may show the necessity of employing the resources of art generally for the same great object, viz., that of satisfying the eye in order to affect the mind. The selection and adaptation of particular resources, with reference to particular conditions; the view of nature, and the use of art which may be calculated for different circumstances; have all one and the same immediate end. But the test of a due application and economy of the means fitted for such various cases will be, that their conventions should be unmarked, and that art and its contrivances should be forgotten in their ultimate impression.

It remains to observe that if the qualities in various departments of art above considered are fit for works executed under the conditions of dimensions, situation, and light, before enumerated, then fresco-painting (supposing due practice in the method) is calculated to display those qualities. For example, its unfitness to represent large masses of shade is not objectionable because such a treatment is not desirable according to the above conditions. In colour, the stress on local hues and the integrity of masses (not incompatible with harmony and due gradation) which have been employed by great painters in works chiefly intended to be seen at a distance, are quite consistent with the resources of fresco; while in form, the distinctness and simplicity which appear to be desirable are especially adapted for its means.

It has been already observed that the Venetian painters were in a great measure indebted to the practice of fresco-painting for that comprehensive style of colouring which treats objects and their surrounding accompaniments in their largest relations. The early rivalry in fresco of Titian and Giorgione, on the exterior of an edifice near the Rialto, in Venice, has been already noticed. Their works, chiefly consisting of single figures, were there numerous. Besides that building, the following houses in Venice were painted on the outside by Giorgione. A façade near Santa Maria Zobenico, another near S. Vitale, two others in the same neighbourhood, the Casa Soranza, near S. Paolo, his own house, near S. Silvestro, and the Casa Grimani, near S. Ermacora. The houses painted fresco on the exterior, by Tintoret, Paul Veronese, Zelotti, Pordenone, Schiavone, Salviati, and others, would form, in each instance, a longer list.

The modern revivals of fresco on the continent appear to have chiefly had the Florentine style in view; it may remain for the English artist to engraft on this and on the maturer Roman taste the Venetian practice. It was formerly a question whether Venetian colour was compatible with the grandest style of painting, but that prejudice may be considered extinct. Unfortunately, the best of the Venetian frescoes were painted in the open air, and most of them live only in description. The frescos of Pordenone, in Piacenza, and two of Raphael's (the mass of Bolsena and the Heliodorus) in the Vatican, are probably among the best examples of colour in this method now existing. The last mentioned, according to every hypothesis, were painted under the influence of an artist of the Venetian school. Their date corresponds with the arrival in Rome of Sebastian del Piombo, whose powerful style of colouring may have been emulated by Raphael; and Morto da Feltre appears to have been employed on them. Both were of the school of Giorgione.

Opposite conditions to those first enumerated.

The resources which have been here dwelt on are to be considered as applicable, in many cases, to one class of conditions only. The different means and aims, which entirely opposite circumstances might require or suggest, have been already occasionally noticed, and may now be recapitulated; with a view to obviate the partial conclusions which a somewhat exclusive view might appear to involve.

The external conditions, relating to light, situation, dimensions and methods, at first proposed for consideration, were called "*causes of indistinctness.*"

Let those conditions now be reversed. Let the dimensions of the picture and of the objects represented[89] be such that the spectator may contemplate the work at the distance of two or three feet (or whatever distance may be requisite to insure most distinct vision). Let the picture be opposite the eye. Let the light be altogether adapted. And let the means of representation be oil-painting, the resources of which are all-sufficient for complete imitation.

88 From the scarcity of the works of this great artist, Mengs hesitates to believe that he was the inventor of the deep and glowing style of colour which his Italian eulogists attribute to him; the latter are, however, safer guides. The early pictures of Titian, and the works of Sebastian del Piombo, especially his portraits, attest the influence of Giorgione.

89 A small picture may contain portions of large or even colossal figures, in which case the distance of the spectator from the work is no longer regulated by the dimensions of the frame, but by those of the objects represented. A distance corresponding with the average limits of most distinct vision is here purposely assumed.

Consequences in style.

On the former principle these conditions may be called *causes of distinctness.* They are compatible with, and therefore invite the introduction of, all (agreeable) qualities which in nature can be appreciated only by near inspection. Such qualities now become characteristic of the style, for the above external conditions—involving a just adaptation of technical means, not only permit, but require that every excellence which was inadmissable or unattainable under other circumstances, should now assert its claims. On the same principle, provided the work can be seen with perfect convenience, the means before employed to counteract indistinctness may now be thrown aside—not merely as unnecessary, but because they may interfere with the complete representation of a new order of facts. These appear to be the general principles of the school of the Netherlands, especially in subjects of figures. The leading qualities which are the result may be thus enumerated.

The assumed near point of view, permits and invites the introduction of a large proportion of low tones, all the gradations of which are now appreciable. These are rendered luminous by intenser but still transparent shades and acquire richness from the scarcity of strong light. Accidents of light—not excepting sun-light, are admissable, and often even desirable; they are no longer in danger of interfering with the intelligible representation of form and colour, and may be necessary to give that degree of interest which the subject cannot always command.

The employment of perspective and foreshortening is unrestricted; the last appears to be avoided in no case in which it would be intelligible in nature. Varieties in the place or "position" of objects are especially sought in depth.

An assemblage of broken, harmonious, and nameless hues is next to be remarked, among which the slightest approach to what is called positive colour is effective. This sobriety has nevertheless the effect (with occasional exceptions in the school) of giving a predominant impression of warmth, and of thus vindicating the general character of colour as distinguished from mere chiaro-scuro.

The varieties of sharpness and softness in the boundaries of forms and in their internal markings, must ever exist where there is a background and light and shade; the relation between them is therefore the same as on a larger scale, but the extreme diminution of figures in cabinet pictures generally induces utmost precision in the sharper parts. Lastly, where each object may be discerned without difficulty, yet by means of delicate gradations of light can keep its place and thus be easily intelligible, details may be copious and forms altogether individual. Thus is again furnished the link between appropriate technical means and the choice of incidents, and hence the predilection with the masters of this style for familiar and even trivial circumstances. On this last point it is however to be remarked, that where so much judgment and well-directed skill are present in the work, our respect is commanded even by the unpretending nature of the subjects; and where these are not offensive, they can hardly be said to diminish the satisfaction of the spectator who is alive to the higher objects of the artist. A greater danger to which this style is liable (in finished pictures where human actors form the subject), is that of making the accessories and inanimate objects truer to nature than the representation of life. This defect is, however, avoided, even in elaborate works, by the best masters of the school.

To conclude; the resources, whether abundant or limited, of the imitative arts are, in relation to nature, necessarily incomplete; but it appears that, in the best examples, the very means employed to compensate for their incompleteness are, in each case, the source of a characteristic perfection and the foundation of a specific style. As it is with the arts compared with each other, so it is with the various applications of a given art; the methods employed to correct the incompleteness or indistinctness which may be the result of particular conditions are, in the works of the great masters, the cause of excellences not attainable, to the same extent, by any other means. In the instance last mentioned—the school of the Netherlands—it is apparent that no indirect contrivances or conventions are necessary to counteract the effects of indistinctness; on the contrary, all that would be indistinct in other modes of representation is here admissible with scarcely any restriction. The incompleteness overcome, which is here the cause of peculiar attractions, therefore resides solely in the conditions and imperfections in the art itself, which, on near inspection, are in greater danger of being remembered. These are a flat surface and material pigments; and these are precisely the circumstances which, by the skill of the artists in the works referred to, are forgotten by the spectator. The consequences of the difficulty overcome are, as usual, among the characteristic perfections of the style.

The two extremes of "external conditions" and their corresponding styles have been here chiefly considered. The intermediate modes and combinations are innumerable; but in considering the question to what extent and in what respects the extremes of style may be compatible with each other, it will appear, on a review of what has been stated, that the grander view of nature and of the technical means fitted to represent it may be satisfactory in reduced dimensions in the department of form rather than in those of colour and light-and-shade; and that, on the other hand, the combination of the usual characteristics of small pictures with large dimensions, if possible in light-and-shade and colour, is impossible in form. The last-named attribute being the indispensable medium of the artists' conceptions, it follows that the interchange of subjects fitted respectively for the two styles can only be admissible as regards the treatment of grand subjects in small dimensions, and even then at the risk of the conventions of the grander style being too apparent.

ON THE QUALITY OF LIME PRESERVED FOR FRESCO PAINTING.

By Professor Faraday.

Led by the statement that the keeping of the lime in a slaked condition for a couple of years is a great advantage to it, I took some specimens from the stores which have been so laid up at the Houses of Parliament, for the purpose of examining them in this respect. It appears to me that this lime (which is in a state of paste) is in a very soft and smooth condition in comparision with what would probably be the condition of the lime recently slaked; a condition which seems to be due to its thorough disintegration as a mass, and its separation particle from particle. On analysing it I found that it contained a little carbonic acid, but not much; for in 100 parts of the dry substance there were but 5¼ parts of carbonic acid; these 100 parts, therefore, would contain 88 parts of quick or uncarbonated lime, and 12 parts of carbonated lime, which considering the processes of burning, carrying, slaking, &c., that it had to go through, and the necessary time of exposure to air before it was laid up in store, is a very small proportion. I do not believe that the lime, which is more than 4 inches in, from the exterior, has received any portion of carbonic acid during the two years of its inhumation.

In respect of the effect of keeping lime for a time, I am led to think, without however having formed any strong opinion on the subject, that the benefit is due to the fine texture which it gradually acquires; and as there is no doubt that if two surfaces were prepared, the one with fine sand and lime in particles comparatively coarse, and the other with the same kind of sand and lime in particles comparatively far more perfectly divided, that these two would act very differently both as to the access of carbonic acid from the atmosphere and the transition of lime dissolved in the moisture of the mass from the interior towards the surface; so there is every reason to expect that there would be a difference in the degree of action upon the colours at that surface, and also in the time at which that action would come to a close.

WOODCROFT'S SCREW PROPELLER.

WOODCROFT *v.* SMITH.

The Judicial Committee of the Privy Council met March 11, Lord Brougham, Dr. Lushington, the Duke of Buccleuch, and Lord Cottenham being the members present, to decide upon an application for the extension of his patent made by Mr. Woodcroft, the inventor of a particular form of screw propeller.

Mr. Jervis appeared to support the application; and the Solicitor-General, besides watching the proceedings on behalf of the Crown, appeared in opposition on behalf of Mr. Smith and the Ship Propelling Company, who have adopted his patent.

Mr. Jervis, in stating the case for his client, said, that the invention for which a renewal of his patent right to which application was now made, differed entirely from every other kind of propelling screw in existence. It was formed on the principle of a spiral, represented by the winding of a circular line round a cylinder. The patent was granted in March 1832, and he now applied to their Lordships for an extension. The history of patents for screw propellers (of which he enumerated the advantages) was as follows:—In 1794 Mr. Littleton had taken out the first patent for an invention of that kind, which he proposed working by hand with the capstan, and which was to be either partially or totally immersed in the water, according to circumstances. The next patent for a screw was Mr. Shorter's, taken out in July, 1800. It consisted of the two vanes of a smoke-jack, not submerged, and adapting itself to the movement of the vessel by a universal joint. In 1815 Mr. Trevethic proposed the Archimedean or fixed screw, working in a cylinder. In July 1816, Mr. Millington got a patent for the application of a smoke jack placed beyond the rudder, and worked with the universal joint. In February, 1825, Mr. Perkins patented an invention for having two vanes, working in opposite directions, placed at the side of the rudder. In 1829, Mr. Commeraux patented a perfect one-turn screw fixed parallel to the keel, and held by a stage erected for that purpose beyond the rudder. The date of Mr. Woodcroft's patent was in March, 1832, and the difference between his spiral and the screw of his predecessors was, that whereas the former consisted of a straight line coiled round a cylinder, the latter was made by a circular line so coiled round. The effect of this invention has been to economize the power of the engine, to destroy the vibration, and to produce a greater speed with fewer revolutions. If a spiral worm was coiled round a cylinder, the angle given thereby would decrease, and the "pitch" therefore increased throughout the length of the shaft. Mr. Woodcroft, in his specification, proposed applying this "spiral" in different parts of the ship, and amongst other places before the rudder-post, by cutting away a part of the hull. Mr. Smith's patent, which was on the application of a perfect screw of one turn placed in the centre of the dead wood, was taken out in May, 1836. In 1837 Mr. Ericson patented an invention which differed from that of Mr. Perkins only in being submerged and placed behind the rudder. In 1838, it being ascertained that a perfect screw of one or two turns could not be worked by the obstruction of the back water, Mr. Lowe took out a patent for cutting the screw into arms or blades, which worked between the rudder and the stern-post. In April, 1839, Mr. Smith entered a memorandum of disclaimer, by which he stated that he found that a screw of two turns would not do, that the true principle was to take two half turns of a screw planted in the centre of the "dead wood." After explaining the evidence that he had to produce as to the usefulness of Mr. Woodcroft's invention, Mr. Jervis concluded—Having expended 1,200*l.* and upwards in pushing his invention, and having only received in return about 430*l.*, Mr. Woodcroft was entitled to such a renewal of his patent as would enable him to remunerate himself, not only for capital laid out, but for the time and talent which he had spent upon it. Mr. Woodcroft had made several other inventions, and in applying for a renewal of his patent, he proposed introducing an improvement on the original plan, by which to alter at pleasure the variations in the "pitches."

Mr. Carpmael stated that he had studied the subject of the screw propeller for several years. In the use of ordinary screws, the water was put in motion by the first part of the screw, and being of the speed of the second part of the screw, choked the screw. The advantage of this screw was that the second part was so constructed as to outstrip the motion of the water, so that the instrument was an operative one, whatever might be its length. All other screws consisted of a straight line wound round a cylinder, but that of Mr. Woodcroft was a circle, or segment of it, wound round a cylinder. Tredgold, in his work on propulsion, proposed that the screw should go on with a decreasing angle on an increasing pitch, but he stated nothing about a circle wound round a cylinder, which was Mr. Woodcroft's principle.

Cross-examined by the Solicitor General.—Mr. Commeraux's patent was a spiral by language, but a screw by description. The word "spiral" or "screw" did not truly designate the distinction. The word "helix" was used at present. He had seen the screw of Mr. Woodcroft in a vessel at Bristol, which had come in from sea about three years ago. With that exception he had never seen it in use. He had never known a screw used practically till the time of the Archimedes, in 1839 and 1840. From that time the use of the screw had increased greatly, both in the Royal and mercantile navy. The screw he saw at Bristol was only one fourth of a convolution, and a three-threaded screw. In practice it was called the one-eighth of a convolution. He had never seen the ordinary screw in operation of more than one convolution; but as far as his experience went it would not work. He was satisfied that Mr. Woodcroft's spiral would work with more than one convolution. The varying angle would, he thought, operate all through. The spiral was between the stern-post and the rudder-post, raised for the purpose. Smith's patent was placed in the dead wood. Woodcroft's was not technically a spiral, because it did not run up to a point.

Mr. S. Slaughter said he had built two vessels fitted up with Mr. Woodcroft's "spiral." He had tried other screws in the vessel before Mr. Woodcroft's, and he greatly preferred the latter.

Cross-examined by the Solicitor-General.—The other screws he had tried were not under any patent, and had varied from one-fourth to one-tenth of a convolution. He tried nine screws of varying diameter and the same pitch. Being dissatisfied he tried an increasing pitch and found the advantage of it. He had thus accidentally stumbled on Mr. Woodcroft's invention, and finding that, he applied for a license. With Mr. Woodcroft's he had attained a speed of 14 miles an hour, while with others he had only secured a speed of seven or eight miles an hour. In the one case the water "slipped" off the blades, and in the other it did not.

Mr. Murray, assistant-engineer to the Admiralty, said that he could speak to two trials, one on the 18th of April last, and the other on the 18th of March, in which the relative merits of Mr. Smith's and Mr. Woodcroft's invention had been attested. With that of the former the results were as follows:—With the engine giving 26·28 strokes the rate of speed was 8·18 knots, the slip being 3·143, or 27·758 per cent., and the revolution per minute 104.34. With that of the latter the results were—with the engine giving 24·152 strokes a revolution per minute of 95·99, a speed of 8·159 knots and a slip of 2·155, or 23·562 per cent. The result exhibited in Mr. Woodcroft's favour a speed nearly as great, with less power of the engine, and much less slip. If the facts which he had stated were reduced, a difference would be shown of one-sixth of a knot per hour in favour of Mr. Woodcroft. He was aware that by other experiments Mr. Smith's screw had attained a greater velocity.

Mr. Cowper, an engineer, said, that the invention was a new and very ingenious one. He illustrated its effect by an experiment on the air with tin blades modelled after Mr. Woodcroft's screw, and which when spun rapidly round on an axis by a piece of twine, as a top is spun by a boy, flew up with great force to the ceiling. When the side was reversed, and the experiment repeated, the model was not moved from the axis it revolved on.

The Solicitor-General submitted that the present was no case of a useful invention at all. There was nothing new in the idea of using a screw for propelling vessels, as it had been in existence as long ago as 1794. It was Mr. Smith's discovery that the screw should be placed in the centre of the dead wood which first led to its practical utility. When the screw was so placed and reduced to between one-fourth and one-eighth of a convolution all other points with regard to its construction became immaterial. Before Mr. Smith's invention the screw was placed in unsuitable parts of the vessel, and none of them had ever succeeded. The Solicitor-General then proceeded to explain, with reference to the models produced in court, that it was only by adopting Mr. Smith's discovery and inserting the screw in the dead wood that Mr. Woodcroft had succeeded in making a practical application of his patent. He read an extract from the specification of the latter gentleman, the strongest point in which was as follows:—"The spiral propeller may also be placed under the stern of the vessel, as seen in figures 5 and 6, where a part of the hull is removed." The improvement claimed by him had nothing to do with the position, but was one in reference to an increasing angle. At the time when Mr. Woodcroft took out his patent it was no improvement at all, for want of the discovery that it should be placed in the dead wood.

Lord Brougham.—But it is now beyond a doubt that some steamers may have no "dead wood" at all.

The Soliciter-General.—Practically it might be so in the case of a Dutch built vessel, but not one for steam communication. In all vessels there was but one stern-post, and it was playing with language to introduce the terms which had been used in the evidence. He should refer to Mr. Woodcroft's specification hereafter, but in the mean time he would ask if the space filled by Mr. Woodcroft's screw were not so occupied, would it not be the "dead wood." If so, then Mr. Woodcroft's screw was inserted in the dead wood. In his drawing there was no continuation of the keel, but an undue prolongation of the deck, and a stern-post to which the rudder was attached. No particular ratio of angular increase or decrease was claimed by Mr. Woodcroft, and Mr. Commeraux had already discovered the principle. In the patent of the latter the term "spiral" was used, and in the drawing the increasing angle was clearly marked. The convolutions in the drawing were as three to two.

Mr. Cowper was here recalled, and stated that there was no intimation of an increased pitch in the drawing, even taking into account the word spiral in the specification.

The Solicitor-General then gave up that point, and proceeded to argue that as Mr. Woodcroft had in his specification only provided for one convolution or more, and as there was only evidence of its answering for one-eighth of a convolution, there was no direction in the specification which would guide a workman to the only form of the invention which had practically been found to answer.

Lord Brougham.—The drawing No. 12 shows only one-eighth of a convolution, being exactly what is now used. His claim is quite general.

The Solicitor-General.—Mr. Carpmael had stated that the spiral would work with any number of convolutions, but notwithstanding the amount of experience on the subject now, not more than one-quarter of a revolution had in any screw been found to answer. After 14 years' opportunity for experiment, it had been so, and the *onus probandi* therefore lay on Mr. Woodcroft, for showing that the spiral would work at more than one revolution.

Lord Brougham delivered the judgment. In all cases where there was a disputed right as to patent, and where the validity of the patent might come into question, there were two things to be considered. The first was whether the case to prove the invalidity of the patent was so clear as to remove all ordinary doubt; the second was whether the case was so doubtful that that Court would rather retire from its consideration and not decide it. In the former case they would not grant the extension, because they did not see the merits, and because they would not put the opposing parties to the vexatious process of bringing their *scire facias* in the law courts. But where the matter was doubtful—where conflicting evidence and questions of law equally arose, that Court would not refuse the discretionary power vested in them by Parliament merely because it was also a case in which the validity of the patent was contested. The present case came under the first principle he had stated. There was nothing to make it clear that the patent should not be sustained until they took away the merit of the invention. If the patent turned out to be invalid, it would only be the extension of such a patent for so many years. Now, as to the merits in this case there could be no doubt. His Lordship gave it as his own opinion on a scientific point, that Mr. Woodcroft's invention was a most ingenious application of mathematical principles to mechanical ends, and he commented on the evidence which had been adduced on the subject. It was not enough to object that the patent had been long in coming into operation, for the steam-engine, and many other discoveries, were open to the same observation. All his time, his ingenuity, and his labour had probably been exhausted by Mr. Woodcroft on this work. They had every reason to believe that he would be for the next few years in happier circumstances, and more likely to receive compensation. On the grounds he had stated, their Lordships were of opinion that a period of six years should be given by way of extension to the petitioner. What he had said was without reference to Mr. Smith's invention, which might be a most ingenious one.

The Skew Arch an Old Invention.—"Now visiting the Alcazar (cathedral at Seville), but first observed a singular Moorish skew arch, in a narrow street leading from the cathedral to the Puerta de Xeres; it proves that the Moors practised this now assumed modern invention at least eight centuries ago."—*Ford's Spain.*

THE BOODROOM MARBLES.

For the following communication from Boodroom, Asia Minor, we are indebted to a correspondent of the *Times*.

Our arrival at this once celebrated place, anciently called the city of Halicarnassus, is caused by a request from his Excellency Sir Stratford Canning, the Minister at Constantinople, to remove and receive on board for conveyance to England some ancient marbles, supposed to be a part of the tomb of Mausolus, erected by Artemisia to the memory of her husband, and which was, in the days of the kings of Caria, considered as one of the seven wonders of the world. The monument, in question was, no doubt, a mass of unusual splendour, and from this magnificent sepulchre tombs and the like edifices received their names; it was built by four different architects—Scopas erected the east side, Timothens the south, Leochares the west, Brucis the north. Pithis was also employed in raising a pyramid over this stately superstructure, and the top was adorned by a chariot with four horses; the expense was immense, and called forth the remark made by the philosopher Anaxagoras, when he saw it, "How much money changed into stones."

The marbles were found inside the fortress, and built into the ramparts, and counterscarp and bastions, at various heights from the ground, varying from 40 feet to 12 feet; are of considerable size, being from 7 feet by 5 feet, and of great thickness, varying from 25 to 46 cwt., and 14 in number. This fortress withstood many sieges, especially the one maintained against Alexander the Great, under Memna, and another during the time of the knights of Malta and Rhodes. It is now a Turkish castle, miserably provided with the munitions of war, and bearing striking evidence of the state of Turkish command. Three of the friezes were outside facing the north, one was embedded under a high wall on the left side of the second entrance, three were under the drawbridge leading to the citadel, three more were taken from an outer wall of a moat or trench; two from the right of a wall in the fourth portal, and two from the south-east wall. They were thickly coated with whitewash to correspond with the rest of this stronghold of chivalrous knights, and the greater part resisted, for some time, the impression tried to be made npon them in loosening the brickwork tor their extraction. It may here be mentioned, that the citadel of Boodroom, as it is called, has, on its various walls, ramparts, and bastions, many shields in marble, and near to every one of the antiquities were specimens of the same. No doubt they were considered by the holders as ornaments to their heraldic devices, and their position evidently bespoke that they were so placed as a commemoration of some gallant achievement of the warrior who defended that particular spot. In the inside of the largest tower there appeared one with the figure of St. George and the Dragon, having on each of its sides nine lesser shields, and over the first gate of the drawbridge one betokened that the knight had served in Palestine, bearing underneath the following inscription:—

"I. H. S.
"Salve, nos, Domine vigilantes;
"Nisi Dominus custodierit civitatem
"Frustra vigilet qui custodit."

Leaving, however, these mementos of peculiar interest, it may be mentioned that the figures on the marbles are in a very masterly style. The majority of them are sadly defaced by time, weather, and lime; from their character they are evidently meant as a picture of the wars of the "Amazons;" a few are in a state of preservation, and present to the eye a rare specimen of the sculpture of the age in which they were executed; some pourtray women stricken down by the ruthless hand of the warrior, and their subdued bodies are exquisitely chiselled. But to illustrate this remark, there is one which cannot fail to impress the spectator, and which I think stands pre-eminent—it is the death of a woman by the hand of a man, stretched on the ground, with her head fallen on the left arm, the right hand clenching the earth in the last struggle for life, her conqueror, with head bent and shield before his breast, stands looking with peculiar ferocity on the bloody deed he has committed, whilst an Amazon, with outstretched body and uplifted arms, appears in the act of wreaking vengeance on him who has slain one of her sex.

The village of Boodroom, for it cannot be called a town, is a specimen of Turkish indolence, and were it not for its ancient site, would offer little pleasure to the visitor. There are some fine remains of what the city of Halicarnassus was, on a hill, besides what was most likely an amphitheatre; and though many of its massive stones and marble seats lie scattered in the grass and rank vegetation with which it is overgrown, still there is a sufficient perfectness to dénote that 6,000 people could have witnessed the scenes therein enacted. On a summit at a short distance from this spot are several catacombs, containing chambers or vaults for their dead, some were sealed by stone slabs, and so firmly, as to resist an iron crowbar; one of them was found to contain nearly 40 lachrymatories. These chambers of death have a very curious appearance from the entrance of the harbour, and are seldom visited either by Greek or Turk. About a mile in the country stands in tottering form what was once a gateway, but which is in a very ruinous state, and not far from this place are several small arched buildings, near which must have been an entrance to the city, as several parts of the wall can be traced through the rich olive groves. Adjoining, under the wide spreading branches of a tulip tree, is a sarcophagus, apparently of great antiquity. Time and [illegible] destroyed its sculpture. In another orchard [illegible] piece of a temple, much decayed. Several [illegible]

it, and the pillars are in a very tottering condition. There are about 2,000 houses in Boodroom, inhabited by Turks and Greeks. The soil is rich, but in lieu of green pastures, unwholesome weeds spring up before the eye, proving how much given to indolent habits the Turks are, how they manage to sustain life cannot be told. There is the appearance of their cultivating the olive, fig and almond trees, but even these require but little manual assistance. Some coins of ancient date were obtained; sickness and disease appear in almost every family, and some, from want of medical assistance, were found to be beyond human skill.

Thanks to Sir Stratford Canning, England may now congratulate herself on possessing some of the finest specimens of ancient sculpture in existence; for although those in the interior have been guarded with such jealousy by the Turks, that no eye, save those of the officers of the Siren, have ever been set on them, those on the sea bastion have been visited by celebrated travellers, and pronounced to be little inferior to those of the Parthenon.

REPORT OF EXPERIMENTS ON GUNPOWDER, MADE AT WASHINGTON ARSENAL, IN 1843 & 1844.

By Captain Alfred Mordecai, of the Ordnance Department.

This Report embodies the results of many thousands of accurate experiments made by Capt. Mordecai, under government authority, with instruments constructed in such a manner as to ensure perfect accuracy. Having had the satisfaction of inspecting the instruments, and of hearing from Capt. Mordecai an account of the methods of experimenting, we can speak of them with the greater certainty. The force of gunpowder, since the time of Hutton and the French experimenters, has been calculated by means of the *balistic pendulum* and of a *gun pendulum*. The *gun* (in these experiments a twenty-four and a thirty-two pounder) is suspended in an iron frame, hung on knife edges of hardened steel, like a balance beam, the whole supported (a load of 10,500 lb.) on massive stone pillars. The recoil is measured on a limb of brass, having a curve, of which the frame work and the gun are the radius, and graduated to read to seconds by means of a vernier which is moved by the recoil, and retained at the point of greatest vibration by a slight spring. When the gun is adjusted and at rest, its axis is a horizontal line, and the vernier stands at zero on the scale.

At a distance of only fifty-five feet (between the centres), is inserted the *pendulum block* for receiving the shot and measuring its velocity. This *pendulum* is a counterpart to the gun, as regards its mode of suspension and motion, which is also measured in like manner on a graduated arc. This "*block*" as it is called, resembles a mortar or wide howitzer, with a bore of four and a half feet deep and fifteen inches calibre, and filled with leathern bags of sand, and a bedding of lead. This block, the frame and counterpoise weights, weighed 9,358 lbs., and was suspended so as to hang when at rest, with its axis perfectly in one and the same line as the axis of the gun. When prepared for use, the aperture of the pendulum block was covered by a sheet of lead, which served to make the deviation of the ball from a right line, by the hole which was pierced in it. This deviation was found to be very slight.

It seems, to a person unaccustomed to such experiments, a rather daring attempt to fire a thirty-two pound shot, at the distance of only 50 feet, in the mouth of another gun. But that velocity which, left unrestrained, would serve to carry the shot for miles, is in this apparatus restrained within the range of a few feet, and imparts only a moderate motion on the great mass of matter on which it impinges, which can be wholly and accurately estimated. Capt. Mordecai remarks, that "an observer, placed in such a position as to see the face of the block unobscured by the smoke of the gun, perceives, at the moment of impact, a circle of *reddish white flame* surrounding the hole made by the ball." He supposes "that this flame may be produced by the combustion of minute particles of iron and lead ignited by friction." He further remarks, that "in firing a thirty-two pound ball into the pendulum block with a charge of eight pounds, the sand immediately before the ball was compressed into a solid mass, forming an imperfect sandstone sufficiently firm to bear handling. A specimen is still preserved in that state, after a lapse of more than eighteen months." This sand, when examined, was found quite free from any calcareous cement. An apparatus of quite similar structure, on a proporsionate scale, was used for muskets. In these experiments powder from a great number of manufactories, and of great variety of composition, grain, and finish, was tested. The elements for calculating the strength of gunpowder, obtained by these experiments, were resolved by the formulæ of Hutton and those which more recently have been employed by the French at Metz. This portion of the labour is performed with the accuracy and skill which characterize all the highly educated officers from West Point Academy. Capt. Mordecai concludes from the results of his experiments, that the only reliable mode of proving the strength of gunpowder is to test it, with service charges, in the arms for which it is designed; for which purpose the balistic pendulums are perfectly adapted.

[illegible] pounder gun, new cannon powder should give, with a [illegible] of the ball, an initial velocity of not less [illegible] ball of medium size and windage.

The initial velocity of the musket ball, of 0·05 in windage, with a charge of one hundred and twenty grains, should be

With new musket powder not less than	1,500 feet.
" " rifle " " "	1,600
" fine sporting " " "	1,800

The common eprouvettes are of no value as instruments for determining the relative force of different kinds of gunpowder.

The proportions used in making our best powder, 76.14.10, and the English 75.15.10, appear to be favourable to the strength of powder. The best mode of manufacture is in what is called the cylinder mills under heavy rollers, and this process alone is considered capable of making good sporting powder. The English have employed this process for fifty years, but the French still use the old method, by stamping or pounding. The "*gravimetric density*" should not be less than 850, nor more than 920. The charge for cannon for all ordinary purposes should be one-fourth. No purpose, even breaching a battery, requires more than one-third the weight of the ball. For small arms the following charges are proposed; for the percussion musket, 110 grains; the percussion rifle, 75 grains; the percussion pistol, 30 grains of rifle powder. It is proposed that musket and rifle balls should be made by compression, instead of casting, as at present.—*Silliman's Amer. Journal.*

REGISTER OF NEW PATENTS.

If additional information be required respecting any patent, it may be obtained at the office of this Journal.

FIRE ALARUM.

Francis Taylor, of Romsey, in the county of Hants, surgeon, for "*Improvements in giving alarum in case of fire, and in extinguishing fire.*"—Granted August 6, 1845; Enrolled February 5, 1846.

Fig. 1 shows a transverse section, and fig. 2 a front elevation of an apparatus for giving alarum in case of fire; *a* is a tube of glass having a bulb or enlargement about the middle part thereof, this tube which is to be filled with mercury and hermetically sealed at both ends is supported in

Fig. 1.

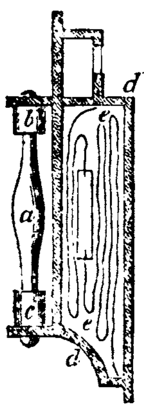

Fig. 2.

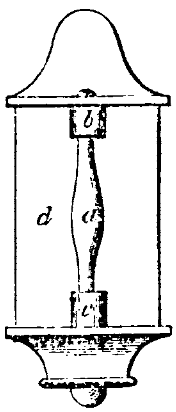

Fig. 3.

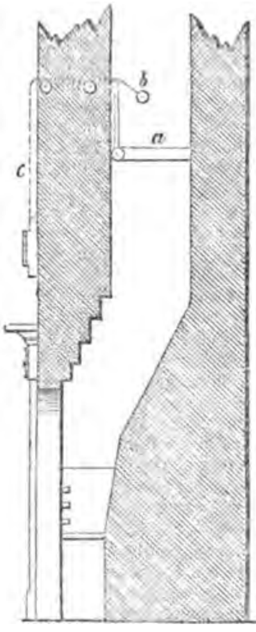


two brass sockets; *b c, d d*, is a brass or other metal box composed of two parts, the front part *d* being attached to the back part by the strength of the glass tube; *e e* are two pieces of tape of about half a yard each, more or less; one end is attached to the upper and lower, or front and back part of the box, the opposite ends being joined to a detonating packet containing some explosive mixture. This apparatus may be hung up in any part of a room most likely to give immediate alarum in case of fire, which fire on attaining a few degrees of heat above the temperature of the room would expand the mercury, and have the effect of bursting the tube, and thereby let fall the front part of the box, and cause the explosion of the detonating mixture, which would give the alarum required. The specification shows several modifications of this principle; it also shows the application of one for stopping the draft of the chimney, so as to impede the progress of the fire. Fig. 3 is a transverse section of the chimney, having fixed therein a few feet from the bottom, a rectangular frame *a*, and plate *b*, which plate is kept in a vertical position by a chain *c* passing over two small pullies, the opposite or lower ends of this chain are attached to an apparatus constructed on the same principle as that above described, fixed over the mantle-piece, which in case of fire would burst as aforesaid, and let fall the plate *b*, and have the effect of stopping the draft, thereby impeding the progress of the fire.

COPPER ORES.

Frederick Bankart, of Champion Park, Denmark Hill, in the county of Surrey, Gent., for "*certain improvements in treating certain metallic ores, and refining the products therefrom.*"—Granted August 7, 1845; Enrolled February 7, 1846.

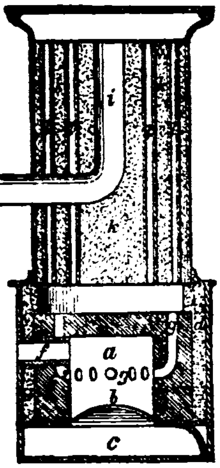
The improvements relate to ores containing copper, whether combined with sulphur or not; and consist in mixing the different ores in such a manner, that those which contain sulphur in excess may compensate for the deficiency of sulphur in the other ores, and submitting the ores so adjusted to successive roastings and lixiviations, whereby a solution of sulphate of copper is obtained, from which the copper may be precipitated in a refined metallic state, which is done in the following manner:—The copper ore is first reduced to powder, and the relative proportions of sulphur and copper which it contains are ascertained by analysis; then if the sulphur bears a less proportion to the copper than one to two, iron pyrites or copper pyrites, also pulverized, are added, in such quantities as will bring it to that proportion. If two or more descriptions of copper ores are to be treated, they must be mixed together in such proportions as will make the sulphur of the mixture bear to the copper at least the proportion of one to two; iron pyrites or copper pyrites being added, where necessary, to ensure that proportion of sulphur. And there must always be a sufficient quantity of sulphur ores for the conversion of the copper into a soluble sulphate, and also to allow for the escape of part of the sulphur during the processes. The copper ore, prepared in this manner, is then submitted to such a degree of heat, in free contact with atmospheric air, as will oxidize the metals not already in a state of oxide, and convert the sulphur into sulphuric acid. For this purpose, a common reverberatory furnace is used, and the ore submitted to a dull red heat, in free contact with the air, until the mixture attains a state of seeming fluidity, and it is retained in that state until the evolution of sulphurous vapour nearly ceases: the whole of the mixture is not put into the furnace at once; but it is divided into several portions, and one portion being put into the furnace, another is added when the first has attained a dull red heat, and so on until the whole has been introduced;—the mixture is frequently stirred during the process. The evolution of sulphurous vapour having ceased, or nearly so, the mixture is removed from the furnace to a vat or pit, and water (or a weak sulphate liquor from a previous lixiviation) applied at about the boiling temperature, and retained at that temperature for some time, by means of injected steam, to ensure the solution of the sulphate of copper. When the sulphate of copper liquor is drawn off from the residual mixture, the latter is mixed with as much iron pyrites or copper pyrites as will supply the requisite proportion of sulphur; the whole is then subjected to a second roasting, and to a second lixiviation; this process of adjusting the proportion of sulphur in the mixture, and roasting and lixiviating, is repeated until the whole of the copper is obtained from the ore. The next process is to precipitate the copper from its sulphate solution; after which it is to be fused, and run into moulds, for sale as fine metallic copper. Various modes of precipitation may be adopted; but the patentee prefers to employ cast or wrought-iron plates, keeping the solution at a temperature of from 120° to 150° Fahr., and as nearly as may be of the same strength, by means of a circulating stream of fresh sulphate solution, which, entering at the top, and being conducted by a pipe downwards, tends, by its greater specific gravity, to displace the lighter solution; the latter, overflowing, is to be returned into the lixiviating vat, to be recharged with sulphate of copper, and this again precipitated, until the refuse liquid becomes a nearly saturated solution of sulphate of iron, when it is set aside to crystallize.

The claim is for mixing of the different ores of copper and iron pyrites in such proportion, according to the quantity of sulphur relatively with the copper which they respectively contain, and adjusting them in such manner as that ores which hold sulphur in excess may compensate others which are wholly or partially deficient in sulphur, and subjecting such mixture to a succession of roastings and lixiviations (the residuum, after each roasting, having the proportion of copper to sulphur adjusted as before), and thereby obtaining a solution of sulphate of copper, whence the copper is obtained, by precipitation, in a refined metallic state.

STOVES.

Charles Searle, of Bath, in the county of Somerset, doctor of medicine, for "*improvements in stoves.*"—Granted August 9, 1845; Enrolled February 9, 1846.

The improvements consist, firstly, in the employment of a heat retaining mass in connection with the fire-chamber, for the heated gases to pass through on their way to the flue, instead of the vessels now in use as the connecting medium between the fire-chamber and the flue. Secondly, in so constructing the fire-chamber or furnace as to obtain solidity of substance, and isolation from surrounding conducting media as far as may be practicable, with confinement of space or closeness of the fire-chamber; the patentee's object being to absorb and retain as long as possible the heat derived from the combustion of the fuel, to prevent its escape, and to concentrate its operation upon the fuel, in aid of its more perfect combustion.



The annexed figure shows a vertical section of a stove. *a* is the fire-chamber, of fire-bricks, about two inches thick, of a cylindrical shape (or either conical, square, or polygonal, if preferred), and the top is perforated with numerous holes, from ⅛th to ¼th of an inch in diameter, on the side, as shown at *g*, for the escape of the gases from the fire; at the bottom is an iron grating *b*, and beneath it an ash-pit or chamber *c*. *d* is a packing of sand or clay, between the fire-chamber and the outer cylindrical case of iron *e*, to prevent the radiation of heat at that part; and *f* is a door-way or opening for the introduction of fuel. The smoke and gases, in their escape from the fire-chamber, having to pass through the apertures in the top or side (which in time becomes red-hot), are consumed or intensely heated. The combustion is carried on in the lower part of the chamber; the upper part serving as a magazine or store of fuel.

Besides these methods of constructing fire-chambers, they may be composed of two vessels of a cylindrical or other shape, one within the other; the gases from the fire being allowed to escape between the two by openings in the side of the inner one, which contains the fuel, and is closed at the top; or the current of gases may be made to descend through the body of the ignited fuel and grate, and then pass up between the two vessels, by admitting air above the fuel, instead of from below.

The heat retainer of the stove, through which the gases have to pass in their course to the flue *i* is made of slabs or discs of burnt clay or brick, fitting closely within the casing or body of the stove; or the retaining mass may be composed of any number of smaller parts, with intervening spaces for the passage of the gases, instead of the perforations above-mentioned. Or slabs of soft stone or brick, of any shape, may be employed; the gases either passing through openings in the slabs, or circulating between them. Or the body of the stove may consist of a vessel of iron or other material, filled and packed with sand, clay, or other suitable substance, as represented at *k*, through which tubes of metal or pottery *l*, about an inch in diameter, extend; in this arrangement, as well as when perforated slabs or discs are used, a solid mass, of not less than two feet in sickness, is considered desirable. A series of hollow cones, or cylinders of pottery or brick, might also be arranged one within the other, to act as a heat-retaining mass; the gases passing between them. Or a "tubulated cylinder," filled with tallow, oil, or other fluid possessing a great capacity for caloric, might be employed for the same purpose.

The patentee does not confine his invention to stoves for heating apartments; but proposes to apply it also to apparatus for cooking.

MOTIVE POWER.

Mathew Francois Isoard, of Paris, for "*Improvements in obtaining motive power.*"—Granted August 28th, 1845; Enrolled February 28th, 1846.

This invention consists in the application of the reaction of steam for the purpose of producing rotary motion, and in the peculiar combination of parts forming a rotary engine. Fig. 1 shows a sectional elevation of an

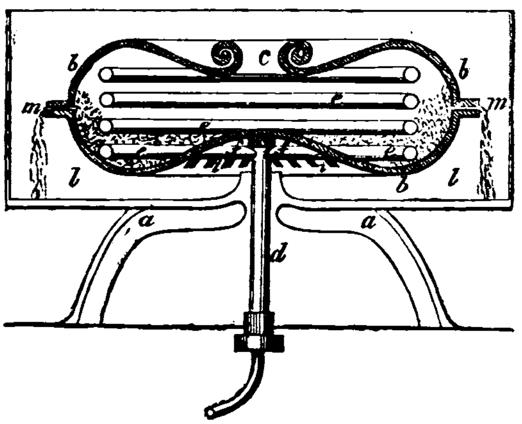


Fig. 1.

engine constructed according to this invention, in which *a* shows a portion of the frame work supporting the engine, which consists of a vessel of the form shown at *b b*, having an opening at *c*; this vessel is supported upon a hollow axis *d*, so as to admit of the same turning freely; *e e* are one, two, or more, coils of pipes, and are made in the form of a single or double threaded screw, depending upon the number of pipes employed. Each of these pipes communicate with the hollow axis *d*, by means of pipes *f f*, and are provided with outlet pipes *g g*, made to pass through

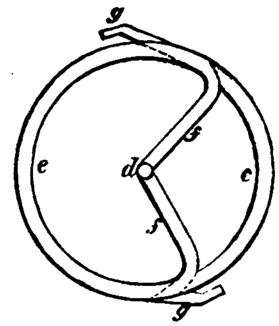

Fig. 2.

the sides of the vessel *b b*, see Fig. 2, which shows a plan of two pipes coiled one within or between the other. *h* (Fig. 1) is a pipe leading from a force pump (worked by the engine), and is intended to supply the pipes *e e* with water. *k k* represents the combustible matter of which the fire is composed, which is lighted within the vessel *b b*, and provided at the lower end with a number of openings, *i i*, for supplying the fire with air. The action of this engine is as follows: the pipes *e e* being filled with water, a fire is lighted within the vessel *b b*, and steam is generated within the pipes *e e*, which is allowed to escape through the outlet pipes *g g*, the reaction of which against the air causes the vessel *b b*, together with the pipes *e e* and hollow axle *d*, to rotate. Upon the hollow axle *d* is keyed a wheel (not shown in the diagram) for the purpose of imparting such motion to the force pump, which supplies the pipes *e e* with water as steam is generated; from such wheel, motion may also be imparted to other machinery intended to be driven by the aforesaid engine. *l l* is the ash-pit which receives the ashes as they fall from the openings *m m*.

IMPROVED CUPOLA FOR MELTING IRON.

Constructed by Messrs. Franklin Townsend, & Co., Albany, N. Y.

This cupola is of the ordinary construction, only being of enlarged dimensions, and made of cast iron. Its diameter at the *tuyères*, when lined with fire brick, is three feet; and its height, from the hearth to the charging door, eleven feet. When charged full, it will contain three tons of pig iron, and is capable of melting upwards of twelve tons at one blast. The air is admitted into the cupola by six tuyères, which are placed about fifteen inches above the hearth, and equidistant on the circumference of the cylinder. To avoid the number of pipes which would be necessary if the air were conducted into the cupola by the usual method, an air chamber is made to surround the cylinder and enclose all the tuyères, and into this the main blast pipe is introduced. An opening is made through the outside of this air chamber, and directly opposite to each tuyère, which, being protected by a plate of glass, allows the *melter* to observe the working of the furnace. This plate of glass is so attached that it can be easily removed, and thus give free entrance to clear the tuyères whenever it may be necessary.

The air is heated by being forced through a number of small pipes, placed in such a manner in the interior of the stalk immediately above and directly over the cylinder of the cupola, that their outside surfaces are exposed to the full action of the waste heat of the furnace. For reason of the difficulty caused by the expansion of the metal when heated, these pipes are required to be of peculiar construction. By this arrangement, the air becomes heated during its passage from the blast reservoir to the tuyères, upwards of 400° Fahrenheit's thermometer.

This cupola has been in operation during the past three months, melting ten tons of iron daily. The iron is *charged* in the shape of *pig* and *scrap* (*sprues, gates, &c.*) in about equal proportions, and is cast into stove-plates, which require that it should be very hot and liquid. The average consumption of coal (Lehigh) in melting this quantity of iron, is 225 lb to the ton of iron, and the rate of melting is from two to three tons per hour. An ordinary cupola, operated with cold blast, consumes upwards of 500 lb. of coal to the ton of iron, and its rate of melting is from one to two tons per hour.

Not having the results of the operation of any hot blast cupola in this country, the comparison of the *working* of this improved cupola with them cannot be given; but its evident superiority to those of England is shown by the following extracts from a report made by M. Dufresnoy, chief engineer of mines:—

"The cupola furnaces at the Tyne Iron Works are operated with heated air. The consumption of coke is 309 lb. to the ton of iron; rate of melting, one ton per hour.

"At Wednesbury, the cupolas are operated with hot blast, and consume

16

287 lb of coke to the ton of iron. Before the adoption of the hot blast, the consumption of coke was 441 lb. to the ton of iron. The same quantity of iron is melted in one-half of the time that was required before the adoption of this process."—*Franklin Journal.*

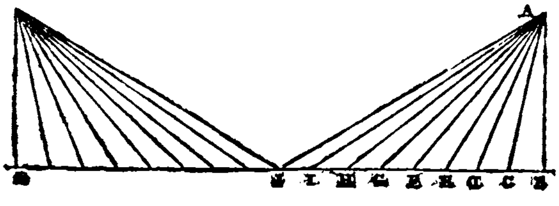
AUST PASSAGE BRIDGE.

(*With an engraving, Plate* V.)

The proposition to build a bridge across the old passage of the Bristol Channel, at Chepstow, has arisen from the intended improved connection of South Wales with England by means of railways, and whatever may be the objects of crossing the Bristol Channel elsewhere, the old passage is unquestionably the point where the nearest junction of South Wales with Bristol, the West of England, and London, can be effected.

In the session of 1845 I recommended, in my evidence upon the South Wales Railway, that this bridge should be constructed with a span of 1,000 feet from pier to pier, and height of 120 feet above high water mark of spring tides. Since then, I have had a correct plan and sections made of the Channel, from which I find it practicable to place the piers on rock foundations, accessible at low water, but at distances of 1,100 feet apart. The bridge will therefore require four spans of this length, and one at each end of nearly 550 feet. In addition to which, another bridge should be built across the Wye, with one span of about 500 feet in length, and one at each end of about 250 feet each. I expressed my opinion in the session of 1845, that the suspension principle adopted at Menai Bridge and elsewhere, would not be sufficiently steady for the Aust Bridge without material improvements in it. I have accordingly, in conjunction with Mr. Francis Bashforth, Fellow of St. John's, Cambridge, designed a bridge for the Aust Passage, which the accompanying engraving represents (see plate V.); the calculations for which are subjoined, for the scrutiny of scientific men, and I have great pleasure in associating my name with Mr. Bashforth's in this work. FRANCIS GILES.

Experience has shown that the instability of suspension bridges is their great defect, whilst they may be made of sufficient strength to bear any load that can ever be placed upon them. To guard against their liability to undulation an arrangement is proposed, so that every part may be always in its proper position to support any heavy weight placed on the roadway. The bars radiating from the tops of the piers are of variable thickness, so that each is capable of sustaining the same weight as when placed at its extremity on the platform (supposed to be a rigid lever moveable about the end). These radiating bars are kept straight and connected together by transverse rods, but the former alone are calculated to sustain the whole of the load, the latter being employed to keep them in their proper position and to ensure the assumed rigidity of the platform. The supporting bars are attached to the platform at equal distances and are passed over the top of the pier (side by side or otherwise). On account of their number the space covered would be considerable, but this would be an advantage as the tendency would be to keep the platform steady. In addition, the main chains are proposed to be connected by rods overhead to within about 20 feet of the roadway. So as to form an immense trussed beam. Let t denote the number of tons that a bar of iron of 1 square inch



section would bear without injury. $AB = h$, $BB = s$, $BC = CD = DE = \&c. = \delta$. Let AF be the r the bar from AB. Then $BF = r\delta$ w, the weight supported by AF at F on the platform. k = weight of a bar of iron 1 foot long and 1 square inch section. n = number of bars between B and J.

$$\text{The tension of AF} = w\frac{AF}{AB} = w\frac{AF}{h}$$

$$\text{Weight of AF} = \kappa\frac{\text{tension of AF}}{t} \times AF = \frac{\kappa w}{t}\frac{AF^2}{h} = \frac{\kappa w h}{t}\left(1 + \frac{r^2\delta^2}{h^2}\right)$$

and giving to r successively the values 1, 2, 3——n we get the necessary weight of each bar, and four times their sum will be equal the weight of the supporting bars between the piers = W suppose

$$\therefore W = 4 \times \frac{\kappa w h}{t}\left\{n + \frac{\delta^2}{h^2}\left(1^2+2^2+3^2+\ldots n^2\right)\right\}$$

$$= \frac{\kappa w h n}{t}\left\{1 + \frac{n^2\delta^2}{h^2}\left(\frac{1}{3}+\frac{1}{2n}+\frac{1}{6n^2}\right)\right\}$$

But if W be the weight to be supported on the platform when uniformly distributed, $W = 4nw$ and $n\delta = \frac{S}{2}$

$$\therefore W' = \frac{W\kappa h}{t}\left\{1 + \frac{S^2}{4h^2}\left(\frac{1}{3}+\frac{1}{2n}+\frac{1}{6n^2}\right)\right\}$$

It is manifest that W′ cannot be made a minimum by the variation of n, but as n increases W decreases, and the least possible value is given by $n = a$ in which case $W' = \frac{W\kappa h}{t}\left\{1 + \frac{S^2}{12h^2}\right\}$. In this case we should have the bars replaced by a very great number of wires, but there would be no rigidity for preventing the platform being raised in the middle. A bridge so constructed in Scotland was soon destroyed by the wind and replaced by one of the common form. Hence the greatest number of bars must be made use of, consistent with the rigidity of the whole. W′ is also a function of h, the height of the platform above the roadway. Making $\frac{dW'}{dh} = 0$ we find $h = +\frac{S}{2}\sqrt{\frac{1}{3}+\frac{1}{2n}+\frac{1}{6n^2}}$. The positive value of h makes $\frac{d^2W'}{dh^2}$ a positive quantity and $\therefore$ gives the minimum value of W.

But the expense of raising the piers to a height necessary to ensure the minimum quantity of iron being required must be taken into account. Let H denote the height of the roadway above the ground, and x the height of a course of stones on the pier above the platform. Suppose now the cost of any course of stones varies as (height) s, where s is integral or fractional, and also that μ is the expense of a course at height unity from the ground, expressed in terms of a weight of iron of equivalent value.

Expense of the pier above the platform,

$$= \int_0^h \mu\,(H + x)^s\,dx = \frac{\mu}{S+1}\left\{\overline{H+h}^{\,S+1} - H^{S+1}\right\}$$

Hence h must have such a value as makes

$$\frac{\mu}{S+1}\left\{(H+h)^{S+1} - H^{S+1}\right\} + \frac{W\kappa h}{t}\left\{1 + \frac{S^2}{4h^2}\left(\frac{1}{3}+\frac{1}{2n}+\frac{1}{6n^2}\right)\right\} = \text{a min.}$$

It must be remarked that the extremities of the radiating bars would remain in the same straight line for all variations of temperature, provided each bar expanded in proportion to its length. Thus the equation to a straight line is $\rho\cos\theta = a$ (1) If we suppose ρ to receive an increment $\mu\rho$ proportional to its length, the radius vector then becomes $\rho + \mu\rho = \rho'$ (2). (suppose) and eliminating ρ between (1) and (2) we get $\rho'\cos\theta = a(1+\mu)$ ... (3), which is the equation to a straight line, parallel to (1) and at a distance μa. For a span of 900 feet; $a = 90$ feet suppose, and for ordinary changes of the atmospheric temperature

$$\mu = \frac{1}{1800} \therefore \mu a = \frac{90}{1800}\text{ feet} = \frac{12}{20}\text{ inches} = {\cdot}6\text{ inches.}$$

It has been objected that there would be a tendency in the network to "buckle;" this would be perfectly correct in the case of a girder bridge, but there would be no occasion to fear that defect if the proposed plan were properly carried out. For it must be remarked that everything is made subordinate to the radiating bars. The *straight* horizontal rods are intended to insure the rigidity of the platform. When a weight passed over the bridge, the tendency of the supporting bars would be to rotate about the top of the pier, but these *straight* bars acting directly by tension on one side and compression on the other, prevent this, and cannot buckle unless the rods stretch. The bars must be connected so as to admit of adjustments without injury to the strength of the material.

The weight of the material required for the supporting bars on this plan would be from half to two-thirds of that required for the main chains of a catenary of equal strength, but on account of the numerous cross pieces, the saving effected by this plan would not be important, but it is satisfactory to know that suspension bridges may be made much firmer and free from undulation without increasing the cost and adding to the weight to be supported.

RESEARCHES IN HYDRAULICS.

Sir—In Weale's "Quarterly Papers on Engineering" for Michaelmas last, there is an article, "Researches in Hydraulics," by a Mr. Peacocke, in which he attempts to prove the several formulæ of Genieys, Dubuat, Piony, Eytelwein, Dr. Young, and Smeaton, for calculating the discharge of water from pipes, are incorrect, and joins his faith to that of Mr. Provis, whose formula, he *thinks*, might be carried out for a length of pipe of 1,500 feet (!) at least, without any considerable inaccuracy. Ignorant he must be that mains are sometimes three or four miles long, and even more than that. It would be doing Mr. Peacocke and the profession a service, were you to review this in your usual clever style and expose its absurdity.

In Smeaton's Reports, vol. 1, page 231, you will see that by measurement, one of the mains of the Edinburgh Water Works is 4·5 in. diameter, and delivered 21·07 cubic feet per minute. By calculation with Eytelwein's formula he gives 4·49 in. for diameter and 12 feet discharge; and again, vol 3, page 231 (1st edition), the actual velocity from a main of the same Water Works was 1,815 feet per second, whilst the calculated velocity was 1,816 feet per second. I remain, &c.

Macclesfield, March 14th 1846. S. C. S.

[A review of Mr. Peacocke's paper has already appeared in our January number.]

THE BRITISH MUSEUM FACADE.

Sir—The "Idea" shown in the last Number of your Journal would effect so decided an improvement in the façade of our national museum, that it is a thousand pities it did not originate with the architect himself, its adoption being now altogether out of the question, unless it could be made compulsory. Such an important public edifice is a very legitimate subject for public interference; it ought, therefore to be made a matter of consideration whether *something* of the kind at least ought not to be now done. Be such the course or not, it is highly to the credit of your Journal to have shown what might be done to redeem the Museum façade.

I remain, Sir,

London, March 11th, 1846. A Constant Reader.

PROCEEDINGS OF SCIENTIFIC SOCIETIES.

ROYAL INSTITUTE OF BRITISH ARCHITECTS.

February 23.—The successful competitors for the *Prize Medals of the Institute*, for the year 1845, were announced as follows:—

To Mr. T. Worthington, of Manchester, the Medal of the Institute for the best Essay on the History and Manufacture of Bricks.

To Mr. S. J. Nicholl, the Medal of Merit, for his Essay on the same subject.

To Mr. J. F. Wadmore, of Upper Clapton, the Medal of Merit, for a Design for a Royal Chapel.

March 9.—J. B. Papworth, Esq., V.P. in the Chair.

Mr. E. Woodthorpe was elected a Fellow. Amongst the donations announced, was a Medal struck by the Society for the Encouragement of the Industrial Arts in Prussia, in honour of their President, the Chevalier Beuth, presented by the Chevalier Hebeler, who likewise exhibited Herr Ternite's work, "On the Frescoes at Herculaneum and Pompeii."

A portion of the Prize Essay, "*On the History and Manufacture of Bricks*," by Mr. Worthington, was read, and comprised chiefly an account of the earliest recorded instances of the application of brick, both in a crude and burnt state, in the walls and structures of Babylon, Nineveh, Ecbatana, and other cities of Assyria, in China, Egypt, Greece and Italy, involving frequent allusions to the Sacred Writings, and lengthened quotations from Herodotus, Pliny, and other well-known ancient authors, as well as modern travellers.

March 23.—W. Tite, Esq., V.P., in the Chair.

Mr. Poynter, the Honorary Secretary, read a highly interesting and valuable paper on *the Stained Glass in Sainte Chapelle, at Paris.* We must defer this paper until next month, when we propose to give it fully, illustrated with several engravings.

A paper, by Dr. W. Bromet, (accompanied by a drawing,) *descriptive of some moulded bricks*, of various forms, found in the walls of a church, at Sanson-sur-Rille, in Normandy, taken down a few years ago, was read. From the circumstance of these bricks being of ornamental form, and from their being found imbedded as *materiel* in the walls of a building which is mentioned in a book of the year 1210, they are believed to have been portions of the abbey founded at Sanson, in the sixth century, by King Childebert, but destroyed during one of the incursions of the Northmen, in the ninth century. From the pyramidal form of most of these bricks, and the similarity in shape of some to the stones in the Tour-Magne, at Nismes, it is thought probable that they were made after Roman models, if not in Roman times. On the church walls of Ainay, at Lyons, at Tourness, on the Saone, and of Notre Dame du Port, at Clermont,—all nearly of Carlovingian times,—there still exist moulded bricks, geometrically arranged as ornaments; and Dr. Bromet thought it probable, that during Saxon times many of our buildings were adorned with moulded bricks, such as those forming a band on the tower of Sompting Church, in Sussex, and which Rickman deemed to be Saxon, because never seen by him in Normandy or elsewhere. "In conclusion," says Dr. Bromet, "I will venture to express an opinion, that, in no part of the Romanized world could so useful an art as brick-making ever have been lost; although Eginhard tells us to the contrary, and that his master, Charlemagne, re-introduced it from Italy into his French and German dominions.

The Chairman drew attention to the expected arrival in England from Boodroom of a valuable addition to the treasures of ancient sculpture which this country already possesses. The marbles alluded to are generally supposed to have formed a part of the tomb erected by Queen Artemisia to the memory of her husband, Mausolus, though the fact is questioned by Dr. Clarke. Mr. Tite took occasion to express his satisfaction at the success which had attended the efforts of the architects of England, in 1841, to interest the Government in the preservation of these valuable relics, at which time a representation was made by the Institute, to Lord Palmerston, of the importance of rescuing these antiquities from the degradation and destruction to which they were exposed. The suggestion had been received most courteously and acted upon in a way to effect this satisfactory result.

ROYAL SCOTTISH SOCIETY OF ARTS.

February 23, 1846.—Sir George S. Mackenzie, Bart., F.R.S.E., President, in the Chair.

The following communications were made:—

1. *Notice of an Improvement in his Model of a Self-acting method of Throwing the Shuttle in the Common Hand Loom*, &c. By Mr. James Miller, Watchmaker, Perth. In this model an improvement is introduced, calculated, in Mr. Miller's opinion, to prevent the recoil of the shuttle, viz., by interposing a *driver*, as in the common loom. He has also made simple arrangements by which the strength of the driving springs may be tempered or increased at pleasure.

2. *On the applicability of the Electro-Magnetic Bell to the trial of experiments on the Conduction of Sound, especially by Gases.* By George Wilson, M.D., F.R.S.E. The apparatus was exhibited. The object of this paper, and his illustrative experiments, was to show that the Electro-Magnetic Bell is a better and cheaper means of ascertaining the capabilities of different gases to conduct sound than the method of a bell struck by clock-work, as hitherto commonly used. The Electro-Magnetic Bell is much more under command, and we are not troubled with the clock-work running down, and being obliged to remove the receiver of the air-pump to wind it up again. It was exhibited to the Society, by means of the Electro-Magnetic Bell; the difference in the conduction of sound betwixt atmospheric air and hydrogen gas, showing that the latter has greatly less capability to transmit sound. He experimented by placing the bell within the glass receiver of a common air-pump, full of common air, and making the hammer strike the bell by connecting the wire of the temporary magnet with the battery, when the sound of the bell was distinctly heard; and then by exhausting the air from the receiver, and introducing hydrogen gas, and again making the hammer strike the bell, when the sound produced was so weak as to be scarcely audible.

3. *Description and Drawings of an Improved Crank Planing-Machine, and of its advantages over the Common Crank Planing-Machine.* Manufactured by Messrs. Thomas Shanks & Co., Engineers, Johnston, Renfrewshire. This is a very beautiful application of the ellipse to produce alternate quick and slow motion. Two elliptic wheels are made to work into each other, the *driver* working round the one focus, and the *follower* working round the opposite focus of the ellipses, by which means the two ellipses roll upon each other, and always keep in contact. When the driver has its *shorter* lever turned towards the *longer* lever of the follower (to which the crank is fixed), a slow motion is produced, suitable for taking the cut: but when the driver is turned round, and its longer lever becomes opposed to the shorter lever of the follower, a quick motion is produced, thus sending back the planing table very rapidly, so that little time is lost betwixt that and the next cut of the tool.

4. *Description of a Modification and Improvement of the Voltaic or Electro-Chemical Telegraph.* Invented by Mr. R. B. Smith, Lecturer on Chemistry, Blackford. This is an improvement of the Electro-Chemical Telegraph formerly communicated by Mr. Smith. In this telegraph a ribband of cotton or paper, which has been made to pass through a trough filled with a solution of ferro-cyanide of potass, to which has been added a few drops of nitric acid,—is drawn by clock-work, or otherwise over a cylinder of lead, which is in communication with the negative wire of the battery; while there is in communication with the positive wire an impress iron wire, resting immediately on the cotton or paper ribband as it passes over the leaden cylinder. When the circuit is completed by pressing down a key with the finger, the electricity passes along to the impress wire, and a blue coloured mark is printed on the paper, or cloth, caused by the action of the electric fluid decomposing the ferro-cyanide of potass, and forming ferro-cyanide of

iron. If the circuit is closed and broken rapidly, a succession of marks or dots will be printed on the ribband; but if closed for a longer time, and then broken, the marks are longer; so that long spaces, and short spaces, dots, long and short lines, are formed at pleasure. An arrangement of these marks constitutes the Telegraphic Alphabet.

Monday, March 9. John Adie, Esq., F.R.S.E., V.P., in the Chair.
The following communications were made:—

1. "*Description of a Machine for drawing the perfect Egg Oval, and a Method of producing Curvilineal Figures.* Invented by D. R. Hay, Esq., Edinburgh.—A model of the machine was exhibited to the meeting; it will draw correctly the egg form, or oval, as it differs from the ellipse; and also a mode of producing, upon the principle of harmonic ratio, and by a very simple process, a series of curvilineal figures, by which beauty and originality may be imparted to the ornamental works of the architect, and to those of the silversmith, potter, &c., from the most expensive to the humblest product of their respective arts, such as vases, tureens, teapots, cups, &c.; and proved, by specimens executed on a large scale, in presence of the meeting, that, if the most approved works of this kind that have been handed down from the Greeks and Etruscans, were not produced by the same means, his method could produce, with ease and certainty, equal beauty and elegance of design, in endless variety.

2. *A specimen of ornamental Oak Carving*, executed by Mr. John Steel, sen., Edinburgh, was exhibited. It was a very beautiful specimen of Scottish art, exhibiting a number of figures of dead game, &c., from the stag and the heron to the grouse. It was much undercut, some of the figures nearly relieved, and met with general admiration.

3. Some Specimens of the Native useful Arts of New Zealand, and a Specimen of the *Flax Plant* of that country, were exhibited by Mr. W. Wells.—The specimens consisted in various articles of dress, of native manufacture, woven from the native flax, and ornamented in a curious manner with portions of the plant. They form very thick and comfortable outer garments. Some specimens of dyed stuff were also shown; and a specimen of the flax plant, together with the flax produced from it, which, when formed into cordage, was said to bear a considerable strain, provided the strain be equal, but is very apt to snap if a sudden strain be applied; or if a knot be formed on the cord it is apt to break at the knot. It was stated that these bad qualities might result from the imperfect manner in which the flax is prepared, and that they may possibly be removed by skilful preparation of the flax.

SOCIETY OF ARTS, LONDON.

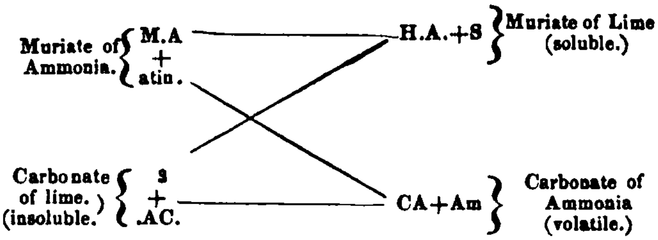
Feb. 25.—W. H. Bodkin, Esq., M. P., V. P. in the Chair.

The following papers was read "*on a new form of Locomotive Steam Engine*," by Mr. T. R. Crampton. The object being to prevent rocking and vibratory motion, and to obtain the advantage of large driving wheels without increasing the height of the centre of gravity. The principal features of the invention are first, the driving wheels are placed at the fire-box end of the boiler, so that the wheels may be made of any height without raising the centre of gravity of the engine, thus a lower centre of gravity is obtained, and also greater stability than is the case in any of the usual forms.

It is also conceived that by placing the driving wheels beyond the extremity of the boiler greater steadiness would be given from the absence of overhanging weight. With these essential changes the remainder of the working parts of the ordinary engine may be maintained without any other alteration in their position.

On the Formation of Incrustations in Steam Boilers, and on the means of preventing it, by Dr. Ritterbrandt. The first part of the paper shows that incrustation is the cause of the majority of Steam Boiler explosions. Secondly, that it is incompatible with the economical use of fuel. Thirdly, that it rapidly destroys the boilers, and that the extra heat necessary to raise water to a given point greatly increasing oxidation or scaling, and fourthly, that it is a source of serious expenditure, by rendering labour necessary to remove it, and by the destruction of the boiler, to which this mechanical removal gives rise. In order to obviate these difficulties, Dr. Ritterbrandt proposes to use the *salts of ammonia*, it being known that if to a soluble salt of lime be added a solution of carbonate of ammonia, precipitation takes place, and the acid which held in solution the lime, unites with the ammonia while the carbonic acid of the carbonate of ammonia combines and falls down with the lime, but upon the water being heated, the precipitated carbonate of lime combines with the salt of ammonia, is re-dissolved and the carbonate of ammonia is formed, and escapes with the vapour of the boiling water. On feeling convinced that this peculiar re-action took place, viz: that carbonate of lime precipitated from a salt of lime by carbonate of ammonia would be again dissolved by the application of heat, it only remained to be proved how far this principle was applicable to decompose the carbonate of lime already existing in calcareous water, and the results exceeded the most sanguine expectations; however, highly charged with lime the water may be, the process answers, and the solution is in all cases perfect.

The rationale of the chemical reaction was explained by the following diagram:



March 11.—T. Winkworth, Esq., in the Chair.

The first communication was by Mr. Waterhouse, "*On his Machine for the Manufacture of Mechlin Lace.*" It appears from the description of the machine and the specimens of the lace exhibited, to be one of great capabilities; the number of warp-threads in the width alone is 4,700, and a corresponding number of bobbins or weft-threads, which represent the same number of bobbins, and are all kept in motion at the same time. In making pillow lace, it requires as many hands as there are bobbins, for on the cushion one hand must wait for the other, in order to obtain the requisite crossings of the threads. Some idea may, therefore, be formed of the intricacy of the machinery, and of the ingenuity displayed in its arrangement, as by it every motion given to the threads by the hand is exactly given by the machinery, but with greater rapidity and precision. The process of the manufacture was described at length, and illustrated by diagrams and parts of the machinery itself; there were also specimens exhibited,—one of which was twenty-six yards long and four yards wide, and had four patterns woven upon it. The number of motions or throws that would be required to produce a similar piece of lace by hand would amount to not less than 2,111,616,000. The lace is said to be in no respect inferior to the foreign lace.

The next communication was, by Dr. Paltrineri, "*On a New Steam Engine, Magnetic Engine*, and other machines in which the moving power is applied simultaneously, by Action and Reaction, to the work to be performed, being illustrations of a system for obtaining all motive powers and maximum of effect." Dr. Paltrineri conceives that the maximum of effect is to be obtained by applying simultaneously the action and reaction of every motive power with equal velocities to the production of the useful effect. He exhibited a double turbine, in which the water, steam, or other moving fluid, is applied by means of two concentric wheels, through which the fluid passes successively, and by this means he showed that a residual effect, which is lost on the ordinary single wheel, would be converted to use by the double. He showed the same results in the case of his new magnetic engine, and he illustrated the fact by a machine in which the constant force of a spring is applied to raise a weight, first by having one bend released and the other fixed, and next by releasing both bends simultaneously, and in which latter case the maximum of effect is utilized. The machines were simple in their construction.

ON THE MANUFACTURE OF GLASS.

Abstract of a paper read at the Royal Institution. By Mr. Pellatt

Though we have accounts of foreign glass having been used in this country during the 7th century, yet the manufacture of glass in England is comparatively of recent date; the first manufactory having been established at Savoy House, in the Strand, in 1557, probably by French Protestant refugees, most of the technical terms in glass-making being from the French. In 1670, the second Duke of Buckingham advanced the manufacture by the introduction of Venitian workmen; and three years afterwards the first plate of glass was produced at the works of that nobleman at Lambeth. In 1773 a royal charter was granted to the governor and company of British Plate Glass Makers; their works are at Ravenshead, Lancashire, and are the most capacious in Europe. Since this period the manufacture of glass, notwithstanding the restrictions to which it has been subjected, but which are now removed, has continued to advance.

Crucibles and Furnaces.—Before considering the manufacture of glass, it is necessary to say a few words respecting the mode of preparing the crucibles and furnaces for melting the materials. Every glass-maker is his own potter and furnace-builder. The preparation of the crucibles involves the greatest care, because upon the quality of them depends all the after processes and results. The material used is fire-clay. The clay best suited is that which contains the most silica. The crucibles or pots are made by forming the clay into small rolls, which are spread, layer over layer, with considerable pressure: the whole is thus built up little by little, allowing the clay to harden so that the shape is preserved. During the building and afterwards, the pots are in a room in which the temperature is regulated at about 60°, and all drafts excluded; five or six months are required in this temperature to dry them. The reason of so much care is to exclude as much air from the clay as possible; which, if it existed in quantity, would, upon the pot being brought into contact with the high temperature of the glass furnace, become so expanded as to burst; and also to insure a capacity in the pot to withstand the sudden contraction and expansion to which it is exposed. Pots are of two different constructions—closed and open; the former are used only for *flint* glass, the latter for all other descriptions in both shapes. The upper part is the most capacious: the reason for this is, that the heat reverberates from the top of the crown of the furnace directly upon the top of the pots. The pots cannot, of course, be exposed *cold* to the heat of the furnace, but have to undergo a gradual heating till they attain a white heat, and this is done in a furnace constructed for the purpose, from which all air is carefully excluded; from this furnace they are removed upon iron carriages to the glass furnace. The heat required to melt glass, especially that made without lead, is very great; yet, on account of the danger to the crucibles from any sudden rush of air, it is impossible to make use of blast, or even fanners: the proper draft is secured by the construction of an air funnel, called a cave, and by having the glass-house so constructed that it can be closed from the entrance of external air above. Upon the arch of the cave the furnace floor or seige (from the French *siège*, seat of the pots) is constructed, formed of strong heavy square bricks. The round furnace is used for flint glass, the flames finding vent by flues passing through the pillars of the furnace, having chimneys upon the outside for carrying off the smoke. Square furnaces, again, are employed for glasses without lead, a greater heat being required; which is obtained by the grate-room running the whole length of the seige. The proper construction of the furnace is of great importance to the operations of the glass-maker; in fact, good glass cannot be made without a good furnace.

There are several distinct varieties of glass manufactured; and so different are they, both in preparation and manipulation, that they may be considered separate manufactures. There are, however, only two methods by which fluid or semi-fluid glass is formed to shape, viz. casting and blowing. Casting applies *exclusively* to *plate* glass, and is the emptying glass out of the pot by casting it out upon a table, the casting of glass as metal is cast, being yet unpractised; *blowing* applies to *all* other descriptions of glass.

The tools used by the glass-maker are simple: the blowing-iron—simply a hollow tube; with this the semi-liquid glass is gathered from the pot and blown out into shape; the punty, for attaching to the bottom of glass after blowing, so that the blowing-iron may be detached, and the glass, being heated up, may be cut with scissars, and afterwards formed. The shears or procellos, for shaping the glass whilst it is turned by the workman upon the arms of his chair, or working bench. These, with the addition of a pair of scissars and pincers, are the whole of the tools.

All glass requires *annealing* or *cooling;* the process is performed in a furnace called a lier, from the French *lier*,—figurative, perhaps, of the change in state, as well as atomic arrangement, which takes place during the cooling. We know that a change *does* take place, from the fact that glass before cooling is of greater bulk and less specific gravity than when cold; that it parts with a portion of *colour* during the process, probably by giving off oxygen; and that though, whilst in a fluid state, glass is a good conductor of electricity, when cold it is a non-conductor. The object of annealing is, by a gradual diminution of the temperature, to allow of that arrangement of particles necessary to the body at a low temperature, and which particular arrangement alone enables the glass to support sudden changes.

The base of all glass is silica: the most convenient form in which it is found is in fine sand; upon the due proportion of this substance in glass depends its compactness of body, brilliance and capacity to withstand sudden changes. It often happens, either on account of want of sufficient heat in the furnace, or in order to save time in the melting or founding, that too small a proportion of silica is employed. Glass which has this fault may be known by its rapidly attracting moisture. The different descriptions of glass made are known by the names of plate glass, German sheet or British plate, crown or window glass, bottle glass, and flint glass; there are others, but they are merely modifications of these, and need not be noticed.

Plate Glass is composed of sand, carbonate of soda and chalk, with small quantities of arsenic and manganese; the proportions vary at different works, but the general proportion is —Lynn sand, 400; carbonate of soda, 250; ground chalk, 35, by weight. The quality of the glass depends upon the quality of the alkali. Plate glass is melted in large open pots. The furnaces are square, containing sometimes 4, sometimes 6 pots each; when the glass is melted, which takes 22 hours, it is removed to another furnace, where the pots are smaller, of a cylindrical form. Here it is fined, which occupies 4 to 6 hours, and when free from air bubbles and impurity the pot with the glass is removed bodily from the furnace by means of a crane, and hoisted to the end of the casting table, upon which the glass is emptied; a large iron roller which works inside the flanges of the casting table, is then made to pass over the melted glass, in order to flatten it out; it is then removed upon a wooden table on wheels to the annealing arch, which is now at a high temperature, and here it is excluded from the atmosphere until cold. The glass is rough and uneven, but is afterwards cut flat by machinery, and then smoothed and polished; it is these processes which render plate glass so costly.

Crown, or window glass is of much the same composition as plate glass, except that a cheaper description of alkali is used; the ordinary mixture is, 500 cwt. Lynn sand, 2 of ground chalk, and 1 cwt. each of sulphate and carbonate of soda. The square furnace and the open pots are used, there being generally 6 pots on each furnace. It takes from 14 to 20 hours to melt this glass, and it then requires to stand 4 to 8 hours to allow it to become free from all air bubbles, and to cool sufficiently for working. Window glass is formed by blowing: upon the blowing-iron is gathered at three several times (the fluidity of the glass never allowing fewer) the weight of glass necessary to produce the table, and which weighs 11 lb.; this is then blown out, leaving a solid lump at the farthest extremity from the blowing-iron, for attaching the punty; this is called the bullion. The punty being fixed to the bullion, the blowing-iron is relieved by merely touching the glass with a wet iron; being firmly attached to the punty, it is removed to a small cylindrical furnace, called a flashing furnace, where a rotatory motion being given to it, increasing as the glass becomes softened by the heat, the centrifugal force, together with a little sleight of hand on the part of the workman, produces a flat circular plate or table, as it is then called.

British plate, or German sheet-glass is of the same composition as plate glass, but the manipulation is different. The glass is blown into open cylinders, and, when cold, these are cut open along the length with a diamond, and placed in a flatting furnace, which is at a sufficient heat to bring the glass into a semi-fluid state, so that it falls quite flat. The sheets thus made are afterwards cut flat and polished. The size of the sheet is restricted to what can be blown and worked by one man; it is cheaper than plate glass, because all waste is avoided, and less cutting is required.

Bottle glass is composed of the cheapest materials which can be procured—ordinary pit sand, refuse alkaline waste from soap works, refuse lime from gas works, &c. The proportions of the materials vary according to quality. Bottles are blown in moulds: the glass having been blown in the mould, nothing remains but to form the mouth; this is done, the bottom being attached to an iron punty, by holding the extreme edge of the neck to the heat for a short period, and, having collected a small quantity of liquid glass upon the end of a small iron, called a ring iron, a ring of glass is allowed to cover this extreme end, and this is afterwards worked into shape by a machine which forms the inside and outside of the mouth at the same time, merely by the workman turning the bottle on the iron upon his knee once or twice. The rapidity with which bottles are made is almost incredible; a workman, with the assistance of a gatherer and blower, will begin and finish 120 dozen of quart bottles in 10 hours, which averages nearly 2¼ per minute, and this is ordinarily done; and in some works the men are restricted to 2 per minute, to prevent the work being slighted. It may not be uninteresting to observe the low price at which this description of glass can be procured, now that the duty has been removed: quart bottles can be produced at the works at about 14s. per gross: each gross weighs 2 cwt., which is equal to 7s. per cwt., or £7 per ton, for manufactured bottles; if from this we deduct for workmen and incidental expenses, £2 per ton, it would leave the price of bottle glass £5 per ton.

Flint glass is thus designated from calcined flints having been formerly used in its composition; this is now replaced by fine sand. The term flint glass is now applied to all glass into the mixture of which lead enters, and is used in the manufacture of table glass, &c. In the manufacture of flint glass the circular furnace is used, the pots surrounding the grate room; on either side of the pots are flue-holes, which pass through the pillars, the smoke being carried up by flues outside these. The heat thus reverberates from the crown of the furnace, and is drawn round the pots previous to passing through the flue-hole. The melting pots are covered in, to protect the glass from dust, which would affect the colour. The materials used in flint glass are sand, red lead and litharge, carbonate and nitrate of potash, arsenic, and manganese; and the greatest care is taken in the selection of them—the beauty of the glass depending mainly upon the quality of the materials. The best sand comes from Alum Bay, Isle of Wight; this is carefully washed and dried previous to using. Red lead, or litharge: this assists as a flux, and gives density, brilliancy, and ductility,—the latter quality being particularly required in flint glass; it is, perhaps, owing to the superior quality of the oxides of lead prepared in England that we are in advance of other nations in the manufacture of fine flint glass. The carbonate and nitrate of potash are used wholly as fluxes; soda, though more active, is never used where quality is required, as it affects the colour. For almost every purpose, the best glass of every description is that which contains the greatest amount of silica. If the sand, lead, and alkali, even though the quality were never so pure, were melted, the glass which would be produced would not be colourless, but of a pale green; and this, in all probability, is not so much the result of impurity, as the deoxidating effect of the fusion. To obviate this, it is necessary to use oxide of manganese, which, by supplying oxygen, retains the different substances in that state of oxygenation necessary to a colourless glass; if too much manganese be used the colour is slightly purple, designated by the glassmakers "high; the green tint, again, is called "low:" in other words, the glass is high when it contains more than sufficient oxygen, and low when too little. Minute quantities only are necessary; from a quarter to half an ounce per cwt. is sufficient. Arsenious acid is sometimes used in flint glass, its use being to expel the carbonic acid gas present in the materials; if too much is used it gives opacity.

Glass must be considered, unfortunately for science, an imperfect body. The principal imperfection, more especially of flint glass, arises from what are called cords, or striæ in the body of the glass, which give it the appearance of alcohol and water imperfectly mixed; through these striæ the rays of light will not pass, but are diverged and broken. This defect is attributed to the difference in specific gravity, or want of homogeneity of the particles: this, no doubt, is true; but the question is, to what cause is this attributable? I would suggest, that it may arise from the unequal distribution of heat to the materials during fusion and whilst in a fused state, and to the particular action consequent thereupon. The number and variety of articles manufactured in flint glass are great, and require considerable practical experience on the part of the workmen. It is impossible to describe the manner of operating, which appears even to those who have often seen it almost magical. It is certainly surprising to see an apparently opaque and fluid body in a moment become transparent and solid, and, whilst undergoing this rapid change, to see it take beauty of form.

Coloured Glass.—The substances used for producing coloured glass are the metallic oxides, the quantity being proportioned to the depth of colour we desire to obtain. For *blue* glass we use oxide of cobalt; this produces a rich colour: the material, however, being expensive, it is seldom used by the glassmaker alone, but generally with an equal quantity of manganese; this materially affects the richness of the colour. *Green* is obtained from the oxides of copper and iron, mixed, the protoxide of copper and the peroxide of iron: equal quantities may be used, the proportions being varied according to the tint desired to be obtained: the copper produces a blue-tinted green, and the iron the *yellow* tint. *Purple* is obtained from the oxide of manganese; the purer this substance is, the finer will be the colour. The pyrolucite already referred to, especially when used in small quantities, gives a beautiful and delicate amethyst colour. Ordinary yellow is got from carburate of iron and oxide of manganese. *Ruby* is obtained from the oxide of gold, called the cassius precipitate; it is a colour which is neither obtained nor retained with any certainty—in fact, the modern glassmaker is quite at a loss for this colour. There can be no doubt the ancients manufactured ruby of a much finer colour than any now made, from suboxide of copper; this art has been lost for centuries: the difficulty is, the preventing this substance from peroxidising. The oxides of uranium produce beautiful tints in yellow and green. Copper scales give *azure blue*; oxide of chromium, *emerald green*. Opaque glass is produced by the addition of phosphate of lime, arsenic, and other substances. The addition of many of the metallic oxides renders glass less ductile; and in making use of these it is always well to employ an additional quantity of lead. We often hear of the superiority of the colour of ancient sheet glass to the modern, and are bound to conclude, when we see, particularly in church windows, the difference, that there is good ground for the assertion. With the exception of ruby, the modern colours are all finer than the antique. I speak of body colours—that is, glass made of coloured mixtures, called pot metal; but this is seldom used, all our modern church windows being made of white glass stained with metallic colours; this saves trouble and expense in the fitting. Glass of various colours in the same piece is obtained by casing one metal or glass with another. A small quantity of one colour having been gathered, it is blown into a small ball, and dipped into a pot of a different colour; this being rolled on an iron slab, so that an equal thickness of the second covers the first, the ball is a trifle enlarged by blowing, and may be dipped into a third and fourth colour. Care must be taken that the character of these different glasses exactly agree, that the contraction in cooling may be alike.

RAILWAY PROCEEDINGS.

Selections from the decisions of the Sub-Committees on Standing Orders. House of Commons—Session 1846.

Gazette Notices.—In the Committee on the Runcorn and Prestonbrook Railway, it was stated by the solicitor for the bill that the notices had only been twice published in the *Gazette*. He had delivered the notices at the *Gazette* office on October 23, with instructions for three insertions. Mr. Watts, the editor of the *Gazette*, said he found by an entry in his book that the notice had been withdrawn. Has no means of knowing by whom it was withdrawn. Mr. Turner said he had given no instructions for the withdrawal of the notice. Mr. Watts said it might have been a mistake, arising from the pressure of business at that time. The committee decided that in this instance the standing orders were not complied with.

Public Roads.—In the Committee on the Wexford, Carlow, and Dublin Junction Railway, an allegation was made that a public presented county road, in the townland of Killurin, was described to be in the ownership of the Earl of Arran, whereas in fact it was a public road under the jurisdiction of the grand jury and road surveyor of the county of Wexford. The allegation turned on the ownership of these roads, whether in fact the right owners had been entered in the book of reference. The chairman observed, what is intended is, that the fee in the land is in certain other parties, but the public have a right of road. That comes to the state of English roads. There the property is not in the surveyors or trustees. A mine under the road does not belong to the trustees. The practice in England is to treat the ownership of the surface as that which entitles the parties to be served. The question is, whether there is anything which entitled you to take the Irish roads out of this condition. We cannot draw any distinction between the cases. If so, you ought to give notice to the persons in Ireland, who answer the same description there, as the surveyors of roads in England. As regards these allegations, we shall report that the standing orders have not been complied with, inasmuch as the grand jury of the county of Wexford have not been inserted in the book of reference as owners of certain roads particularly specified.

Ownership of Lands.—In the Committee (No. 2) on the Glasgow and Ayr Railway, the petitioner opposing the bill alleged that in several instances the promoters had inserted, in their book of reference, the name of the reputed and substantial owner of the land, in cases where there was a superior owner or feu lord, to whom a merely nominal payment, in respect of the land, was annually made. It was submitted that the book of reference ought to have contained the names of such feu lords. The chairman remarked on that point, that the committee had always considered the reputed owner, in such cases, as sufficiently the owner for the purposes of the book of reference, and not the superior lord, who, in most cases, had only a peppercorn rent reserved to him.

Notices.—In the Committee (No. 3) on the Midland and Bradford Railway, the petitioner opposing alleged that the *Gazette* notices had been given for six lines of railway, and the bill was only for one. In the cases decided last sessions, the Direct Northern, the Wells and Dereham, and Goole and Doncaster Railways, where they came to Parliament for a shorter line than they had given notice of applying for, were held as not having complied with the standing orders. The promoters contended that the cases quoted were not analogous to the present. The notices given announced the intention of the promoters to apply for powers to construct six railways, and this might be called the first of the series. In the case of the Direct Northern, who gave notice of making a railway from London to York, and afterwards only came for powers to make a line from Cambridge to York, a landowner on the line between Cambridge and York might be willing to concur in the whole line, but might object to have his land cut up by the shorter line. The committee were of opinion that there had been a sufficient compliance with the standing orders in this case upon that point.

Withdrawal of Petition.—In the Committee on the Grand Union Railway an opposition was about to be entered into by Mr. Thomas, when Mr. Burke objected, as the petitioner had withdrawn his consent after the presentation of the petition. It was contended on the other side that it was not competent to any person to withdraw a consent once given. The chairman after conferring with the chairman of another committee stated, that the committee had given their best consideration to this case, and they regretted that the standing order No. 9 was not more clearly worded. If they abided strictly by its words they would not decide according to the intention of the house, as there would be constantly raised questions as to the manner in which consents had been obtained. Their decision therefore was, that it should be in future in the power of any petitioner to withdraw his consent to the petition. The petition was then withdrawn.

Levelling Books.—The Committee (No. 2,) sitting on the Edinburgh and Glasgow and Dumbartonshire Junction Railway, in a case of dispute as to the correctness of the levels, decided that the promoters of the Bill should produce the notes of the levels.

Parish Boundaries.—In the same Committee, and on the same Bill, a petition alleged that in the plans deposited with the sheriff clerks of Dumbartonshire and Lanark, the parish boundaries of the parish of Dumbarton were not written in words, whereas the boundaries had been so written in the plans lodged at the Private Bill-office. This allegation was sustained, as was also the second, which had reference to a discrepancy in the plans lodged with the sheriff-clerk of Dumbartonshire, and that deposited at the Private Bill-office, in regard to another omission in the county plans of the words "parish boundary."

Cross Sections of Roads.—In the Committee (No. 7) on the Cornwall Railway, the opponents to the bill objected that the 42nd of the standing orders had not been complied with in respect of a proposed alteration of a turnpike road not having been shown in figures nor on the cross sections.—Mr. Brunel stated that any surveyor or engineer would understand the section. The Chairman, having inquired whether there was any case reported, in which, after argument, it had been held that the standing orders had been complied with, although such alteration or inclination had not been set down in figures, ordered the room to be cleared, and upon the doors being re-opened, stated, that the Committee were of opinion that the standing orders had not been complied with in respect of any of these cross sections.

Petitioners.—The Committee (No. 4) on the Dublin and Enniskillen Railway decided that it was absolutely necessary, in order to comply with the standing order No. 9, that the petitioner, authorising an agent to appear for him, should be proved to have been cognizant of the actual allegations contained in the petition. In the absence of this proof the petition could not be entertained.

Withdrawal of a Portion of a Line after Notice.—In the Committee (No. 2) on the Northumberland and Lancashire Railway, two important allegations were made against the bill; the effect of the *first* was substantially this—that whereas the promoters of the bill gave notice in the newspapers, and to the petitioner, amongst others, of their intention to make a railway, commencing at a point called A, and terminating at a point called C, with divers branches therefrom; but their petition only asked for the authority of the House to bring in a bill for executing a portion of that work only, and that a very small portion. The promoters had, in fact, greatly modified their original project, and had abandoned a considerable portion of it, but had not given fresh notices to the landowners on the line or in the newspapers of such modification and abandonment. After the question had been argued at some length, the Chairman announced that the standing orders had been complied with. The second allegation was that a sum equal to one-tenth part of the amount subscribed in the subscription contract deed had not been deposited with the Court of

Chancery, inasmuch as the sum actually subscribed was the sum of £1,285,840, which would require a deposit of the sum of £128,584, whereas the amount which the promotors had deposited was only £93,066. The question depended upon the construction of the standing orders 39 A and 29 A. The point appeared of some importance, and the Chairman retired, with the view of consulting the Speaker upon it. After hearing the arguments of the agents on each side, the Chairman (Sir John Y. Buller, Bart.), on his return, said the Speaker quite agreed with him that the intention of Parliament was quite clear on the point, and that three-fourths of the amount of the estimate was all that was required by standing order 29 A to be subscribed, and that one-tenth part of the amount subscribed should be deposited with the Court of Chancery by the order 39 A. In this case the sum actually subscribed was £1,285,348, but, in consequence of the promoters abandoning a considerable portion of the works, the sum required for the undertaking was reduced to £758,000, and they had deposited £93,066, a sum larger than they would be called upon to deposit in respect to £758,000, the estimated cost of the work, even if the construction of the standing orders required, as was contended by the petitioners' agent, one-tenth of the sum subscribed to be deposited. He (the Speaker) thought the House had no right to find fault with and punish parties for doing more than the requisitions of the House demanded. The Committee, therefore, thought that, on this point, the standing orders had been complied with.

NOTES OF THE MONTH.

We are sure that many of our readers who were acquainted with the late Mr. Loudon, will feel gratified to hear that a pension for life of £100 per annum, has been granted by her Majesty to Mrs. Loudon. Sir Robert Peel has just communicated to Mrs. Loudon this act of beneficence. To her it will be doubly grateful, as it is conferred in consideration of her deceased husband's labours and writings on subjects of science.

At the Marquis of Northampton's second soirée there was exhibited a cast of "Charity," moulded out of pounded marble combined by a cement, so as to imitate the original marble.

The Archæological Institute, under the presidency of Earl Fitzwilliam, will hold their next annual meeting at York, on Tuesday, 21st of July next.

It is proposed to construct a glass saloon at the Botanic Gardens, Manchester, of sufficient size to receive the usual exhibition of flowers, plants, and fruit, and all the promenades, and to be also available for lectures. It is to be 150 feet by 45 feet; and 22 feet in height to the centre of the dome, or 32 feet to the centre of the dome ventilator. The whole of the front is to be made of glass, and moveable, so that it may be removed in fine weather. The west end of the building is to have a semicircular alcove or recess, for the reception of the band. The area of the building will be equal to 6,750 square feet, and will accommodate nearly 2,000 persons. The whole space of the interior is to be made available; no pillars or other obstructions are to be introduced; but the ribs of the frame-work are to be tied beneath the floor. Messrs. Irwin and Chester, architects, of Manchester, have been entrusted with the designs by the Council, for approval.

A very interesting experimental trial of Nasmyth's steam hammer of 50 cwt., lately took place at the Chatham dockyard, where it has been recently erected. The trial commenced with breaking up old and condemned anchors, under the superintendence of the patentee and Captain W. H. Sherriff, superintendent of the yard. Anchors of various sizes were broken up in lengths with perfect ease—in some instances by one fall of the hammer; after which, a part of the shank of an anchor, of about 30 cwt., was heated to a welding heat, and beaten out by the hammer to a rod of about four inches in diameter. Here proof was given of the perfect control under which the inventor had the hammer in finishing off or rounding up. It was brought out from under the hammer quite equal in finish as it would have been by the small forge hammer. In beating out iron for conversion, the blows are so powerful and effective that it drives out all spurious materials from the iron, and perfectly consolidates the whole mass; in proof of which, the four-inch rod was cut into various lengths and exhibited a beautiful specimen of solid metal, whilst the part of the shank, that had not been under the hammer, showed nearly every bar and rod with which it had been made, except within about an inch of the outer surface. Mr. Nasmyth has orders to provide a patent steam hammer for each of her Majesty's dockyards.

The *Roman Amphitheatre at Dorchester* which by the timely interposition of the British Archæological Association has been preserved from destruction, is one of the most interesting of our national antiquities. The area is about 218 feet by 163 feet; it is of an oval form, and is surrounded by a mound of considerable thickness, formed of blocks of chalk cut from the centre, which is consequently much lower than the external surface. This wall is about 20 feet high. The amphitheatre at Silchester is of nearly the same form and dimensions as that at Dorchester, but it is not in such a perfect state of preservation. The area of the Coliseum at Rome is a trifle larger, being 263 feet by 165 feet. Mr. I. K. Brunel, the engineer of the Weymouth Railway, which was planned to cut through the amphitheatre, very readily and courteously admitted the plea of the association for the preservation of this ancient monument, and took proper measures to divert the line.

Architectural metamorphose has just transformed the originally dowdy and most mean-looking exterior of Bedford Chapel, Bloomsbury Street, into not merely a sightly, but a rather striking object, one moreover that displays considerable novelty of design,—in which some good as well as fresh ideas are thrown out. At the same time it is to be regretted that it betrays great inequality of taste. While there has evidently been a good deal of petty parsimony in some respects, money has been not only uselessly, but rather mischievously expended on what are intended for ornaments, but in reality eyesores,—we mean the trumpery obelisks stuck up at the angles of the building, and producing at a little distance the effect of pinnacles, consequently quite inconsistent with the style. On the other hand, something certainly ought to have been done to what was left of the old gable and the belfry lantern upon it, for the latter is not at all in keeping with the new exterior, and the other shows most awkwardly as a mere triangular bit of wall, seen poking up behind the front, but not at all belonging to or connected with it. Another very great blemish marring the front— which would else possess considerable merit—is occasioned by the two smaller doors next to the middle one, being out of the centre in regard to the intercolumns or arcades, in which they come. This very disagreeable irregularity might easily enough be remedied even now, by merely hanging additional outer doors before the two mentioned, so as to be flush with the wall, and painted or coated over so as to be of the same colour, in other words those should be what are called *jib* doors,—as is the case with the additional carriage entrance in the front of Northumberland House.

Sir Robert Peel has announced to the House of Commons her Majesty's intention of appointing a Royal Commission for considering the various projects for railway termini in the Metropolis.

In consequence of the valuable collection at the Museum of *Economic Geology* having increased so rapidly, it has been found necessary to build a larger museum, for which purpose a large plot of ground has been cleared of its buildings in Piccadilly, near St. James's Church.

It is proposed on the projected railway from Lyons to Vaise, to have a tunnel on that part of the line under *Croix Rousse*, with shafts to communicate with the commune above, through which the passengers are to be raised and lowered, seated in elegant boxes or apartments.

Travelling by Steam on the river Thames between London and Westminster Bridges is reduced to the low fare of one penny for each passenger.

The Metropolitan Improvements of New Oxford Street are fast approaching completion, and it is expected that the roadway will shortly be thrown open for the passage of vehicles; the whole of the buildings having an architectural frontage, presents a pleasing appearance.

It is stated that the laying down of wooden pavement and subsequent removal for the old granite, cost the city of London £40,000 last year.

The new street from Farringdon-street to Clerkenwell is to be called Victoria Street.

The site for a new church has been selected by the Metropolitan Church Commissioners in Old-street, City-road, the first stone of which will be almost immediately laid.

The repairs and restoration of Chester Cathedral are nearly completed, with the exception of the pulpit, for which orders have just been given, it is to be constructed of Painswick stone, from a design by Mr. Hussey, of Birmingham, under whose superintendence the restorations in the choir have been effected.

The Terrible War Steamer.—The Terrible war steamer is in commission, and lately made a trial of her speed down the Thames from Woolwich to below the Nore; she has twenty guns mounted, also a brass field-piece and carriage, and a wagon for powder to accompany it. On her upper deck, each side the bow, are two long 56-pounders, Monk's 11 feet guns, to fire fore and aft in a line with the keel; these are mounted on a slide, and will cross fire with each other, and also sweep round to the sides; two more of the same guns, right aft in the stern, will also cross and sweep to the broadside on their pivot, so as to fire forward, acting as chase guns if required. She has two 68-pounders on each broadside, to carry shells or solid shot, which can be trained fore or abaft, according to circumstances. On the deck below, which is also flush fore and aft, are eight guns, viz., two long 56-pounders, Monk's guns, 11 feet long, in the bow ports, to fire in a line with the keel, and also several degrees of training on the broadsides, and two of the same guns in the stern, right aft, which can give such depression as to prevent even a small boat from coming under her stern; with four guns, 68-pounders, on her broadsides, for shells or solid shot. There are four smaller guns on the upper deck, to be traversed to any place or carried on shore in her paddle-box boats, if required for use in landing troops, &c. She has four separate boilers, independent of each other, which may be connected when required; four funnels, one to each boiler; the two after ones strike down, so as to allow a square mainsail to be set when sailing, and still using the two foremost boilers, thus working half her power, at the same time saving a considerable consumption of coals. This is an excellent contrivance, as there are four small funnels, instead of one large one, which is a great advantage, as the ship will not be wholly disabled by losing one, two, or even three funnels, like the one funnel ship would be on hers being carried away; her one funnel lost, she has lost all. The Terrible has two magazines, and two shell-rooms, one of each before the engine-room, and one abaft for the safety of the vessel, to prevent any powder passing the engine room when firing the guns. She can store 400 tons of coals below the lower deck, and is prepared on the midship part of the deck to take 200 or 300 tons more, packed in bags, as a defence from shot to the engines and boilers, filling up a space of 18 feet. In addition to her thick, substantial, solid sides, she has good capacity, and if required for any particular service can carry more coal in sacks. With regard to the conveyance of troops, she can berth 1,000 men under cover on her second gun-deck, independent of her ship's company, their berth being below forward, and the officers' cabins, gun-room, &c. abaft; so that each gun-deck is entirely clear and always ready for action, without removing a bulkhead, and the deck being perfectly free from the captain's cabin abaft, to the bow of the vessel. She is constructed in the strongest and most substantial manner, on Mr. Lang's improved method of uniting the frame timbers, making her perfectly water-tight, so that she would swim even if her external keel and plank were off her bottom. This method is also adopted in the Royal Albert, 120 guns, now in her frame, and may be seen on the slip in Woolwich dockyard. The engine-room of the Terrible is most splendid;

on deck, the whole length of the engine-room, are gratings open and well ventilated by hatchways, giving light and air to the engineers, stokers, &c. It is an admirable plan, such as no steamer as yet has the advantage of; and each boiler has a separate hatchway, and may be readily taken out for repair, without interfering with the other boilers. This method of Mr. Lang's invention prevents the necessity of ripping up the deck, which is the case with other steamers when the boilers are required to be taken out from those vessels, and there too, the deck covering the boilers, the engineers and stokers have the light admitted by the hatchway over the engines only. The Terrible's engines are most majestic; they are 800-horse power, the production of Maudslay, Sons, and Field, and show to advantage in this large war steamer. Her decks have hatchways in various parts, scuttles, sky lights, &c., for ventilating the ship even to the lower parts of her hull; and there are many other conveniences too numerous to mention, contributing to the efficiency of the ship and the comforts of the officers and crew, so that she may be said to be the largest and most perfect war steamer ever built. The Terrible is commanded by Captain Ramsay, late of the Dee steam-vessel, and she is to have a complement of 240, officers, men and boys. At the trial, when she was off Sheerness, her rate of speed, by Massey's log, was 10·8 knots per hour; the engines making 14 to 14½ strokes per minute.

LIST OF NEW PATENTS.

GRANTED IN ENGLAND FROM FEBRUARY 25, 1846, TO MARCH 25, 1846

Six Months allowed for Enrolment, unless otherwise expressed.

John Samuel Templeton, of Sussex-place, Kensington, artist, for "improvements in propelling carriages on railways; and improvements in propelling vessels."—Sealed February 27.

Peter Armand Lecomte de Fontainmoreau, of New Broad-street, London, for "a new mode of manufacturing and glazing cotton wadding, and its application to the making of mattresses." (A comunication.)—February 28.

James Soutter, of Limehouse, engineer, for "an improved pump, applicable to steam-engines, or other purposes."—March 2.

John Fuller, of Beacham-well, Norfolk, farmer, for "improvements in apparatus for sowing corn or other seed."—March 5.

William Nicholson, of Manchester, Lancaster, engineer, and George Wardsworth, of Sutton glass-works, in the same county, manager, "certain improvements in the manufacture of glass and other vitreous products."—March 5.

Robert Lewis Jones, of Chester, railway agent, for "improvements in reducing charcoal and other similar matters, to powder, and in treating the same when in a state of powder, so as to render them suitable to be used in place of vegetable black-drop, black, lamp-black, and other matters."—March 5.

Robert Warrington, of Apothecaries'-hall, London, chemist, for "improvements in preserving animal and vegetable substances."—March 5.

William Green, of Hyde, Cheshire, baker, and Mark Walker, of the same place, grocer, for "certain improved apparatus for facilitating the putting on of boots to the feet."—March 11.

Godfrey Woone, of Kensington, Middlesex, gent., for "certain improvements in the art of engraving in relief."—March 11.

Jean Joseph Ernest Barruel, of No. 172, Rue St. Jacques, Paris, chemist, for "improvements in working of certain sulphurets to transform them into metal or oxides, and to collect the latter; also to collect the oxides from oxydised ores, equivalent to these sulphurets."—March 11.

William Nairne, of Millhaugh, Perth, North Britain, flax-spinner, for "a new mode, or new modes, of propelling carriages along railways.—March 11.

Parfait Grout, of Rouen, France, but now residing at Leicester-street, Leicester-square, doctor of medicine, for "improvements in the manufacture of plaster-of-paris, lamp-black, and coke." (A communication.)—March 11.

Frederick Crace Calvert, of Paris, for "improvements in the preparation of the article called 'Jute,' rendering the same suitable for various useful purposes."—March 11.

William Price Struve, Swansea, civil engineer, for "improvements in ventilating mines."—March 11.

Erasmus B. Bigelow, Boston, Massachusetts, for "certain new and useful improvements in looms for weaving certain kinds of carpets, or other fabrics of like character." —March 11.

George Hinton Bovill, of Millwall, and Robert Griffith, Havre, France, engineers, for "improvements in apparatus applicable to the working of atmospheric and other railways, canals, and mines, and in improvements in transmitting gas for the purpose of lighting railways and other places."—March 11.

Benjamin Shaw, Bradford, York, overlooker, for "improvements in preparing for spinning worsted and other yarns."—March 11.

Thomas Vaux, Frederick-street, Gray's inn-road, Middlesex, land-surveyor, for "improvements in the manufacture of horse-shoes, and horse-shoe nails."—March 11.

Charles Robert Robinson, Strines, Derby, calico-printer, and William Bowden, of the same place, mechanic, for certain improvements in machinery for washing and cleansing cotton, linen, or woollen fabrics."—March 11.

John Benfield, Birmingham, Warwick, organ-builder, for "certain improvements in making signals and communications on railways, and between railway-engines, carriages, and trains, which are also applicable to other localities."—March 11.

Henry Austin. 10, Walbrook, London, civil engineer, and Joseph Quick, Summer-street, Southwark, Surrey, engineer, for "improvements in the construction of railways, railway-carriages, and conveyances."—March 11.

Thomas Hancock, Stoke Newington, Middlesex, esquire, for "improvements in the manufacturing and treating of articles made of caoutchouc, either alone, or in combination with other substances, and in the means used or employed in their manufacture."—March 18.

John Longbottom, of Edward-street, Leeds, mechanist, for "improvements in the manufacture of oil-cake, and in the machinery and processes for pressing and moulding the same: which machinery and processes are also applicable to the manufacturing of other articles from plastic materials."—March 18.

Bennett Woodcroft, of Manchester, printer, an extension of letters patent for the term of six years from the 22nd day of March, 1846, being the expiration of the first term of fourteen years for his invention of "certain improvements in the construction and adaptation of a revolving spiral paddle for propelling boats and other vessels on water."—March 21:

John Haskins Gandell and John Brunton, of Birkenhead, Cheshire, civil engineers, for "an improvement in the construction of, and in the mode of opening and closing of moveable bridges or arches for the purpose of carrying railways, tramways, or other roads across canals, locks, docks, or other open cuttings."—March 25; two months.

Charles Robert Robinson, of Strines, Derby, calico printer, for "certain improvements in machinery for tiering, in the printing of calicoes and other fabrics."—March 25.

Charles Iles, of Bordesley, Birmingham, machinist, for "an improvement in the method of carding certain descriptions of dress fastenings, and other articles, and in the fabrics employed for that purpose."—March 25.

Thomas Howard, of the King and Queen Iron Works, Rotherhithe, engineer, for "improvements in steam-engine condensers."—March 25.

Robert Warrington, of South Lambeth, Surrey, gentleman, for "improvements in the operation of tanning."—March 25.

Thomas John M'Sweeny, of Killarney, gentleman, for "improvements in steering ships and other vessels."—March 25.

George Fergusson Wilson, of Belmont, Vauxhall, George Gwynne, of Chester Terrace, Regent's Park, James Pillans Wilson, of Belmont, aforesaid, and John Jackson, of South Ville, Wandsworth, gentlemen, for "improvements in producing light, and in materials and apparatus applicable thereto; and in treating fatty and oily matters."—March 25.

Alexander Parkes, of Birmingham, artist, for "improvements in the preparation of certain vegetable and animal substances, and in certain combinations of the same substances alone, or with other matters."—March 25.

Thomas Pope of Kidbrooke, Kent, gentleman, for "improvements in apparatus for moving railway carriages on to railways, and in machinery for lifting and moving heavy bodies." (A communication.)—March 25.

Louis Serbat, of Saint Soulve, in the department of the Nord, in France, chemist, for "a new method of constructing the roofs of houses, buildings, sheds, and all other erections."—March 25.

William Unsworth, of Derby, silk manufacturer, for "certain improvements in looms for weaving."—March 25.

Charles Smith, of Newcastle-street, Strand, Middlesex, for "improvements in cooking and culinary utensils, and methods of heating and suspending, or fastening articles of domestic use, and similar purposes."—March 25.

Joseph Needham Tayler, of Chelsea, captain in the navy, for "certain improvements in propelling vessels; and also certain improvements in constructing vessels, so as to be used in combination with certain machinery or apparatus for moving sand-banks and other obstructions to navigation, part or parts of which machinery or apparatus may be used on railways, or may be adapted and applied to carriage or common roads."—March 25th.

Edward Crump Dell, of Highgate, Middlesex, surgeon, for "certain improvements in apparatus for lighting the magazines and other parts of ships; applicable also for the general purposes of lighting buildings, roads, or ways."—March 25.

Edwin Cotterill, of Birmingham, manufacturer, for "certain improvements in articles applied to windows, doors, and shutters, part of which has been communicated to him by a certain foreigner residing abroad."—March 25.

William Carpenter, of Bridge-street, Banbury, Oxford, watchmaker, for "certain improvements in threshing-machines."—March 25.

CORRESPONDENTS.

Messrs. Blair and Phillips have written to us denying that they have confounded the laws of motion and equilibrium in their tract, reviewed in this Journal last month, and entitled "An Essay on an Improved Method of Construction for Viaducts, Bridges, and Tunnels, being an Application of the Principle of Universal Gravitation, as illustrated in the Solar System." If they really have not made this mistake we cannot help saying that they have been particularly unfortunate in the choice of a title to their work. Their opinions have certainly the merit of novelty, but as they are not supported by any proof except those which may be supposed to be derived from an inspection of their diagrams, it seems no more than fair that they should point out where the standard writers on the theory of the arch—Moseley, Poncelet, Rondelet, &c.—have failed in their reasoning.

Christ Church, Plymouth.—In answer to our old contributor Candidus, (see page 68), we would observe that we assumed it to be an essential principle of Pointed Architecture that the north and south walls of a church should have windows, simply because we find this to have been universally the case, without one single exception, in the ancient examples of the art as practised by its inventors. It is also an indispensible principle of *all* good architecture that the light should be generally diffused, so that no part of a building may be rendered inconvenient or useless by its darkness. In a church lighted by clerestories only, the north and south aisles being deep recesses without windows, this defect must exist; and it will be only aggravated by bisecting the recesses by galleries—unless indeed the light be of that convenient nature that it can shine round a corner. The extent of unbroken surface of the north and south walls is also a great objection. It is a characteristic distinction between Christian and Greek architecture that large continuous surfaces without openings are contrary to the spirit of the former. The case of the lanthern of Ely Cathedral is a strong precedent—for our view of the question, for at Ely it is a matter, not of opinion, but fact, that the intersection of the nave and transepts is lighted not only by the lanthern but by the lower windows. The main principle for which we contended is that in Ecclesiastical architecture, the vertical lights are modified by the horizontal.

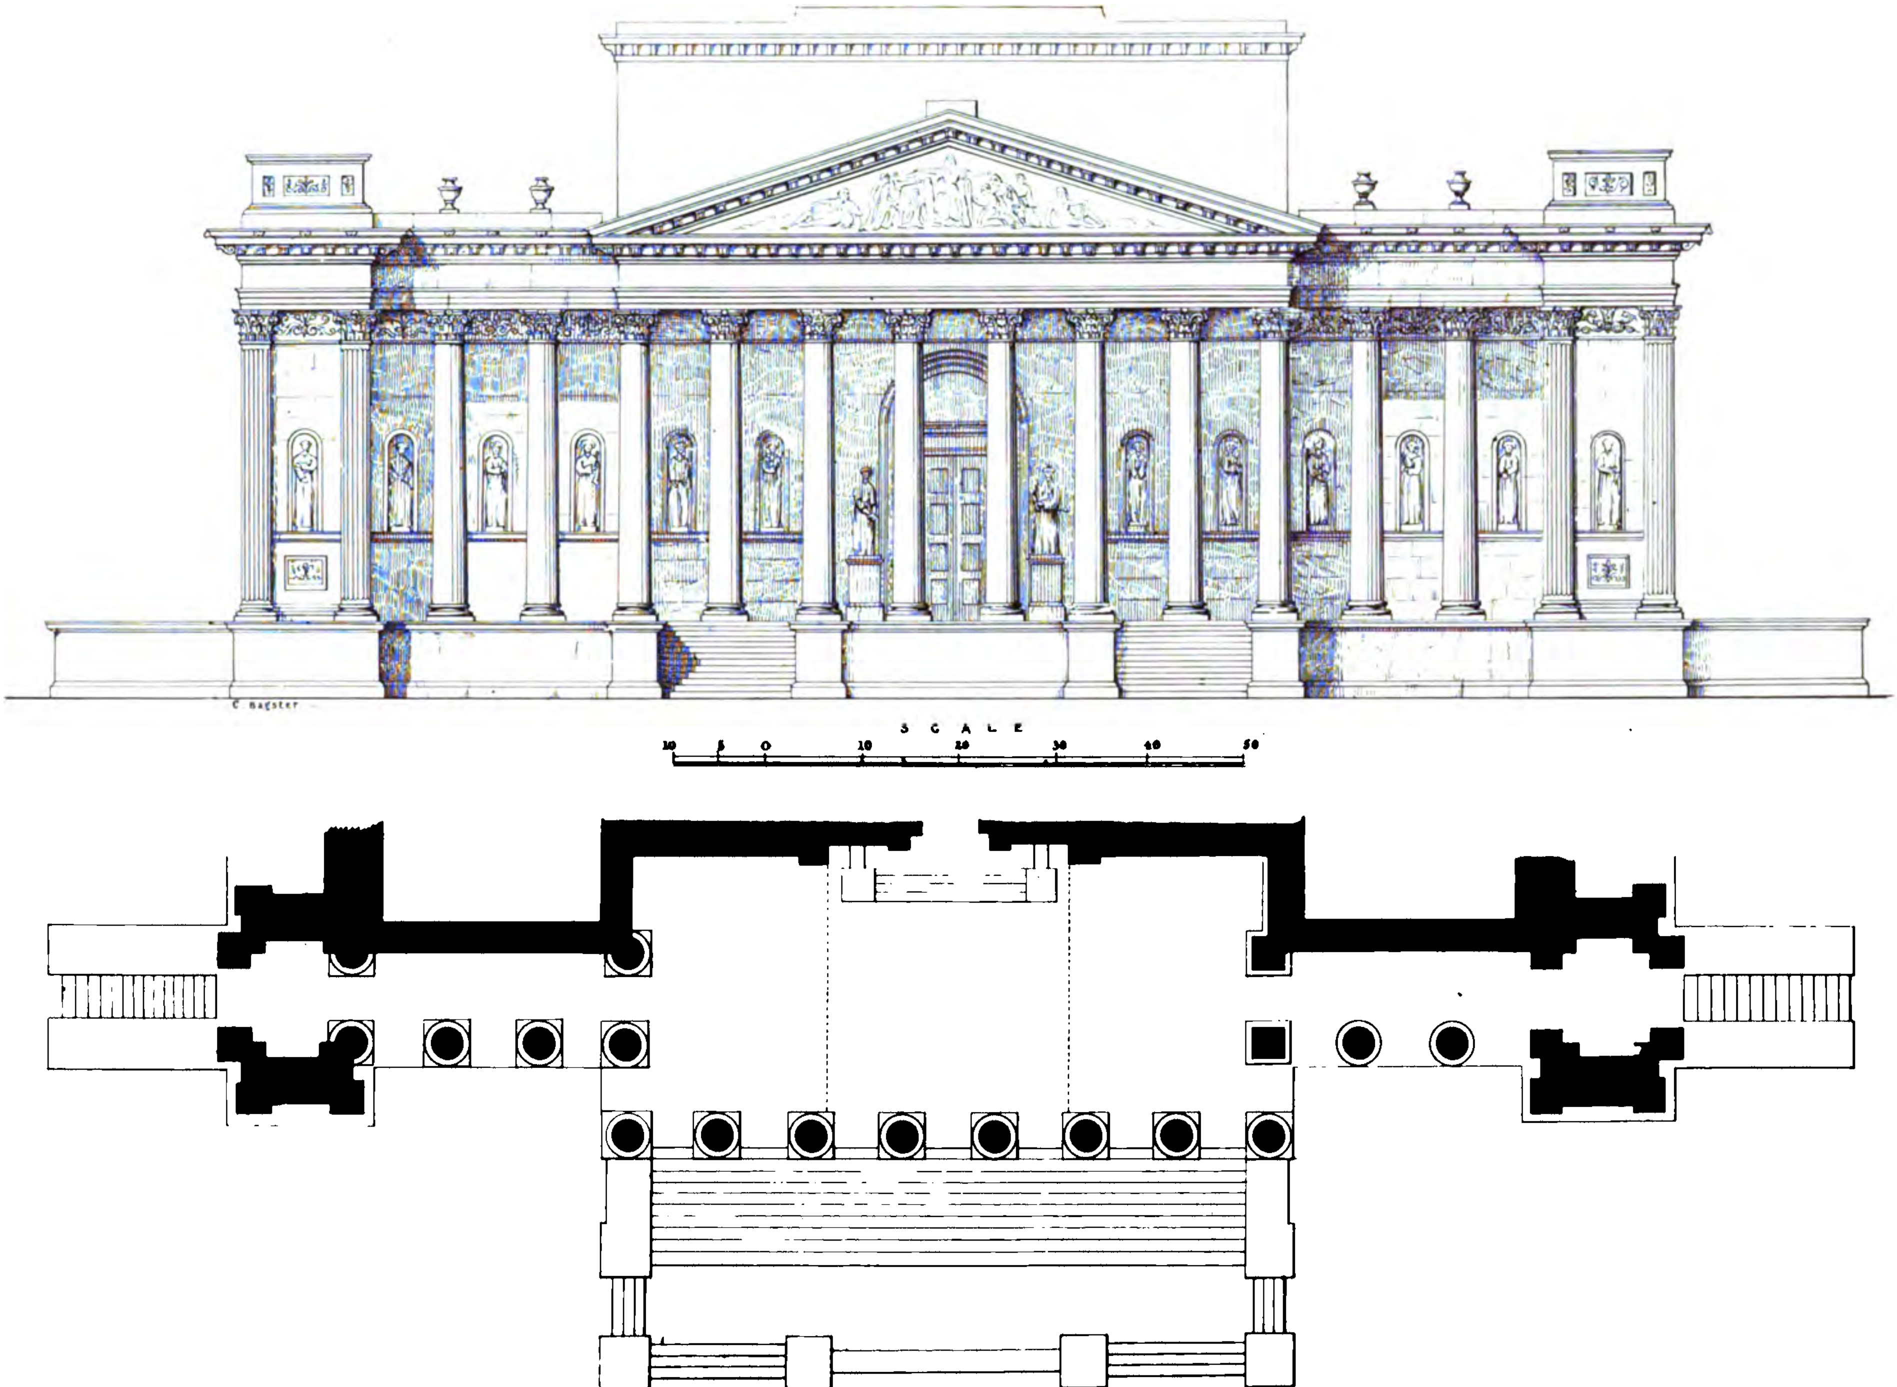
Amicus.—Simms on Levelling.

ERRATA.—Page 106. In the article on "Unfaithfulness in Architecture," in the concluding sentence of the last paragraph but one, after the words, "instead of supporting a building, it is supported by it," add "are instances of architectural unfaithfulness."

Page 108. "Parsey's Air Engine." In the last paragraph but three, for $\frac{100}{x}\,dx$, read $\frac{1000}{x}\,dx$.

Page 102. "Tubular Bridge over the Menai." In the last paragraph of the section on the "Practical limits to the length of the girder," for "independent of the arch of the cross sections," read "independent of the area of the cross sections."

FITZWILLIAM MVSEVM - CAMBRIDGE



GEO BASEVI - ARCHT -

THE FITZWILLIAM MUSEUM.

(*With an Engraving, Plate VI.*)

Possessing some points of resemblance, the façade of the Fitzwilliam and that of the British Museum are the antitheses of each other in regard to architectural composition and taste. The Cambridge edifice was infinitely more fortunate than the metropolitan one will have been; and perhaps very much better than it might have been had there been no competition—no trial of skill, but had the building-trustees merely placed themselves in the hands of some "crack name" in the profession. And whatever may be said against the little dirty jobbing that is so rife in the paltry hole-and-corner competitions in which ten or twenty guineas are offered for the *successful* design,—the Fitzwilliam Museum is a proof of the beneficialness of Competition when conducted with good faith, and with the sincere intention of obtaining a good design, no matter by whom it might be. At that time hardly would the name of George Basevi have been any recommendation, for he had given no great promise of particularly good taste in any of his previous works,—to own the truth, we ourselves should have felt more prejudiced against than prepossessed in favour of him. However, when the opportunity for accomplishing something of note did present itself, he responded to it worthily, and produced what is by far the most elegant structure in the classic or modern style that Cambridge can show,—beyond all comparison superior to the affected would-be Grecian style, and miserable pedantic dulness of Downing College. Had not the latter been so decided a failure, it is probable that its architect would have been engaged to make designs for the Museum, yet we question whether he would have produced anything so good by many degrees, for Wilkins was not at all gifted with imagination or invention: he had in him more of the archæologist than of the architect—that is, the artist;—he had too much of the mere rust of antiquity, and too little of the sterling metal of his art.

Pre-eminent among all the buildings at Cambridge with which it at all admits of comparison, the Fitzwilliam Museum, at least its façade—is hardly rivalled by any other of its time in this country, in point of novelty and felicity of idea, and for equally captivating and striking effect. Or if there be any other which has so much of *picture*, and of the poetry of the style in it, we shall be glad to learn where it is to be found, in order that we may honour it accordingly, and have something we yet wot not of, upon which we can bestow our cordial admiration.

Were it little remarkable in any other respect, the façade we are speaking of, most strikingly exemplifies the possibility of obtaining decided novelty of composition, and consequent originality of character, in perfect accordance with the style followed. The idea here adopted is so exceedingly *natural*, that our chief wonder is at its having been missed so long; and that it was, is to be accounted for only by that unlucky adherence to routine, which apparently prevents architects from seizing hold of fresh ideas, and new combinations. We do not say that all fresh ideas are to be laid hold of indiscriminately and actually adopted; all we mean is that those which can be made something of, and be satisfactorily matured, ought to be brought forward whenever opportunity offers. Nevertheless in regard to columnar composition architects seem to have voluntarily renounced all originality of design. Modern porticoes—and their name is "legion"—are almost one and all the most common-place affairs imaginable,—the work of the stone-mason rather than of the architect, consisting as they do only of so many columns in front—four, six, or eight, wrought after some prescribed standard example. Dulness seems to have set its mark upon almost every thing of the kind, for out of some hundreds of modern examples—or, we should say, instances—there are hardly half a score which exhibit aught of design, or even study. Indeed, the majority of them are no better than arrant "Brummagem,"—a few columns beneath a pediment tacked on to a front which in many cases would be a degree less intolerable, certainly less paltrily vulgar without them. Among the exceptions, the portico of the Fitzwilliam Museum deserves an honourable place: instead of being *after* some antique specimen, it has the better merit of being *before* almost all modern ones, in respect to beauty of arrangement, in which respect it can be but imperfectly appreciated from the elevation alone, much of the peculiar merit of the design arising from the plans, and not to be understood, except in the building itself, where it is plainly enough felt, without a drawing of the latter kind. The Fitzwilliam Museum has in consequence been taken in the article "Portico" in the Penny Cyclopædia, as an example of peculiar arrangement, and we might fairly call it one that at present constitutes a class by itself, or else the model for a class that would afford scope for design. Confined as they now are to mere columniation in its simplest mode, porticoes are made features stamped by most monotonous and wearisome sameness; yet after all that can be done, there must ever be enough of characteristic resemblance and conformity to the original type, the *frontispiece* or external elevation of the prostyle or portico division, invariably consisting of a line of columns beneath a pediment. In that respect there is but one stereotype idea to work upon, and all the variety that can be imparted to it amounts to no more than minor differences as regards matters of detail and execution. Still it is this mere stereotype frontispiece that chiefly obtains notice, and if that be but *secundum artem*, and upon a tolerably imposing scale, the whole obtains credit for being a fine portico, let its other deficiencies and defects be what they may. Such is most assuredly the case with regard to the extravagantly cried-up portico of St. Martin's, which is so far from possessing any unity of design, that it rather exhibits two decidedly opposite styles brought into violent contrast with each other, the inner elevation* forming the back ground to the external one or Corinthian hexastyle, being the very reverse of the latter in character and taste—positively barbarous in comparison with it. To say the truth, as usually treated, a portico is little more than an arrant plagiarism, and as frequently as not betrays equal sterility of imagination and vulgarity of taste, there being nothing at all in common between such pretentious feature and the building to which it is applied, but to which it does not seem at all to belong. Thanks, however, perhaps to the intense vulgarity and dulness together of many things of the kind, the portico-mania which prevailed some years ago, has latterly subsided. Nothing could be more desperately dull and dowdy than the majority of the things of that kind which were then perpetrated, when in order to provide for what after all looked no better than an excrescence, if not actually an encumbrance, all the rest was left quite bare or nearly so, instead of being decorated and finished up in accordance with the other. Thus instead of encouraging architectural design, the application of ready-made porticoes became a substitute for it; and instead of improving the appearance of the buildings themselves, they were actually the cause of their being left more bare and poverty-stricken than they else might have been without at all greater cost being incurred.

A portico is so decidedly a feature of parade, and such a direct avowal of pretension to classical dignity of manner that unless the latter can be fully maintained, it is what had better not be attempted; and in regard to convenience such architectural appendages are in general so exceedingly deficient in depth that so far from affording adequate shelter at the entrance to a building, they rather express the want of it, by making it too evident that what seems to be thought requisite is not obtained. In order to be effective a portico demands depth and spaciousness of plan; yet it is very rarely indeed that they can be—at least, are afforded, which becomes an additional reason wherefore things of the kind should be reserved for suitable occasions—for those rare opportunities when they can be treated with gusto, and made to partake of the poetry of the art.

The façade of the Fitzwilliam Museum answers truly to the latter character, nor is there aught of the ordinary and prosaic to disturb the impression produced by the general composition. As the front or external line of the plan, it consists almost entirely of columniation, regularly disposed (all the intercolumns being equal throughout), yet so as to combine play and variety with continuousness, in which respect we consider this design to be an improvement upon Schinkel's façade of the Berlin Museum,—we know not if Basevi took a hint from it,—which is too much of a mere colonnade (eighteen columns in antis), and would be rather tame and monotonous were not some effect thrown into it by the disposition and decoration of its background and interior. In the Cambridge edifice the projecting octastyle and its pediment are now so well proportioned to the rest, and maintain such superiority in the composition that more probably would have been lost than gained had the extent of front been greater, unless the whole could at the same time have been on an enlarged scale, so as to obtain increase of height as well as of length. For although extent of façade is generally held to be a positive merit, it may be carried to excess; and when it exceeds a certain ratio as compared with height, instead of at all conducing to grandeur, is rather apt to induce littleness of manner, as may be seen by the façade of the unlucky National Gallery, where in order to give due importance to the portico as the main division, the architect broke up the rest into insignificant parts; besides which, its length—or, speaking

* It is to be wished that this inner front wall were refaced and subjected to such "refacciamento" as would bring it into something like keeping with the character indicated by the order of the portico: the central doorway which although arched, is not loftier than the others, looks quite depressed in consequence, as compared with them, and altogether evidences most vile and barbarous taste.

of a façade, the correct expression would be its *width*—causes that building to look lower than it otherwise would do.

The Fitzwilliam façade, on the contrary, presents itself to the eye as a whole, sufficiently consistent and compact, without too much of mere repetition of parts; and the lateral extension of the portico, in immediate connection with the octastyle, produces a peculiar richness of columniation that instead of being increased, would rather have been impaired had those parts been carried on further so as to be equal to or wider than the octastyle itself, because in such case the arrangement would have resolved itself into the somewhat hackneyed one of a portico between wing colonnades. There is indeed one fault—or if it be not positively a fault, it is what might have been managed greatly for the better, as in our opinion it decidedly would have been, had insulated square pillars been substituted for the two columns behind the extreme ones of the prostyle, (which alteration together with the further one of pilasters, instead of attached columns, we have made in the sinister half of the ground plan). A square instead of a circular shaft at those re-entering angles would not only have produced the appearance of greater solidity, but have conformed better with the junction of the entablatures uniting at right angles. Another advantage gained would have been that of increased variety, and the other columns would have told all the more forcibly in consequence of the contrast so produced. Neither could it by any means have been called a caprice, or have been said to have been done for the mere sake of novelty, the motive for it being sufficiently obvious and legitimate. Rather would there have been a decided expression of intention, inasmuch as those two pillars or pilaster-piers would have plainly demarcated the three divisions of the general colonnade, whereas it now looks as if the architect had at first intended to carry it in a single line the whole way, and afterwards thought of breaking it, by advancing an octastyle crowned by a pediment. There would besides have been more of unity of design in one respect, because each of the lateral divisions would have been in antis, and the composition would thereby have gained in distinctness of articulation.*

It deserves to be remarked that though the shafts of the columns are plain, the pilasters are fluted—quite contrary to Grecian practice, in which a similar degree of contrast and distinction was produced by a precisely reverse mode of treatment; while in the Roman and modern styles the principle of uniformity has generally been followed, and columns and pilasters made, either plain or fluted, alike. Each of the three modes has something to recommend it, and it may therefore be left to circumstances to determine which is best suited to the particular design or occasion. In support of that here adopted, it may be argued that the principle of contrast being assumed, there is very sufficient reason for bestowing what constitutes it upon that which most requires it. Although left quite plain, the shafts of insulated columns always express themselves to the eye with sufficent distinctness; whereas, the faces of pilasters upon a wall require something to distinguish them from the general surface, without which they show themselves very feebly, and chiefly in their capitals and bases, which thereby become spots. The requisite difference of surface between that of the wall and the pilaster faces, is hardly to be obtained except by one of two modes, that of rusticating or showing the *joints d'appareil* of the wall, or fluting the pilasters, which thereby acquire richness as well as distinction, and are made, in artistical phrase, to "hold colour." Difference of application demands difference of treatment; the Greeks employed pilasters merely as antæ at an angle of a building, or at the ends of the side walls inclosing a portico *in antis*, where they exhibit themselves not only plainly but forcibly; whereas, as decoration upon a wall, pilasters require to be relieved from it. In the building under notice this is done by fluting them,† notwithstanding that the shafts of the columns are plain, wherefore it may be thought that, in comparison with the latter, an undue degree of decoration is bestowed upon the pilasters; yet, independently of the reasons already alleged for it, the greater richness conferred on the pilasters is no more than what serves to equalize them in importance with the columns. Still it strikes us that in this instance a very good though unusual effect might have been produced by fluting *some* of the columns, viz., the eight in front beneath the pediment, whereby the octastyle would have been distinguished from the rest of the colonnading, and the columns in that division of it would have been decorated in accordance with the pilasters at the extremities. Nay there is direct precedent for the combination of fluted or plain columns, not only in the same design but almost in juxta-position with each other, namely, in the beautiful loggia forming the north-west angle of the Bank,—a composition distinguished by picturesque effect of the most striking and sterling kind.

The portico of the Fitzwilliam Museum exhibits kindred taste—some of the best quality of that work of Soane's, without the tincture of *Soaneanism*. It is full of perspective effect, mainly produced by arrangement of plan, which, though apparently complex, is not at all *tourmenté*; on the contrary, exceedingly simple, it being in three divisions in both directions, *i.e.*, upon both the longitudinal and transverse section, through the portico. The first gives us the body of the portico and the two lateral colonnades; the other, the projecting octastyle, the lateral colonnades, prolonged to an avenue extending through the building parallel to its front, and the recessed portion corresponding with the projecting one. It is this beautiful combination of plan, in which regularity and variety, harmony and contrast, are all united, which constitutes the surpassing merit of this portico. Its external design is the least part of its merit; and even in regard to plan, it would have been of a superior kind even had it been less perfect, complete, and symmetrical than it now is. Do away with either the projecting or recessed portion of it, and it would lose half its peculiar charm; or had the colonnades terminated against the masses which form the extremities of the elevation, or else been continued by another open intercolumn instead of a closed one, while the façade itself would have been impaired, two most charming effects would have been entirely lost, *viz.*, those of vista, whether as seen from end to end on approaching by one of the side entrances, or on entering through the octastyle in front, when that *transept* suddenly reveals in the most captivating manner. The promise made by the exterior is found to be more than fulfilled by the interior of the portico, which is, in fact, so replete with effect as to be all *picture*, and at every step some fresh combination of perspective lines and of light and shade is produced: no single view, even were it the very best that could be selected for giving some general idea of it, could do more than convey an imperfect because necessarily a very partial and limited one. However, we should have been glad of even something of the kind in the "Memorials of Cambridge," where it would have formed a most interesting illustration; whereas only the façade is shown, and that in such manner that the effect attending the interior is very poorly expressed. Still in one respect the Fitzwilliam Museum has been more honoured in that work than any other structure in the University, it being almost the only one on which anything like satisfactory architectural description is there bestowed. Possibly this may have been in some measure owing to there being nothing but the building itself to speak of,—no ready-made history, or history at all, belonging to it; and perhaps it was considered indecent to make the article a mere peg for *hanging* Earl Fitzwilliam upon it in effigy, *alias* in memoir.

If our remarks have been somewhat *in extenso*—not, we hope, prosingly prolix—we are not likely to be equally diffuse again in a hurry on a similar subject. Very few things indeed of the kind afford aught for either description or comment. Our modern Anglo-Grecian and Roman porticoes are, for the most part, the merest architectural humdrum imaginable. We may fairly apply to them what Pope said of women, namely, that they "have no character at all;" though book-makers and guide-books are ready enough to extol every "four-posted" production as "a fine portico!"

In conclusion, we may express the hope that the gentleman to whom the completion of the Fitzwilliam Museum has been confided since its architect's death will adhere to his intentions, for he is not very likely, we conceive, to improve upon them. Most assuredly, he has never yet conceived anything at all comparable to that façade and portico.

---

* In the portico of the Royal Institution at Manchester, which we might have before observed is so very similar in composition to that of the Fitzwilliam Museum, that the idea of the latter seems to be derived from it, Barry has boldly defined the junction of the lateral loggias and prostyle, the point of union being a pier, whose solidity is increased by antæ pilasters backing the extreme columns of the prostyle (an Ionic hexastyle) and flanking those of the loggias. That building may therefore be quoted as affording an example of picturesque combination, and a highly favourable exception to the equally insipid and common-place things constituting the majority of the class. We regret that having no plan of it, we are unable to say how far in that respect it differs from or is inferior to the Fitzwilliam.

† Barry, who has true artistic feeling for effect and finish of detail, has fluted—and, no doubt, with reason to himself for what he was doing—the pilasters to the windows in both fronts of the Travellers' Club House. Apropos to which we may observe that we dissent from the opinion which has passed unqualified condemnation on the practice of decorating windows with columns, pilasters, and pediments. We cannot pretend to justify the propriety of it here in a note, therefore content ourselves with remarking for the present, that if it be contrary to sound architectonic principle, we must abate our admiration of Gothic, in which nearly all the minor features and decoration in general are made up of forms borrowed from and repeating those of the principal members of the structure.

STAINED GLASS WINDOWS AT SAINTE CHAPELLE, PARIS.

(Paper read at the Royal Institute of British Architects.)

By A. Poynter, Esq., Hon. Sec.

The excellent restoration now in progress at the Sainte Chapelle, in the Palais de Justice, at Paris, has caused it to be lately mentioned in this room on several occasions, on one of which a wish was expressed by some of the members present, for a more particular account of the stained glass with which the windows are decorated, and which, notwithstanding some serious dilapidations, has remained, on the whole, more perfect perhaps than any similar work of the 13th century. I fear the subject will scarcely prove so interesting as may have been anticipated, owing to the want of the illustrations necessary to do it justice; the development of the details, to any great extent, being obviously a work of time and labour. The Sainte Chapelle, it need hardly be repeated, was built by St. Louis in the 13th century. Previously to the restoration of the polychromatic decorations of the interior, the Sainte Chapelle attracted little attention from our travelling students. The decorations had either disappeared or were covered up behind the cases and presses with which the chapel was filled, in order to fit it up for a depository of records connected with the Palais de Justice; and this use to which it was put was a sentence of exclusion to strangers from the interior, seldom remitted. I was however fortunate enough, some years ago, to penetrate into this mysterious sanctuary, and at my leisure to make notes on the stained glass, (at that time the only object worthy of study which the chapel afforded,) the results of which I am about to submit to you.

The Chapel contains sixteen windows—four on the north side, four on the south, and seven in the apsis, which forms the eastern termination of the building. These are all the original windows; the sixteenth is a rosace at the west end, which has been restored, both stone work and glass, in the style of the Gothique flamboyant, probably not earlier than the middle of the 15th century. The side windows are in four lights each, with circles and tracery in the heads, and the windows of the apsis in two lights, the compartments being extremely lofty in proportion, as is usual in the French Gothic. The iron work of these windows, forming the frames of the compartments in which the glass is arranged, is well worthy of attention for its beautiful and varied form of composition, producing, in the tall spaces which it occupies, an effect which in some measure supplies the place of tracery. This is especially the case with the third window on the south side, which will be further noticed in its turn.

In the state in which the chapel was when my notes were made,—and indeed as it may be still, for I believe the restoration has not yet arrived at the glass,—many of the lower compartments of the windows, hidden behind the presses for the records, were destroyed. Some of the glass was probably abstracted when the presses were fixed, and it was unknown what had become of it; but it is probable, from the confusion which exists in some of the windows, that a portion may have been taken to make good defects in those parts which remained visible, for in one or two places, which will be noticed in their turn, the glass has been much damaged, and badly patched up; but these losses are small in comparison with what remains in a high state of preservation, and which may be stated to amount to about 800 compartments, representing subjects of scripture history, and containing from two figures each, up to as many as nine. The total number of figures may amount to between two and three thousand on the most moderate calculation. They exhibit nothing remarkable either in drawing or composition beyond the art of the period; on the colouring there will be some observations to make presently. The grounds and borders of the lights are more worthy of attention. The fleur-de-lis and the arms of Castile, in reference to Blanche of Castile, the queen of Louis VIII, and mother of the king by whom the edifice was founded, are conspicuous throughout these details.

The first window on the north side (to take them *seriatim*) is one of those which has suffered most wrong from time and violence. Part of the more modern erection of the Palais de Justice is built close against it, so that the light is shut out, and the glass is either entirely destroyed, or so patched up where it has been kept in its place as even to render the subjects undistinguishable. The iron work of this window is arranged in circles and semicircles. (Fig. 1.) No. 2, on the north side, contains seventy-two compartments above the line to which the presses formerly reached—eighteen in each of the four lights, besides those in the circular compartments of the heads; the compartments are disposed in the form of lozenges and portions of quatrefoils on the iron frame shewn in fig. 2. The subjects are all from

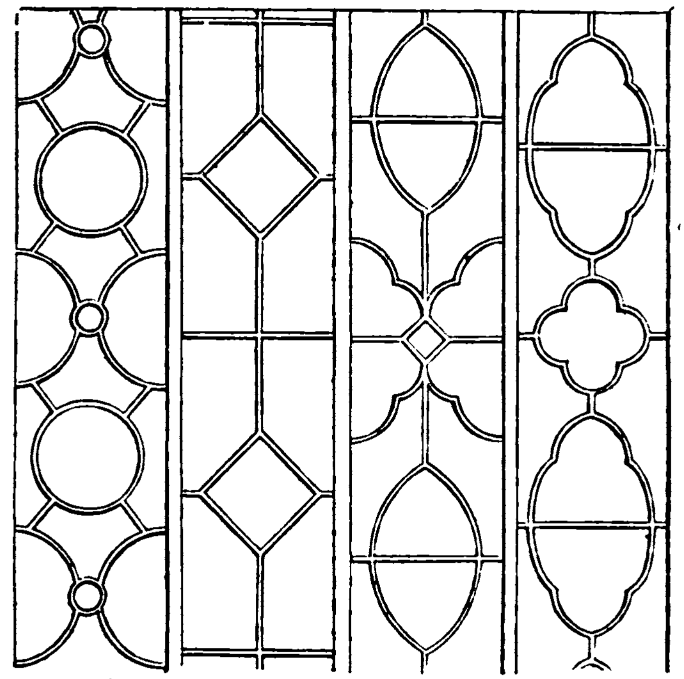


Fig. 1. Fig. 2. Fig. 3. Fig. 4.

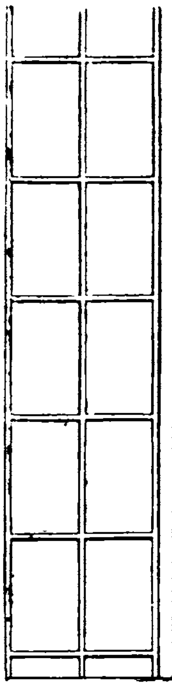
the book of Exodus and in high preservation throughout, except that, in some repair, the drowning of the Egyptians has been turned the wrong way upwards. The ground of this window is a sort of trellis, not very remarkable, with a border of the arms of Castile.

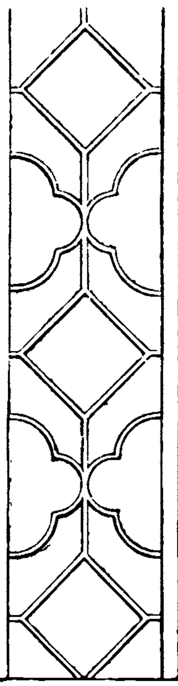
In the third window fifty-six compartments remain above the press line, arranged in portions of quatrefoils, and in the vesica piscis form (fig. 3), each of the latter containing two subjects; the eight lower compartments represent coronations of the kings of France, and more remained at the time these notes were made, behind the presses, which are now brought to light. In the upper part is contained the history of Moses, who is introduced into most of the groups. Among these subjects the plague of flies is represented with the most amusing *naïveté*, the faces of Pharoah and his court being covered with the insects after a fashion which renders the subject quite unmistakeable. The ground of this window is magnificent, being entirely *semé* of fleurs-de-lis, with medallions of Castile. It is to be regretted that it should be placed in the north side of the chapel, from which circumstance, and from being pressed upon by the Palais de Justice, it has not the benefit of a due share of light. The border is not so remarkable. The whole of this window is also in high preservation.

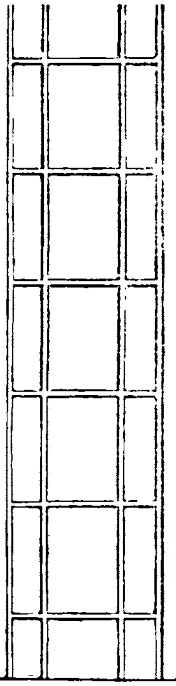
No. 4 exhibits thirty-six compartments, very elongated quatrefoils, each divided into two subjects, with quatrefoils of the ordinary form between. (fig. 4.) The subjects are principally from the book of Joshua, and for the most part represent battles (certainly not of the crusades of St. Louis, as a French artist has supposed), among which the fall of Jericho is conspicuous. Most of the compartments are in high preservation, and it is unnecessary to say that the Israelitish warriors are clad and armed in the fashion of the 13th century. There is nothing very remarkable either in the ground or border of this window, except that the sun and moon are introduced in the heads of the lights.

All these windows contain nine compartments in the heads—one in each, of the curves between the circles, one in the sixfoil light of the middle circle, and one in each of the quatrefoils, which compose the tracery.

The first of the seven windows of the apsis is filled with plain rectangular iron work (fig. 5). This is one of the windows which has suffered the most dilapidation, and only some of the lower panels remain entire. Among the surviving subjects is Sampson, with Dalilah cutting his hair. The head consisting, like all those in the apsis, of three trefoils, contains a cherub in the upper trefoil, and an angel in each of the others; these figures are in circles inscribed within the trefoils, and the surrounding spaces are filled with the arms of France and Castile.







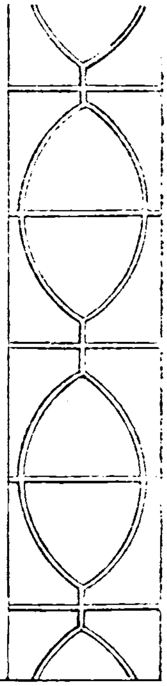


Fig. 5. Fig. 6. Fig. 7. Fig. 8.

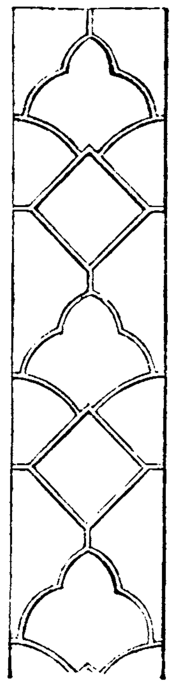
The first light of the second window in the apsis is in sixteen compartments—lozenges and half-quatrefoils (fig. 6). The subjects are generally obscure and do not appear to belong to each other; the ground, which is in figured circles crossed by a trellis, is very handsome; the border, plain red with small blue rosettes.

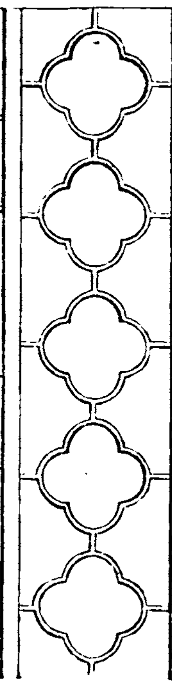
The second light is unlike the first, and differs totally from anything else in the chapel; it fits its place too well to have come there by accident, but the style plainly indicates its date to be the 14th century. It is divided by plain iron work into rectangular compartments (fig. 7), of which twelve remain. Each of these is subdivided into three, and the same subject, with variations, is repeated in eleven of them, viz., in the centre a throned figure, placed within the convolutions of a rich flowing arabesque, and a standing figure under a canopy on each side; the upper figure of the eleven is God the Son, the next below, the Virgin. It is evidently a portion of a Jesse window. In the centre of the upper compartment and in the head of the light the arabesque is beautifully developed, and the Dove appears among the scroll work. In the head is God the Father and two angels, filled up with the arms of Castile. The whole of this light is in the highest degree brilliant and harmonious, and in the best preservation. It is impossible to believe it contemporaneous with the rest of the glass, though how it came to be thus interpolated where all the rest is uniform in style it would be difficult to conjecture.

No. 3 in the apsis contains twenty-two compartments, in the form of the vesica piscis (fig. 8), each divided into two subjects, generally referring to the Nativity, but some do not appear to belong to the rest; some of the damage and patchwork previously noticed is to be observed in this window. In the top compartments and heads of the lights a building is represented, with figures incensing, probably the holy house of Loretto. In the head of the window is an angel, the Virgin and child, and God the Son, with the arms of France and Castile. The ground of the window is a plain trellis, with a border of fleurons.

No. 4, thirty-eight compartments, in squares and quadrants, relating principally to the crucifixion and events connected with it, with groups of saints and angels in the upper compartments. What is not actually destroyed is mostly in high preservation, but three of the principal compartments are lost and the squares filled with patchwork, and two others are misplaced. The ground of this window is a rich and beautiful trellis, with medallions of the arms of Castile, and a border of fleurons, and in the centre of each division of the four quadrants a very rich quatrefoil.

The first light of No. 5 shows eleven compartments, in lozenges, and a sort of quatrefoils (fig. 9), with a common trellis ground, and a border of very





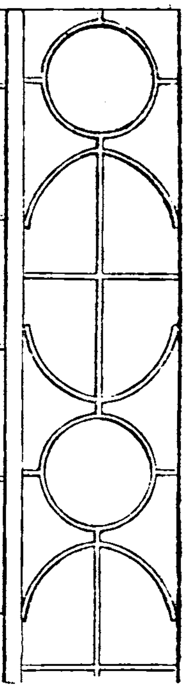


Fig. 9. Fig. 10. Fig. 11.

graceful fleurons. The second light is different,—regular quatrefoils (fig. 10), on a ground *semé* of Castile, and a sort of festoon border, rather ungraceful. The subjects are generally obscure, and apparently unconnected. The circumcision and the beheading of St. John are the only two which are obvious in the first light, and Moses with the tables in the second. In the head are three saints with the arms of Castile misplaced. This window is not in very good preservation, and the glass itself is much corroded and perished.

In No. 6 there are twenty compartments in quatrefoils, The subjects appear to be from the history of Noah, but they are for the most part obscure. This window is in rather better condition than the last; the ground and border the same as in the second light of the last window; *semé* of Castile with festoons.

No. 7, twenty compartments, in circles and half of the vesica piscis (fig. 11); the subjects obscure, but Tobit and his dog, and Daniel in the den, with a lion with a human face, are to be distinguished; the ground is a handsome trellis pattern, with a border of fleurons.

This completes the windows in the apsis.

The first window on the south side contains forty compartments, all in circles (fig. 12); the ground a trellis, with a fleur-de-lis in every square formed by the intersections. The subjects in the two first lights are from the book of Job; of course the devil plays a conspicuous part in the history, and is represented with much liveliness of imagination; the burning of Job's house is represented with edifying simplicity, his satanic majesty performing the incendiary in person. In the other two lights the subjects are not so clear; in the four top compartments are angels incensing. The head of the window is arranged as described on the north side, but the quatrefoil compartments represent buildings surrounded by arabesque work.

No. 2 on the south side is a window of extraordinary beauty; there are eighty compartments, quadrants, with a quatrefoil in the centre of every four (fig. 13); in each quatrefoil is Castile, and between the quadrants is also a medallion of Castile on a ground of rich mosaic. The subjects are various and abound in royal personages—those from the book of Esther are the most obvious. The head of this window is similar to that of the last. This window is particularly to be noticed for its rich, brilliant, and harmonious effect, aided no doubt by its position to the south. The form of the compartments, which the iron work follows throughout, fall in well together, and leave no awkward or irregular shapes in the ground. From the number of thrones and tabernacles on red grounds, there is more rich colour than usual, and this, with the repetition of the arms of Castile on a large scale, effectually balances the general blue tone which pervades this and the rest be windows.

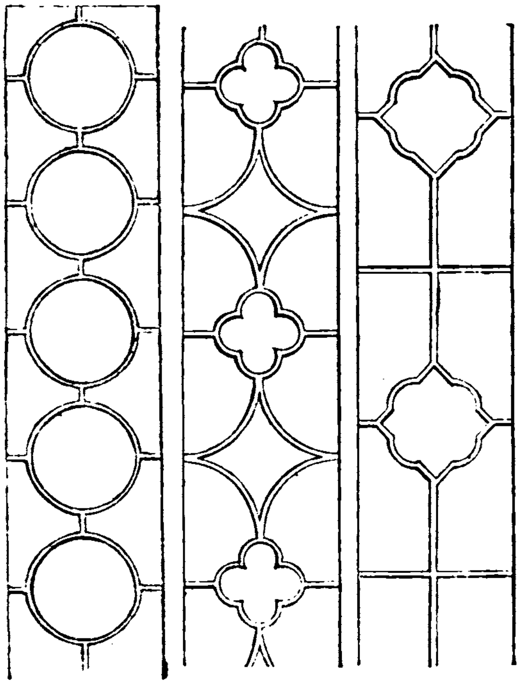

Fig. 12. Fig. 13. Fig. 14.

Notwithstanding what has been said of the last window, No. 3 on this side is perhaps the finest of the whole; the iron wörk already referred to is remarkably elegant; there are eighty compartments, the centre of every five being a very graceful compound form (fig. 14), and as they fill very nearly the whole space without interstices, the colours, of which a great proportion is very rich, are spread without any inharmonious spots. King David figures as the princpal personage in the history illustrated by this window. What little ground there is, is a mosaic, and it is remarkable that the border, which is in fleurons, is the poorest of the whole set. This window is in good preservation generally, but not altogether so perfect as the last.

No. 4, the last of the series has all the appearance of having once been a brilliant window, but it is in bad condition and patched to confusion. The form of the iron work and disposition of the compartments are the same as No. 4, on the other side. There is a large building represented near the centre of the window, which judging from others of the subjects, the priests carrying the Ark for instance, may be conjectured to be Solomon's temple. The ground of this window is particularly fine, diapered circles with the fleur-de-lis in the centre, and Castile in the spaces between.

It is to be feared that this description will have conveyed very little idea in the absence of illustrations, of anytbing beyond the quantity of matter contained in this glass, and the pains with which it has been elaborated. It may be well to add a few words on the effect produced. Every one is familiar with the blue tone of the early style of stained glass, arising from that colour being almost exclusively used in the back ground of the compartments. Such is the case with the glass of the Saint Chapelle, and as the harmony of the general effect is supported by the introduction of a preponderance of the same colour in the general ground works of the lights, this tone prevails very greatly through the whole surface of the glass, reds, greens, and violets, with only a small proportion of yellow, flesh colour, and other light tones, forming the reliefs and contrasts. The glass therefore admits but little light, and on the north side under the influence of sunshine on the opposite side, fails even in its effect of transparency, a result which must have been noticed by all who have had the opportunity of examining glass of this kind under different aspects. It appears, however, from the restoration of the Polychromatic decoration, of the authenticity of every part of which, I believe, no doubt can be entertained, that the architects of the Middle Ages were well aware of this inconvenience, and took very good measures to counteract it, the stonework of the windows being coloured of a sort of deep maroon; and the effect of the glass set in a framework of this tone, is something very different from its appearance between jambs and mullions of dead white as it is most generally seen, and as it really was in this instance, when my notes were made. The confusion which results from the collocation of such an infinite number of small pieces of coloured glass as we find in the compositions of this style, has been sometimes considered one of its beauties, and we hear glass commended because it looks like Turkey carpet. This is certainly the case with the glass of the Sainte Chapelle. The first impression conveys nothing to the eye or the mind, but the unmeaning variety of the kaleidoscope—but let it be observed, that to produce this effect with distinctness is no small triumph of the art of the collocation of colours. And here a remark may be made upon the general belief that there is some extraordinary quality in the colour of the ancient glass. That it is so in many cases is unquestionable, since the fact has been recognized by those who are practically acquainted with the manufacture of glass; but there are instances, and the Sainte Chapelle is one, where much of the red glass is far from being of a good quality; but this is by no means perceptible on a general view, and it proves that the brilliancy of the old red glass depends no less upon its collocation and the effect of judicious contrasts than upon the individual character of the colour. To return to the glass in question, if the forms are confused, the colours are not confounded; and when it is considered how easy it is by the injudicious disposition of small surfaces of transparent blue and red, to fuse them into a general effect of purple, of all results the most disagreeable and inharmonious, we must admit that their art was well understood by those who combined them, as they were combined by the glass painters of the 13th century; and it can hardly be doubted that the result produced was that calculated upon by those artists, viz., the effect of a rich and harmonious *coup d'œil* at the first view, heightened by the obscurity and mystery enveloping the details which a more deliberate survey and examination brought to light. If this were really their purpose, their success is undoubted. Whether this be the best mode of treating stained glass is another question altogether, and opinions may differ upon it. Stained glass was certainly very differently treated when it became combined with fine art, a quality to which the early glass can make no pretence. Perhaps the later Flemish and German glass displays the greatest perfection to which this art has been brought, exhibiting a combination of the qualities of good drawing and composition, with those conditions which are indispensable in glass painting, and separate it altogether from the art of painting on canvass.

One of these conditions which was never neglected as long as glass painting was understood, and which will be found invariably attended to in every successful specimen of stained glass, whether ancient or modern, is the profusion of detail. The earliest and the latest glass, however differing in every other respect, possess this in common. In the glass of the 13th century this quality is produced by the minuteness of the parts. In that of the 15th when the large treatment of the subjects necessitated large masses of the same colour, it is obtained by the introduction of diapered grounds, or sometimes by the minute elaboration of the draperies. It is not enough that this diaper work should be introduced when the eye can distinguish and appreciate it; in the old glass it is developed in situations, and on a scale, where it is inevitably thrown away, except in contributing to the general effect, which would as inevitably be marred by its absence. The rosace at the west-end of the Sainte Chapelle to which reference was made at the beginning of this paper, is a strong instance of the truth of these observations, so far at least as regards the practice of the Middle Ages. In this rosace there are eighty-one principal compartments containing a series of subjects from the Apocalypse, of which about sixty-six remain entire. The style in which this glass is executed exhibits the strongest possible contrast with that of the older series—there is very little colour of any kind—instead of strong contrasts the effect is brought out by chiaro-scuro. In which colour there is the predominating tone is yellow, but there are vigorous touches of red of great value to the effect. There is of course none of the depth and richness which characterize the original windows, but there is a transparency, and a sparkle, scarcely less imposing in its effect, and when to this first impression succeeds the examination of the detail, a proficiency in drawing and composition is developed, united to a refinement and delicacy of execution which can be fully appreciated only by means of an opera glass, and which might be thought thrown away, did experience not prove the elaboration of the detail, whether in one form or another, to be the one thing needful to the full effect of stained glass.

A few words may be added in conclusion, on the phlychromatic duration already referred to, by which this gorgeous display of transparent colour is harmonized and supported; every portion of the interior surface of the Chapel is covered with the richest and most positive colours, relieved by gold. The shafts of the columns, both principal and subordinate, exhibit the brightest vermilion and green, the vaulting shafts, which present the largest surfaces, being broken up by gold lines, disposed in various patterns; the lines themselves being embossed and minutely diapered, and the intervals filled with the embossed arms of France and Castile. The removal of the presses has revealed a magnificent dado, resembling that in Westminster Abbey and other buildings of the period; the back ground elaborately diapered and all the foliage gilt. In the spandrils of the arches are sculptured angels on grounds of blue enamel, diapered with gold. As the dim religious light admitted into the building is too feeble to prevail against the immense mass of colour, an ingenious and successful device is adopted to supply the place of light and shade in the sculptured details, and to give them the sharpness in which they would otherwise be deficient, by defining the edges of the foliage with a thin black line. Against the pillars are brackets destined to receive statues, some of which are restored, but not yet placed; they are all of that superior class of sculpture as compared with contemporary works elsewhere, which marks the French school of the Middle Ages, and are elaborately decorated with enamel and jewels. The only part of this splendid interior not perfectly satisfactory is the vaulting, of which the plain blue ground *seme* of *fleurs-de-lis* is too simple for the rest, and from this observation must be excepted the apsis, where a border round each compartment affords the necessary relief. Under the Chapel is a crypt or sub-Chapel, partaking of the same style of decoration, but not yet restored.

CANDIDUS'S NOTE-BOOK.
FASCICULUS LXVIII.

"I must have liberty
Withal, as large a charter as the winds,
To blow on whom I please."

I. Of all the ancient orders the Grecian-Doric is by far the most intracticable—almost to impracticability, although it has been largely introduced into practice in this country. By impracticability is to be understood not any difficulty as to construction or execution, but the impossibility of applying it consistently or naturally in buildings which are altogether differently constituted from those in which it was originally employed. It is so obstinately stern and inflexible, and so strongly marked in character, that it will suffer nothing else to come in contact with it. Nevertheless it has been patched up with, and patched upon, everything, Gothic alone excepted. So long as the mere columns and entablatures have been *correct*, that is, mechanically-produced fac-similes of some ancient example, and so far, bearing nominal resemblance to Parthenon or Pæstum, the most excruciating violations of the style have been tolerated—why do I say tolerated?—they have even been regarded with self-complacent wonder; and because we have copied it piecemeal, we have given ourselves credit for appreciating and relishing the severe simplicity of that order. Though it has been repeated *ad nauseam*, in hardly any one instance has the sentiment of the style been fairly expressed; and notwithstanding, too, the lackadaisical prating about "proportions," very rarely is any kind of proportion at all observed between the order itself and the structure to which it is applied. Instances have occurred before now, where otherwise very plain ordinary buildings have, the in attempt to give them something of style, been crushed into insignificance by huge Doric columns of greater diameter than the breadth of the openings for windows; while, in others, the same order has occasionally been reduced to minikin dimensions, and applied as decoration to subordinate parts of the general mass; which is surely a very great mistake, there being nothing whatever in the constitution of the Grecian-Doric—an order rigidly expressive of architectonic purpose and nothing more, and possessing no elements of combination and variety—to recommend it for purposes of embellishment. There would be something rational in taking the order merely as a type to be modified according to the exigencies of the particular design, and if needs be, even enriched. But no; that must not be thought of,—that would be quite illegitimate, and would be reprobated as "tampering with the orders," whereas the abusing or misusing them by preposterous mis-application is, it seems, perfectly legitimate and *secundum artem*; though, in my poor opinion, an architect may as well give us columns of his own invention at once, as mar the effect of an ancient order by joining it on, and mixing it up with, what does not at all agree with it. At the worst, were the invention bad, the whole work would be as likely as not to be of a piece throughout; at any rate the genuine and classical would not be degraded by being made to associate with the vulgar and mean. Architects should learn to rely more upon themselves for detail, and less upon their barefaced and wholesale borrowings, which borrowing system has, if nothing else objectionable in it, this unlucky tendency—that it relaxes industrious study, and renders architects prone to rely upon the merit of what is not their own, as excusing the bad that really belongs to them.

II. It would seem that professional men, who may be supposed to have studied the orders thoroughly, can do no more with them than those who are not architects. Just as they find them ready prepared to their hands, so do they make use of them, without any more ceremonious process of appropriation than that which is expressed by the euphuistic term "abstraction." Perhaps their study of them is not of the most fructifying kind: to learn to talk learnedly about dates and the histories of styles, and to know to the fraction of an inch all the dimensions of the Parthenon, is a very different matter from understanding architectural design; knowledge of the former kind constitutes for the architect only the materials for and aids to his proper artistic study. After all our so-called study of Grecian architecture, what have we made of it? Have we acquired from it the power of producing anything in congenial taste? With copying we began—which was excusable enough,—and with copying we go on, and are likely to do so to the end of the chapter, till we lay it aside altogether, for we do not care to take the first step towards any advance beyond the mere copying point. Truly, we have most singular notions of studying the antique, for we learn nothing more from it than what lies on the immediate surface, and mimick rather than imitate it; nor do we even avail ourselves, as we easily might do, of the varieties of the Greek orders which the Greeks themselves have left us. Have we as yet even so much as *attempted* to turn to account the idea for a four-faced Greek-Ionic capital, held out to us by that singular example in the temple of Apollo, at Bassæ,—an example, perhaps, all the more valuable because it is suggestive of further improvement? We seem to search out and accumulate examples only in order to bury them again in museums and in books. There are a few charming specimens of antique inventions for capitals in the British Museum, but for any use that is made of them they might about as well be at the bottom of the Thames at once. Has any service been rendered to architecture practically by the specimens lately discovered in Asia Minor by Texier, (who, oddly enough, was sent out thither by the French government, for the French make no use of the Greek and Asiatic orders,)—has a single idea been adopted from them?

III. If it may be judged of in its present state, Cockerell's building for the new Bank at Manchester does not promise to be any great architectural achievement. It may not unfairly be said to exhibit a sort of *travesti* Greek style, a Doric order, borrowed from that of the temple of Nemesis at Rhamnus (the shafts of whose columns are fluted only just at foot and top), being employed not for the entire elevation, but merely as decoration to the lower division or ground floor, in three-quarter, consequently, attached columns, and so wide apart (for there are five triglyphs over every intercolumn) as to be totally contrary to Greek ideas of proportions for intercolumniation in that order. Greater conformity to characteristic proportions might have been expected from one who descants so fluently *ex cathedrâ*—more fluently, perhaps, than perspicuously—on the doctrine of *proportions*. However, such violation of strict architectural *Dorism* is not greater than that of filling in the three centre intercolumns with large *arched* triple or Anglo-Venetian windows. The upper part of the front will be a sort of heavy Attic, of which the merit may be that it is unborrowed. It could be wished that the order had been equally nondescript, for then the whole would have been stamped by greater originality—at least, greater consistency; and whatever his invention for the purpose might have been, the Professor could hardly have been a degree more heterodox than he has been in the use which he has now made of Greek orthodoxy.

IV. One of the objections raised by way of answer to what I said in regard to a church being lighted on its sides by clerestory windows alone, does not apply either to Mr. Wightwick's building, or the other mentioned by me, because that circumstance does not, in either instance, in the slightest degree affect external character, no part of the exterior being visible except the front. Windows are so expressive in a Gothic church, and design depends so mainly upon them, that to erect an insulated structure of the kind, without other windows on its sides than those of the clerestory, might be deemed improper and perfectly arbitrary; not that I myself should despair of something good as well as striking being produced without any windows below. But did I in what I said, go to the extent of recommending the banishment of side windows, except clerestory ones, from churches? I think not; at least, I did not intend to do so, and therefore, I suppose, expressed myself very muddy-headedly. But what Mr. Wightwick has done is—oh horrible!—not according to precedent. Now ten thousand maledictions upon that said "precedent"—or rather the servile doctrine founded upon a blindly superstitious reverence for it,—doctrine that entirely denies to art the power of further production; or if it does chance at any time to throw out or begin to throw out a fresh shoot, it must be extirpated at once. What is good requires no precedent to justify it, and what is bad is not to be justified by a thousand precedents in support of it, for if the latter be in themselves good, they rather convict the thing that appeals to them of departing from their spirit. Your precedent-mongers do not even know whether they ought to admire or censure what is shown them, until they refer to authorities. Tell them that such or such idea is quite new, and they will instantly begin to frown, although they may just before have seemed disposed to relish; or, on the contrary, they will, on hearing that there is valid authority for what appears to be quite a novelty, be instantly propitiated in its favour, yea, even though an energetic "Damnable!" were actually hovering upon their lips. The present overweening reverence for precedent in some quarters, is likely to prove the *Dry-rot of Art.*

PRESSURE ON RETAINING WALLS.

SIR—In your remarks, at Page 109 of the *Civil Engineer and Architect's Journal*, on a paper of mine on the pressure to which retaining walls may be subjected, a *necessary* preliminary investigation has, apparently, been mistaken for one on retaining walls. The subject was *pressure*, not retaining walls; and you may have seen from the conclusion of the paper, and other parts of it, that it was merely introductory.

It is best to calculate the pressure free from all considerations of momentum at first, because when once this pressure is determined, it can be readily applied to the determination of the strength, &c., required in a retaining wall, so as it may resist being overthrown, being moved forward, or being fractured, by the resultant of its own weight and this pressure.

Mere formulæ without calculations from them are, to the practical man, nearly useless. I have therefore given tables of *pressure;* but tables of *momentum* would, in my judgment be useless. Telford gives pressure, *not* momentum, very properly; and gives separately the leverage, or the position of the centre of pressure; I have not done so, because it was not necessary to do so in this part of my subject, and because, also, any analytical determination of the position of the centre pressure must depend a good deal on an hypothesis, which may be considerably modified by the manner in which a wall is brought up and the filling behind it. Friction at the back of the wall belongs also, most properly, to the next part of my subject.

The formula $\int p\,x\,dx$ is a correct representation of the momentum, but to make it useful, take $p = w\,(h - x)$, a fraction of x, the height h, and a known quantity w: we find then, by integration, &c., the momentum $m = w\left(\frac{h\,x^2}{2} - \frac{x^3}{3}\right) =$ (when $x = h$) $\frac{w\,h^2}{2} \times \frac{h}{3}$ and, as it is easy to show that $\frac{w\,h^2}{2}$ is the pressure, $\frac{h}{3}$ is the leverage; but there are many circumstances in practice which may alter the position of the centre of pressure, whilst the pressure itself remains unchanged.

With respect to the conclusion of your remarks, I believe you will find on a re-examination, that I am *not* mistaken here. I have benefitted a good deal by the study of Telford's works, and if I have pointed out some of his mistakes—which every investigator is subject to—it was for the purpose of warning those who, not being disposed to investigate for themselves, may adopt them without consideration. The mistakes of such men as Telford are doubly dangerous, from the position which his works justly hold.

May I request insertion for this in your next number.

I am Sir,

Your obedient servant,

Dundalk, April 3rd, 1846. JOHN NEVILLE.

[Mr. Neville having stated his intention of completing his memoir in the particular to which we alluded, there now remains but slight difference of opinion between us. We still, however, are unable to assent to the expediency of considering the resistance and the moment of it separately. Mr. Neville says, "there are many circumstances in practice which may alter the position of the centre of pressure, whilst the pressure itself remains unchanged:" he could not have made an admission more in our favour, for this shows that the determination of the pressure by itself adds absolutely nothing to our stock of knowledge.

In the case taken in the present letter—and, indeed, in all other cases, where the sum of the pressures varies as h^2 or the square of the distance from the top of the wall—it is easy enough to find the centre of pressure, because the pressures themselves follow a known hydrostatic law. But in some of the most important cases the pressure does not vary as h^2: for instance, the equation 8, page 4 of Mr. Neville's memoir, which refers to one of the very commonest cases, that of a wall supporting a bank sloping upwards behind it, gives an altogether different law. We do not at present see how it is possible to ascertain the centre of pressure in this instance. (The result, by the way, is identical, *mutatis mutandis*, with equation 453 in Moseley's "Principles of Engineering," and Mr. Neville's investigation, though more general, has the advantage of much greater simplicity.)

Is there not an error in equation 28, page 11 of the memoir? Putting $\delta = 0$ (that is, supposing the upper surface of the bank inclined at the angle of repose), the right-hand side of the equation vanishes, and, consequently, on the left-hand side $c = \phi$; which leads to the strange conclusion that, when the upper surface is inclined at its natural slope, the plane of fracture is parallel to the plane of repose. At the top of the next page, Mr. Neville gives a definite value to the horizontal pressure when the wedge of earth is resting on a plane of repose. But surely, by the principles of the inclined plane, when a body rests on a plane inclined at angle, of which the tangent is the co efficient of friction, the body will have no tendency to slip forward, and cannot, therefore, require an additional horizontal pressure to support it.

We scarcely know what is meant by the allusion to Telford in the present letter, unless there be an accidental mistake of his name for that of Tredgold;—we said, last month, that Mr. Neville had condemned the latter from having misunderstood his meaning. On referring to Tredgold's original paper, we find his conclusion to be in effect this,—that if the sloping bank be carried up so high that the plane of fracture meets the natural slope of the upper surface, all the pressure on the wall is caused by the wedge, included by the plane of fracture, the wall, and the upper surface: in other words, however high the bank of earth may be, the additional height, beyond the place where the plane of fracture meets the surface of the scarp, adds nothing to the pressure on the wall. Mr. Neville says this conclusion is erroneous! But a moment's reflection will show that all the earth behind and above the plane of fracture is in a state of rest by itself, and cannot possibly add to the pressure on the wall. Tredgold further says that if we were to adopt the now exploded doctrines of Belidor and Rondelet, we should get a different and an absurd conclusion. This is all perfectly correct. Tredgold is not infallible, but he ought not to be blamed for errors committed by others—he has plenty of his own to answer for.]

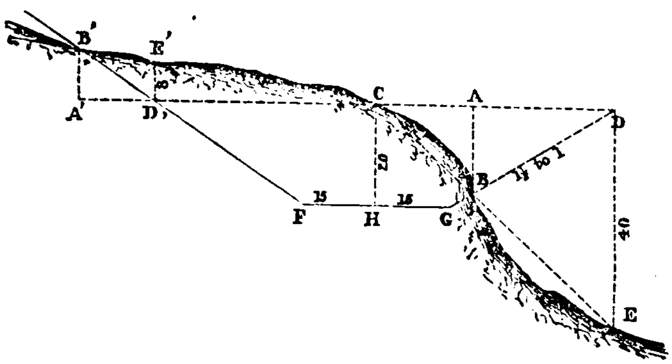
SUBSIDENCE OF THE PRESTON VIADUCT.—This viaduct consists of 27 arches, and it crosses the turnpike road from London to Brighton, near the Brighton terminus. It has been finished several weeks, and the principal portion of the wooden centres supporting the arches taken away.—April 11, the men engaged in ballasting the line over the viaduct discovered symptoms of the middle arch, which crosses the turnpike-road, having given way. Workmen were immediately employed in placing timber to support the arch. It was found to have sunk a foot or 18 inches, and will have to be taken down and rebuilt. This arch was of wider span than the others, and was the only elliptic arch in the viaduct. Some persons foolishly ascribe its subsidence to its being built in that form, but it is more probably owing to the continued wet weather, as another of the arches has since been found to be cracked. They will both have to be taken down and rebuilt. This line was to have been opened in May, but in consequence of this untoward event the opening must be deferred.

SETTING OUT CUTTINGS AND EMBANKMENTS.

Sir—Permit me through your columns to submit the following simple formulæ, for the solution of a most important problem in field engineering, viz., the correct determination of the half widths of cuttings and embankments in sidelong ground. While the methods usually adopted are for the most part tedious, and all, I believe, merely approximative, the following will be found to possess not only the great advantage of facility in practice, but the result is obtained by a very simple calculation which may be made in the field.

I need hardly allude, more especially at the present time, to the practical importance of this problem, since upon a correct staking out of the half widths, not only the quantity of land required but the amount of the work to be executed is mainly dependent; an error, either in excess or the contrary, being equally objectionable—perhaps even more so in the latter case, since an extra quantity of land would be required, under probably less favourable circumstances, for purchase, and the additional increase to the slopes, subsequent to the first formation, would be attended with an increased cost in the labour.

If, in the accompanying diagram of the cross section of a cutting in sidelong ground, B′ C E represents the ground surface, H C the depth of the cutting at the centre point, corresponding to the same point on the lon-



gitudinal section, H F and H G the half-widths at the formation level, it is obvious that the simple addition of each slope (calculated to the depth at the centre) to the half-widths at the bottom would, in the present case, be inapplicable—since the widths so obtained would be too small for the upper side and too much for the lower, and the contrary for embankments.

The method now proposed is simply this:—measure off from the centre stake the half-widths, supposing the ground to be horizontal, and between the centre stake and each of the points so obtained, E and E′, take the difference of level, viz., D E and D′ E′; then the distance H C, or the true position B of the side stake, indicating the superior edge of the slope on the lower side, is equal to $\frac{CD^2}{CD + DE \times r}$ (1.)

where r represents the ratio of the slope, or of the horizontal to the vertical distance. In other words, it is equal to the square of the half width *on level ground*, divided by the sum of the same half-width and the product of the difference of level before observed and the ratio of the slope.

The distance C A′, or the position B′ of the stake on the upper side, is equal to $\frac{C'D^2}{CD' - D'E' \times r}$ (2.)

that is, equal to the square of the half-width on level ground, divided by the difference between the same half-width and the product of the difference of level, before determined, and the ratio of slope.

Thus, for example, in the diagram, if the depth of the cutting H C be 20 feet, the half-widths H F, H G = 15 feet, and the ratio of the slopes 1½ to 1, it is evident that the half-widths C D′, C D on level ground would be 45 feet:—Let D′ E′, D E (the difference of level between the above points and the centre) be respectively 8 feet and 40 feet. Then, by formula No. 1, C A the half width on the lower side $= \frac{CD^2}{CD + DE \times r} = 19{\cdot}2$ feet. And the half-width C A′ (by formula No 2), the half-width on upper side $= \frac{CD'^2}{C'D' - D'E' \times r} = 61{\cdot}3$ feet.

For embankments, the values for the upper and lower sides would be exchanged, which is evident by reversing the figure:—

Demonstration.—Draw A B, D E, B′ A′, and E′ D′, perpendicular to the horizontal A′ C D.

$$\text{Then let } AC \text{ or } A'C = x$$
$$CD \text{ or } CD' = a$$
$$DE \text{ or } D'E' = d$$
$$AD \text{ and } A'D' = a - x \text{ and } x - a$$
$$AB \text{ and } A'B' = \frac{a-x}{r} \text{ and } \frac{x-a}{r}$$

Where r represents the ratio of the slopes,

Then by similar triangles—

$$AC : AB :: CD : DE; \text{ or, } x : \frac{a-x}{r} :: a : d$$

$$dx = \frac{a^2 - ax}{r} \text{ and } drx + ax = a^2 \therefore x = \frac{a^2}{a + dr} = CA. \quad (1.)$$

In the same manner for the upper side—

$$AA'C' : D\ E' :: A'B' : D'E' \text{ or, } x : a :: \frac{x-a}{r} : d$$

$$dx = \frac{ax - a^2}{r} \text{ and } ax - drx = a^2 \therefore x = \frac{a^2}{a - dr} = CA'. \quad (2.)$$

Q. E. D.

It is scarcely necessary to mention that the above formulæ presuppose that the points C, B, E, and C B′ E′ fall on the surface, and are respectively reducible to one plane, which in fact, unless in very extreme cases, may be assumed without leading to material error in the result—at all events, the correction would be so slight that it might be made by the eye; taking the distances C A, C A′ rather in excess when the point B falls within the surface, and the contrary when it falls without.

G. Hawkins.

BROAD AND NARROW GAUGE.

Sir—I have not a single share in a railway, broad or narrow, and, in a pecuniary point of view, care not one iota which way the Gauge Question may be settled; but, for the last sixteen years, I have watched, with the greatest interest, the progress of railway locomotion, and at every increase in the capabilities of the locomotive engine I have rejoiced, as every man ought to do who purely desires the advance of art and science. From recent experiments and from daily experience it appears the engines on the narrow gauge have attained their limit as regards power, while the broad gauge engines are susceptible of an increase of power to any extent compatible with safe velocities. The engines on the Great Western Railway have not varied in their dimensions almost from the opening of the line,—having a boiler remarkably short in proportion to the other parts of the engine; but there is now building, at Swindon, an engine, the boiler of which will be of a length corresponding to the long boilers on the narrow gauge lines; the driving wheels will be 8 feet in diameter, and the calculated average velocity with an ordinary train will be 70 miles an hour. We are told that narrow gauge engines are not safe at velocities exceeding 45 miles. What an exceedingly humiliating reflection that, probably, the whole of the kingdom will be tied down for ever to a velocity of 45 miles. What is to be done? Cannot our great engineers and scientific men rescue us from this unhappy fix?—There is but one hope left for the narrow gauge, and that is, the success of the atmospheric system; but most provokingly, it so happens, that the opponents of the broad gauge are also the enemies of the atmospheric system, and Mr. Stephenson, instead of holding his post as *driver* of railway science, by the force of circumstances finds himself in the unenviable position of its *breaksman*. It is most devoutly to be wished, for the honour of the narrow gauge, that the engineers and scientific gentlemen who are most unmercifully attacking the unfortunate atmospheric system month after month in your valuable journal, would cease their enmity, and, contrariwise, take the almost prostrate system, try what they can make of it, and adopt it as a bantling of their own.

I remain, Sir,

Your obedient servant,

April 12th, 1846. S. T.

ON THE MODIFICATION AND ADAPTATION OF THE ORDERS OF THE GREEKS BY THE ROMANS AND MODERNS.

By H. Fulton, M.D.

"All nations in the most advanced state of civilisation have been unanimous in their admiration of Grecian architecture."—The Earl of Aberdeen.

The learned are agreed and we must agree with them, that the Greeks derived their knowledge of architecture from Egypt, and its neighbouring nations. We find them possessing three orders, all of great beauty; and although these orders differ from each other in many respects, yet, in the opinion of all architects both ancient and modern, they may be resolved into one elementary order—the Doric, which, there is every reason to believe, was the original one. In the ruins of the temple of Amada, in Nubia, we have a very near approach to the Greek example of the Doric columns of the temple at Corinth, the earliest known example of the order in a Greek dress: indeed, it requires but little addition to make the Nubian column an example of the Doric order, from which it does not differ so much as the latter does from either the Ionic or Corinthian. Denon, in his delineations of Egypt, gives a column composed merely of a fluted shaft supporting a low architrave; this shaft is precisely similar to those at Pæstum and Agrigentum. But this inquiry, however interesting in itself, strictly forms no part of our subject; we shall therefore dismiss it by adding, that what the Greeks did we may also accomplish, and find in the rich and almost unexplored field of Egyptian architecture many examples of detail—particularly capitals—which are capable of being Grecianised and adopted into modern practice; an example of which is given, under the name of the Victorine order, in the *Civil Engineer and Architect's Journal* for the year 1845, and is proposed as a substitute for the Roman Doric, which intention it seems calculated to fulfil.

The Greeks then had only three orders, and the Romans in making the addition of two others, effected it, as regards one, by stripping the Doric of all its embellishments, altering its proportions, and supplying a base for the formation of what is called the Tuscan. And the Composite can only be considered as a variety of the Corinthian, or a combination of it and the Ionic, and is not entitled to be received as a distinct order; nor should either the Tuscan or Composite be considered in our elementary works except as mere modifications of the other orders.

That the Romans felt the force and power of the Greek style is readily proved by its extensive adoption throughout their empire, but that they were not able to foster the adopted child with the care and affection of its natural parent, is manifest from the deterioration it suffered in their hands. The taste for, and knowledge of the fine arts amongst the Romans at the time of the conquest of Greece were at a low ebb; that warlike people came, and saw, and admired, but did not acquire a true knowledge of the grand and leading principles of the art as practised by the Greeks, either in painting or sculpture, and still less in architecture. Wealth poured its tributary streams into the lap of all-conquering Rome; everything that riches could purchase was at their command; and magnificent structures were soon raised on the spot where formerly stood the rude hut of Romulus; and so great was the change effected, even in the lifetime of an individual, that, as Suetonius relates, Augustus found the city built of brick, and left it of marble. The most distant conquered provinces felt the genial influence of the newly-acquired taste, as the many ruins still existing in Africa and trans-alpine Gaul attest. Gold has a magnetic power to attract, though perhaps not to create, genius; but the possession of wealth does not always improve the taste, and although we see in the ruins of Possidonia what Greek artists could do in a foreign land when left untrammelled, yet under the influence of Roman patronage they were not altogether so successful. It may have been observed that ignorant persons, on being shown sketches of the three orders, invariably prefer the most ornate; such a preference would also be given by a semi-barbarous people: but those who love all the three cannot censure any for preferring Aglaia, to Thalia and Euphrosyne—nay, we rather rejoice that they should be found to join with us in admiring even one of our beloved Graces, although we may be persuaded that to love one well, we must love all three. But the Romans went further than a mere preference, and rejected the claims of the elder sister; for their modification of the Doric is even worse than a total rejection. Unable to appreciate the grand—the sublime effect produced by this order, when exhibited on the scale and constructed on the principles to which the Greeks trusted for producing effect, they apparently cast this order aside; in the first instance, leaving it for homely practise perhaps; then its new patrons finding it, when deprived of all embellishments, the least expensive, and, therefore, when magnificence was not requisite, the best adapted for their purpose, may have turned it into the order now called Tuscan, as spoken of by Vitruvius; and although subsequently, in such erections as the temple of Hercules at Cori, we see that some vague idea of its former state may have been entertained, yet in Roman hands, neither ancient nor modern, has it up to the present day been treated as if its real beauty were either felt or understood; for the thing which the Romans have left us, and the modern restorers of the Greek style have served up to us as the Doric, is no more like the noble order whose name it bears, than Alexander the coppersmith was to Alexander the Great.

Nor did the other orders altogether escape modification, as for instance the capital of the Ionic, which, instead of presenting, as in the Greek, two faces and two sides, is made, by the angular arrangement of the volutes, to give four faces precisely similar. There is also a very striking difference between the flowing lines of the Greek and the spiral formation of the volutes of the Roman Ionic. Our knowledge of the Greek Corinthian is very scanty, but we may, at least, hope its capital, in the best of the Roman examples, has in some measure escaped unscathed, although in various other matters, such as the contour of the mouldings, the stylobate, and the cornice, extensive alterations were made, both in the voluted and foliated orders.

Some person has called the Tuscan the modified or emasculated Doric; this idea must be grounded on the notion of Vitruvius, who likens the Doric to a man robust and well-proportioned, for take away this character from him or it, and you take away the virility—that is, according to Johnson, the physical character—of a man. The strength or character of an order depends on the proportion of its intercolumniation and height of the shaft to the diameter of the column itself. Now the Tuscan, as given by Palladio, has an intercolumniation from centre to centre of five diameters and an elevation of seven, and, according to the same author, the Doric has an intercolumniation of nearly four and "an elevation of eight or seven and a half at least." Viola and Vignola give the same elevation, and Scamozzi eight and a half, and the same intercolumniation as Palladio, whilst the Athenian Doric has an intercolumniation from axis to axis of little more than two diameters, and an elevation of about five and a half. The ancient harridan, in modern times, finding that the blush of early beauty has deserted her cheek, and that time has bleached her scanty locks, seeks with pigments to give a colour to the one, and supplies the place of the other with the stolen ringlets of youth: but do such dire expedients as the application of paint or *the rape of the lock* deceive any one save herself? So it was also with Palladio and the rest when, with Vitruvius for their guide, they took the attenuated Tuscan and proceeded to dress it up in the Doric garb, giving the shaft a kind of colour (as it were) by fluting, and hanging a profusion of ringlets, *i. e.*, triglyphs on the brow, the frieze of the order.

It is, however, to the credit of the ancient Romans that this modified order, even when dressed in the manly garb, found little favour with them; consequently, we have but few remains of it—some amphitheatres, the theatre of Marcellus, and the temple at Cori, being the only ones handed down to us. Of the deterioration of the other orders, on which the Romans appear to have bestowed their patronage, our proofs are not so strong: they were the orders which the Greeks, for the most part, used in cases were magnitude—so essential to the full development of the Doric—was not required; hence examples of them were more likely to suffer from the hand of time, and to offer to barbarians *and others* more portable materials for the erection of their own temples and domiciles; besides, in the age of darkness and ignorance, when Grecian art was as it were eclipsed, men would naturally view the vast remains of former times (the use of which, as well as the means by which they were or could be erected, were totally unknown to them,) as invested with something of a superstitious character—the works of genii or giants, who, although unseen, had still the power to avenge their overthrow; to this may we not, in some measure, be indebted for those precious remains of the Doric order still existing in Greece and elsewhere, and to the absence of its protection ascribe the paucity of examples of the other orders in the same localities?

It has been stated by an accomplished writer on architecture, Mr. Hosking, that if two persons, acquainted with the Doric order, were desired each to give a design of a Greek temple of any specified class (the dimensions of a single column and the proportion the entablature should bear to it being given), the designs would be exactly similar in size, arrangement, features, and general proportions. Such is the stringent nature of the Greek Doric, in which respect it is unique. The triglyphs, when given, are the index of this proportion, and, except over the columns at the angles, we find one over the axis of each: at the angles of the edifice the column is placed so near to its proximate, that a line let fall from the outer edge of the triglyph will touch the circumferential line of the column at its base, thus giving increased strength to the structure. Stuart makes the measurement of the columns at the angles of the Parthenon 6′ 3″ 5‴, and those between them 6′ 1″ 8‴, and the intercolumniations 5′ 8″ 8‴ and 7′ 11″ 5‴. But the restorers have modified this either by giving half a metope outside the triglyph at the angle, or by showing a disregard to any rule, as we see in the portico of the University Club, in Suffolk-street, London. In such cases as the last-mentioned, would it not be in better taste to omit the triglyphs altogether (as we find they are in the pronaos of the Greek examples), and substitute sculpture in their stead. We stated that it was the rule to have only one triglyph between those over the axis of each column; there is, however, an exception of high authority, as may be seen in the Propylea,—but it forms the exception, not the rule; and although this structure is very beautiful in other respects, yet did we not know that it was erected in the age of Pericles, when art was in its zenith, we should, on account of this deviation from the general rule, have ascribed it to a period subsequent to the Roman conquest. It would appear that the reason of this wide intercolumniation between the centre columns of the Propylea was, that a larger space might be left for the passage of equestrian processions to the Acropolis. If we were constrained to assume the functions of the judgment-seat when the example was pleaded as a precedent, our decision should, in legal phraseology, be, "*Like case only like rule.*" But let us not forget that although we may pay the closest attention to all the minutiæ of the Greek models, yet a repetition of the Doric in small cannot be effective, for MAGNITUDE IS INDISPENSABLE.

Although the Romans proved by conquest that they were superior to the Greeks in arms, yet they were inferior in arts, and for a time had recourse to the importation of Greek artists, and, in the reign of Domitian, columns were taken from an edifice in Greece for the purpose of rebuilding the Capitol; but such was the taste of the Roman architects, that they were altered under the pretence of being polished, and, as Plutarch, who saw them previously in Greece, says, "they gained not so much in the polish as they lost in proportion, for their beauty is injured by their appearing too slender for their height." In the old church of Araceli, on the Capitoline hill, which contains many antique columns, there are some, not difficult to imagine as being the identical ones alluded to by Plutarch. But the wholesome stimulus of good taste in the employer could not be imported as early as the artists themselves, and it is in the nature of the mind not to produce beyond what is required of it. Who will be at the pains of cultivating a flower that must be

"————born to blush unseen,
And waste its sweetness on the desert air?"

It may be replied to this that the ancients, both Greeks and Romans, put the highest degree of finish on parts that never could come under observation as long as the buildings stood—but not so; for superstition invested their gods with the power of visiting their temples, and hence every part which might possibly come under their scrutiny was made as perfect as possible. Another cause for the modification of the transplanted architecture was the scarcity of materials of sufficient magnitude to construct buildings with on the Greek models: if, under such circumstances, Greek employers had been substituted for Roman, and Rome had become a Greek colony, then, indeed, there can be no doubt that all the modifications which materials rendered necessary, would have been guided alone by those principles which had sustained the character of Grecian architecture as the first in the world—superior to the Egyptian in this respect, that whilst, with less bulky materials, it preserved the character of grandeur, magnificence, and simplicity of outline, it imposed thereon an elegance and harmony of detail, which made it rise superior to its prototype. But no such fostering influence met it on the banks of the Tiber: the ancient Romans, like some moderns, had indeed a great desire—a longing after magnificence, without being aware of what its constituents were;—possessing the superiority of conquerors, they were too ignorant—too vain, to learn, or rather submit, to the taste of the vanquished, whose productions they condescended to appropriate in order to grace a triumph and mark a conquest; and although we see in the earlier works of Italy many vestiges of the good taste of their instructors, yet a history of its progress under Roman patronage would be a narrative of its decline and fall, for other principles guided them subsequently, and they in vain sought to give their edifices that grandeur, which the Greeks had been able to effect by a far different method. The art appears to have run riot in Roman hands, if we are to ascribe to them the erection of Baalbec and Palmyra, entire cities built on a scale of magnificence and splendour which would not be credited were the fact not attested by their existing ruins; yet these ruins, extensive as they are, possess no feature worthy of our imitation, except it be a few details of mouldings which have been introduced into the interiors of our domestic edifices.

The principles of the one school were sure and fixed, and incapable of being perverted, whilst those of the other were unstable, and led to every possible variety, until they brought ruin on the art, and so early as the times of Diocletian, obliterated almost every vestige of its origin. In succeeding ages, which we call dark, architecture lay buried under its own ruins: but the most sanguine enthusiast could scarcely have anticipated that out of this chaos a new style should have been created, having claims on the admiration of posterity; and that, in the hands of men who have left no written or other record of their knowledge of science or art, the examples of the florid Gothic of the middle ages should have been brought to that state of perfection which we cannot surpass; this, however, forms no part of our present enquiry. Subsequent to this period, there arose in Italy another set of men, who did not aim, like the Freemasons, to create a new style, but professed, by the aid of the works of Vitruvius, to resuscitate the ancient one out of the incongruous materials by which they found themselves surrounded. If, instead of doing this, they had consigned Vitruvius to oblivion, and followed the example of the Freemasons, they might have given us something good—at all events, they could not have given us anything worse than the so-called revival. Greek models they did not seek for, but even if it had been otherwise in this respect, we have no reason to suppose that the purer specimens would have found more favour in their eyes, than the best of the Roman did. Serlio and Palladio drew and published almost all the Roman examples existing in their day, yet, in their own designs, show how little they studied the best of them, except to copy a capital or a cornice.

The restorers who flourished principally in the fifteenth century are called for the sake of brevity, the Cinque-cento school; they were all of the same country as the earlier debasers of Grecian art: eminently successful in painting and sculpture, the Italians fell far short indeed in architecture. Unacquainted with the Greek models they yet set about the restoration of the style; their country never possessed any example of the pointed Gothic worthy of attention, and indeed the very name *Tedesca* impinges harshly on an Italian ear, and the mere suspicion that Germania was the country of its birth was sufficient to create a prejudice in the mind of an Italian patriot; so it was altogether passed over without notice, and our own Jones and Wren, not finding any mention made of it by any of the admired authors of the Cinque-cento school, at once stigmatised it as barbarian; but it is remarkable that in proportion as the beauty of the pure Grecian is known and felt, so is that of the Gothic appreciated; and so it ever will be in art, a correct taste in one branch leading to the due estimation of others.

It is true that the change of habits and the difference of climate may, in many respects, render what was once appropriate not fitting now, and it must also be admitted that all the examples of Greek architecture which we have, are either of the templar or monumental description, and therefore may not be suited for domestic edifices. We know from the somewhat Greek town of Pompeii, that a great difference existed during the first century in the style of domestic edifices, and no attempt was made to render the former similar to the latter, but, on the contrary, it was at one period unlawful to make the attempt in Rome, and not customary in Greece; for Julius Cæsar obtained permission by a decree of the Senate to make the front of his house like a temple, and Demosthenes, about a century after the death of Pericles, directed the thunder of his eloquence against the practise as an innovation. Columns, both square and cylindrical, were however much used for internal decoration and construction in Roman houses, but the exteriors were plain, and for the most part, devoid of all architectural ornament: according to Vitruvius, the exteriors of the town houses were quite plain, all ornament being reserved for the interior; just as we see at Pompeii, and as is the custom in the towns of China at the present day. However, in the so-called revival of Greek architecture, any building, although its outline might be broken up by receding or advancing wings—although it might have a pediment in mockery only of a gable, or not extending the entire length of the façade—although it might have its frieze pulvinated, its stylobate not graduated, its intercolumniations extended, its columns (some of them sinecure) of different orders—

attenuated, unfluted, coupled, and mounted on stilts: its antæ fluted, diminished, and capped, as cylindrical columns should be; its cornice crowned with an attic, or perhaps a balustrade; its shallow portico a mere afterthought, advanced in front, and thus made the only prominent feature in the composition; instead (as the painters would say) of every part being worked into each other, so as to produce one whole;—or, in short, although it might have all the characteristics of the cinque-cento school, provided that in some respects it bore the resemblance of a caricature to the original, it was designated as a Greek composition.

In this so-called revival, abundant use is made of columns, particularly as dressings for windows and doors; and here there is a marked departure from the principles as practised by the ancients and even as laid down by the restorers themselves, namely, that the intercolumniation should not exceed a certain width. Palladio, in the 13th chapter of his first book, says that "the intercolumniations of the ancients never exceeded three diameters except in the Tuscan." Now if only three diameters, or four from centre to centre, be given, the opening would be too narrow either for a door or a window; hence the use of them in such situations in practice is contrary to the principles so peremptorily laid down in theory. The great object to be attained in the use of columns is the depth of shadow, which has been called the *chiaro-scuro* of architectural composition, but as window dressings are stilted on a lofty stylobate they degenerate into mere *quasi* ornaments, affording no shadow that can be seen. The practice of wide intercolumniations in order to admit a window or door is defended on the ground of the columns being attached, and therefore not requiring to be limited in the interspaces; but this seems like doing a thing in the first instance, and finding out an excuse for it afterwards; and there appears to be no good reason for placing them in such situations, as they then convey no idea of utility, and a wide intercolumniation and lofty situation prevent their being ornamental; besides, attached columns are only to be defended on the ground of their harmonising with those that are insulated, and this they do not when placed as door or window dressings; but it can scarcely be said that when so placed they are *attached* in the usual acceptation of the term, for the architrave, or whatever may supply the place of one, has not the aid of any other support.

For the practice of coupling columns, an expedient by which the simplicity of the composition is marred, without any commensurate advantage being obtained, we are said to be indebted to him who was justly called the Prince of Painters.

We must not omit mention of the practice of adapting single columns for monumental purposes. The first example we have of this is the Alexandrine column, called Pompey's pillar; then the column of Phocas at Rome; these are both of the Corinthian order. Of an earlier date than the latter, we have modifications of the Doric in those of Trajan and Antoninus; and in our own times, a copy of Trajan's in the Napoleon at Paris. In England we have several of both orders, but we are not aware of any in the Ionic. The legitimate practice of architecture rejects a column in the singular number, except as a fractional part of an edifice, and always requires, in the horizontal styles, that it should be surmounted by a suitable entablature, in order to give it that completeness which the eye seeks for from association—the architect's line of beauty, from which he is slow to admit of any deviation. Although, by their sculptured reliefs, the columns of Trajan, Antoninus, and Napoleon, are in a great measure taken out of the class of edificial columns, yet they, as well as those not so circumstanced, are unsuited for the reception of figures on the summit; for if the figure be badly designed and executed it should not have place anywhere, and if well designed and executed it is lost to the eye by its exaggerated elevation. An Irish round tower or an Egyptian obelisk offers a more appropriate model for a monument or landmark than any modification of the classical orders.*

In a Greek composition the columns may be said to form the building itself (supporting its entablature, on which the roof is imposed); not ranged in broken lines, for the purpose of pictorial effect, but presenting an integrity of outline—giving the idea of completeness and unity of one whole, and not several parts badly suited in size and form to be joined together; for, as an accomplished writer has said, "however startling it may be in geometry, it is true in taste that a great many little things do not make a great one." It has been justly said that all the parts of a Greek composition which are useful or necessary are rendered pleasing, and what is beautiful appears to be necessary. The aspect of a building of this description will be a bold unbroken outline; the ornamental parts from a distance, will appear subdued, so as not to interfere with the appearance of unity, and merely solicit a closer examination; and when, to obtain this, the eye approaches, the most highly finished details alone lay claim to inspection,—fitness, completeness, and harmony, will be the distinguishing characteristics throughout the entire. Let us bring some of the edifices erected in the so-called revived style to this test, and the difference in the effect produced shall at once be evident. If then our most elaborate and expensive compositions fail in this, should we not inquire how the defect might be remedied? Perhaps it may be urged that grandeur, magnificence, sublimity, and harmony, have all been attained in the florid Gothic; but it must be considered that although in detail this style is trifling, weak, and often ridiculous, yet the parts in themselves are so minute, and the outline so bold, as rather to afford a proof of the contrary. There was a man who dared to work out the Greek principle, and that man was Michael Angelo Buonarroti—a name that stands second to none either as painter or sculptor,—a name which it is difficult to decide as meriting more praise or censure as an architect. In the noble cornice of the Farnese palace, and the daring dome of St. Peter's fane, we have the principle carried out on another model; the remainder of the Farnese palace was designed by San Gallo, and cannot be laid to the charge of Michael Angelo.* But if, after seeing the dome of St. Peter's, we cross the Tiber, and look at the Capitol, we find it hard to believe that it is the production of the same hand, and would willingly ascribe it to some other San Gallo did truth permit. The beauty of the dome almost covers all the architectural sins of the rest of the edifice, but the Capitol presents no such redeeming feature; all is trifling and unworthy of the name and site, and fit only for the habitation of the feathered guardians of the mount—whose effigies in bronze it contains,—but not to crown a ROMAN FORUM even in ruins!

It must at the same time be mentioned, to the credit of Buonarroti, that his plan was to make St. Peter's in the form of a Greek instead of a Latin cross: with the former figure the dome would have been more effective exteriorly, and on this account it is to be lamented that a sectarian feeling of preference for the abstract figure subsequently prevailed over the better taste of the architect. We participate with Sir Joshua Reynolds in the admiration he expresses for "this truly great man," and gladly turn from his faults to admire his excellencies, and see in the dome and cornicione the efforts of genius emancipating itself from the trammels and false principles of a vicious school. He also intended to have given a portico to St. Peter's on the plan of that of the Pantheon of Agrippa, instead of Carlo Maderno's miserable façade; such a portico, with a colonnade of the same order, on the plan of the present one, but having its entablature and stylobate on a level with those of the portico, would indeed have exhibited what the art was capable of effecting, and given a *coup d'œil* superior perhaps to anything in art the world has ever yet beheld. The genius and taste which designed such examples as the dome and cornicione are exactly what we most require in modern times; not, indeed, for the production of isolated features to redeem a composition from censure, but as parts only of works in which the same character shall be carried throughout the entire.

Much has been written by accomplished authors on the subject of taste, and rules have been laid down for the formation and direction of it. In an altogether artificial art like architecture—a mere creation of the mind—we can glean but little from nature for our guidance, and are driven to refer to the best models of each particular style to form our rules from what we there observe; and it would be wise to take it for granted as a general rule, that those who had the genius to invent a style or sub-division of one, were the fittest persons to give rules for the guidance of those who were to follow them as copyists; therefore it would, in most cases, be more desirable to invent a new style for our purpose in preference to violating the rules observed in the old ones, or applying their peculiar and striking details to other purposes than those for which we find them invented. The architect who does so may indeed lay claim to a kind of invention, but it is of the lowest description, and is anything but a proof of genius. Had we known nothing of Greek architecture save what we see in its restoration, doubtless we should have thought these restorations very beautiful, and have been perfectly satisfied to have formed our tastes on such models; but a single glance at a Greek peripteral temple would awaken in us new sensations of pleasure, and leave an impression that would never afterwards be obliterated from the mind. Seldom do our climate and wants admit of the erection of such a structure, but happy indeed must be the lot of the architect to whom such an occasion shall fall of offering that, the

* See a paper on Obelisks in the "Civil Engineer and Architect's Journal," Vol. VIII. 1845.

* The details of the dome do not deserve commendation.

sight of which is pre-eminently calculated to form the taste both of the public and the profession.

It was unfortunate that architecture, at the period of the revival of the Greek style, was taken up as a profession by painters, whose minds are too much imbued with a love of the picturesque ever to admit of their producing a good effect with such materials as wood and stone. The carpenter's plane and the mason's chisel completely remove all that gives picturesque effect to the tree and the rock; and the painter seeks, by the arrangement of the principal parts of an architectural composition, to produce what a skilful architect will effect by the minor details, namely, a variation of light and shade—not as the principal feature of his picture, but merely as a tinting; to obtain which he has not sacrificed either unity or simplicity. It matters not then to the painter-architect whether his columns be fluted or not; all he cares for is to avoid what is not his line of beauty—a straight one, which happens to be the very main-spring of beauty in a Greek composition. The generality of mankind are better informed on the subject of painting and are better judges of it than of architecture; hence, so many side with the painters, and architects are driven to succumb to the ruling taste of the day, and to fashion their designs, not with reference to how they must appear in the solid, but to how they do appear as pretty pictures on paper. It will not avail anything to argue this with the painters, for—

"Convince a painter against his will,
And he'll hold the same opinion still."

Nor still less can it avail to argue with those who are led by the opinions of the painters, and such are the great mass of those who compose what are called Committees of Selection, who must be treated as children—as babes in knowledge; and, instead of giving them a toy, which they would in a state of innocence seize with avidity and soon after as capriciously throw aside, something that they would prefer and continue to estimate when their judgments shall be more matured and their taste improved should be given. It is generally admitted that the Propylea at the London terminus of the Birmingham Railway is one of the best examples in this country of the Greek style, and justly, one of the most admired; yet we should tremble for its fate if its geometrical elevation were to be exhibited before a Committee of Selection in competition with one of the façade of the Goldsmith's Hall, the production of the same architect: in short, the latter would appear on paper, to the eye of a committtee-man, as much preferable to the former, as it does in stone to the eye of every one. An architect of genius will reject the opinions of such tribunals. Let committees say what they require, and provide the funds—that is their legitimate portion of the division of labour. Would any of the great painters (to whom their art is so much indebted for a true revival) have submitted to the control of ignorant monks (who were their best patrons) in handling their works? Did Titian alter his style because these monks objected to his figures appearing to stand out from the canvas? And shall architects be less free from the intermeddling of ignorant pretenders? It is greatly to be feared that too many in the profession are fettered by the opinions and taste of persons who neither know, nor even profess to know anything about the art—a state of things which it is neither the interest of the public nor the profession should be maintained.

In reviewing the modifications which the style experienced in the hands of the Romans, one of the most important is to be found in the arrangement of the portico, which, in all the edifices remaining in Greece, Magna Grecia, and Sicily, with the exception of the two porches attached to the little octagonal tower of Andronicus Cyrrhestes, called the Temple of the Winds, forms an integral part of the design, from which it is impossible to consider it separately. The earliest example we have of the Roman modification is that of the Pantheon of Agrippa. This magnificent portico, raised on a graduated stylobate of nine steps, has eight columns in front, and, reckoning those at the angles, three and an antæ at each side; if the columns were fluted, and the antæ not, and these latter had suitable mouldings instead of foliated capitals, this portico would perhaps possess all the excellence that taste could require or fancy conceive. The necessity for an isolated portico in that instance is obvious both from the form and magnitude of the principal building, which, for the latter reason, at once forbids the attempt to make the cornice of the one correspond in line with that of the other. The unornamented state of the Great Rotunda also suggests that probably it either was, or was intended to be, concealed from observation by surrounding buildings, leaving only the stately portico itself in view; however this be, the idea of what may be either called an attached or a detached portico seems to have been seized with avidity in modern practice, where it is made not an ornamented part of the design, but rather a mere ornament attached to it. In many instances the difficulties arising from considerations of expense seem to be more powerful than good taste in influencing the selection of a starved-looking portico of four columns only in front, instead of six or eight or more, which would have occupied the entire field; and for the same pecuniary reasons, the rear ranks of columns, which, by the depth of shade they afford, are so essential to the beauty of a portico, too often are dispensed with. In the instance of the nine column portico at Pæstum, we see how indispensable the Greeks considered it to be that the integrity and unity of outline should be preserved. In more modern practice, a building of this description would probably have been furnished with only four or six columns in front, leaving the angles of the exterior of the cella either naked or with a pilaster; thus making the cornice of the portico and that of the rest of the building on different ranges. One of the most beautiful, as well as one of the most perfectly preserved examples of Roman taste we have is the little pseudo-peripteral temple at Nismes, called the Maison Carrée! If, with a transposable model, we take away the flanking columns of the portico, or attempt any other arrangement of them, unless it be to make it peripteral, it will be seen how much it may be deteriorated in effect: but it seems unnecessary to enter into a lengthened condemnation of a modification which no one attempts to defend on the score of good taste, though many practice it on the plea of saving expense, as it must be their poverty and not their will which consents.

Another departure in most of the Roman examples, from the plan of the Greek portico is the larger space left between the two centre columns. In the Ionic and Corinthian orders if not carried to excess, this is scarcely perceptible, but in the Doric it necessarily requires an additional triglyph, and is highly offensive and painful to the eye, as the architrave is elongated, and of course apparently weakened at the place where it has to sustain the loftiest and weightiest portion of the pediment; for although in building (using the term in contradistinction to architecture), it may answer every purpose if the supporting parts be sufficiently strong to bear the imposed burden, yet in the higher branch which commends itself less to the judgment than to the eye, that organ must be satisfied both from analogy and comparison: for instance, the inclining tower at Pisa was erected, and acquired its present inclination of about twelve feet from the perpendicular about 670 years ago, and although the spectator may be assured from the experience of so many centuries that it may remain some years longer, yet after the first effects of astonishment subside, it is a painful object, between which and the eye it is impossible to effect a reconciliation.

It was the practice of the Greeks to make the base of the triangular pediment correspond in length with the cornice on which it was imposed, just as we see a capital correspond in diameter with the neck of the shaft which it crowns; but it is now the practice either from poverty of taste or of purse, or both, to place on the cornice a pediment with a shorter base; it would not be more at variance with good taste were we to suggest that for the sake of harmony the capital also should have a less diameter than the shaft; and again, the pediment was the crowning feature of the composition, and had no wall, attic, or parapet either pierced or unpierced above it, but just as the capital was placed on the summit of the shaft; modern practice in the management of pediments is frequently otherwise, and we might with propriety propose that when it is deemed advisable to surmount the pediment with a mass of building, the columns also should have their elevation increased by the addition of a portion of shaft placed above the capital,* but if any object to this suggestion, then we have only to reply that our proposal is as capable of defence as their practice, and we are willing to let both fall together. We are confident that Mr. Hay will agree with us on the justness of the hypothesis, and from his admirable works on the harmony of colour, form, and proportion, we could not appeal to a more able judge.

The rage for pediments appears to have commenced in the reign of Diocletian; not satisfied with one at the gable ends of each edifice, the exaggerated taste of that day required that they should be represented in small, and turned into dressings for doors and niches; the latter in some measure corresponding with our windows, thus making a kind of mock-gable where no real one could possibly have place. Such a description of window dressing, although more expensive than appropriate mouldings, is very fashionable in our own times, and was also much used by the cinque-cento restorers.

The discovery, or as we should rather say, general introduction of win-

* We do not lay any claim to originality in offering this suggestion, for we have in our possession a much admired columnar chimney piece of cinque-cento design, from which we take the hint.

dow glass, causes a great difficulty in the arrangement of the Greek templar edifices. That the Romans were aware of this use of glass is evident from the discovery of it at Pompeii, as noticed in the second series of Sir William Gell's work, but they appear to have availed themselves of it so seldom that for a long time it was thought they were not acquainted with it. The little use made of it by them is to be accounted for, partly from the bad quality of their glass, and partly because their plans of buildings were matured before the invention was known; and their in-door worship did not require that the light of day should be admitted into their temples. It is quite idle now to dilate on the disadvantages of introducing windows into Greek compositions; the necessity for them is paramount, and all that remains for us to do is to render them as little discordant as we can; nor are we without Greek and Roman models to guide us, as may be seen in the temple of Erechtheum, at Athens, and that of the Sybil at Tivoli. In both instances they are of the size and form of ordinary windows, and merely ornamented with mouldings. The inside of the jambs of those in the Erechtheum are revealed, as if for the insertion of window frames, and they were most probably filled up with thin plates of semi-transparent marble, such as those spoken of by Pliny, and found in the Parthenon by Wheeler. The Chinese sometimes use thin laminæ of the mother of pearl oyster-shell, but more generally oiled silk for the same purpose.

In the palace of Diocletian we also find the pulvinated frieze which was taken into high favour by the *Restorers*, and not yet entirely laid aside in modern practice, though otherwise left undefended from the condemnation it has met with from all authors who have written on the subject: it looks in effect as if the frieze had been made of some soft material, and had given way under the pressure of the cornice, a semblance of weakness which may harmonize with the works of the cinque-cento school, but is totally inconsistent with Greek principles of construction; indeed it is difficult to conceive on what ground it could be recommended, or to guess why, except from carelessness, any architect of ability should disgrace his composition by its introduction, as we see it in the façade of one of the most admired Club-houses in London; but as this edifice, like the Farnese palace, has also a redeeming cornice, may we not be indebted for its window pediments, pulvinated friezes and balustrades to the taste of some modern San Gallo? The pulvinated frieze was thought to be a proper accompaniment to the Roman Ionic capital, and it must be admitted that the capital is quite good enough for such a frieze.

Many and great as the modifications of the Romans were, they are chargeable with nothing so preposterous as turning the graceful column into a hideous pigmy, for such is the dwarf column or baluster of the Restorers. Florence, the Athens of Italy, is said to have been the city of its birth in the first century of the revival; that it ever could have entered into the head of an architect to invent such a thing, is somewhat difficult to believe, indeed as much so as to discover the reason of its preservation in modern practice in preference to various other forms of rails and piercings. It may be described as an unhappy little column compressed into deformity by some process analogous to that by which *gobbi* (for which Italy also is celebrated), are made; and it is often introduced into a composition into which columns of due proportion enter, doubtless in perfect consistency with some laws of harmony with which we are unacquainted.

A striking difference in the practice of the Roman and Greek schools is to be found in the formation of curved mouldings; those of the former being parts of a circle may be formed with compasses, whilst those of the latter being excentric can only be drawn by the hand, and are in fact the line of beauty of Hogarth, in whose time what are now known as Roman, were supposed on the authority of the Restorers to be Greek mouldings. For a careless architect, and an ignorant employer, the Roman forms may do well enough, but by those who have eyes to see them the Greek will be preferred.

Both schools (as far as our observations extend) appear to have agreed in all cases on the necessity for a stylobate, although they differed much as to its form; in that respect modern practice is not similar—for we have seen many porticoes without any, though none so circumstanced that would not have been improved by the addition. With the Greeks it was formed in three receding courses, proportioned to the diameter of the column; but with their imitators no rule of any kind seems to have existed, except indeed, that the ancients, when it was formed in receding courses, thought it necessary that the number of the courses should be odd, in order that the temple might be entered with the right foot in advance. It might appear without due examination, that the triple arrangement of the stylobate was in itself a matter of small importance, but those who have observed the Greek plan particularly, in the Doric order, will not be of this opinion, or admit that any other numerical arrangement could produce the same pleasing effect. The most searching scrutiny into the practice of the Greeks, not only in this but in every particular relating to the art, must end in convincing the mind that they exactly attained the point of beauty. It would appear from all the Greek examples, with the exception of the Choragic monument of Lysicrates, that columns when used externally, were intended to have the appearance of affording facility of entrance into the edifice, or to harmonize with those that did; which intention would be entirely defeated by a lofty stylobate, and in modern practice it has often too much the appearance of a penurious expedient in giving a small column instead of a large one, thus showing a starved design. Besides, when columns are placed so much above the point of sight, as they frequently are, they fail in producing the desired effect. In modern adaptation we see an unhappy expedient, if possible more fatal than that of endeavouring to gain elevation by a lofty stylobate; we allude to the practice of piling columns upon columns. It cannot be denied that the entablature ought to be in proportion to the height of the façade, and therefore the superior must have in such cases a greater projection than the inferior ones. How can any harmony, any just proportion, any simplicity be attained in such compositions?

In this adaptation, for which they are not adapted, the columns and their accessories, whether they be of the same order or not, or whatever the scholastic arrangement may be by which their order of succession is regulated, are debased, and the expedient reflects no credit on their compilers. The most remarkable instance in this country of the practice is the façade of St. Paul's. Sir C. Wren never saw either a Greek or Roman edifice, yet his first thought (and first thoughts are sometimes best), was to make it with only one range. The practice seems to have arisen with the Romans, in the construction of the amphitheatres, for the interior arrangement of some of the Greek temples can scarcely be considered as a precedent.

By far the most important modification which awaited Grecian architecture on its reaching the banks of the Tiber, was the engrafting of the arch. That the Greeks were acquainted with this valuable addition to the science of construction is not certain, for although many persons have inferred it, yet none have been able to prove the affirmative. It is certain, however, from the *corbelled* dome of the treasury or tomb at Mycene, that they were at a very remote period acquainted at least with its form, though not its principle. To the Romans has been given the credit of its invention, and they may be entitled to it, but not exclusively; for the discovery of Mr. Hoskins the traveller, in Ethiopia, sets that point at rest. At Meroë, the ancient capital of Ethiopia, he found in the porch or entrance to one of the pyramidal tombs, which he fairly supposes to be of greater antiquity than any similar structure now existing in Egypt, a regularly constructed circular headed arch, with a key stone, supported by lateral pressure. This arch consists of alternate courses of four and five stones, and when there are only the smaller number, there is no single keystone. The span of the arch is five feet. At Gebel el Birkel, near the fourth cataract of the Nile, in the interior of another pyramid, he found a pointed arch supported in the same manner, having a joint at the apex, and apparently of a later date than the former; he also found a brick arch forming the tomb of Amunolph 1st., at Thebes, and this arch was constructed exactly like those of the present day, and had a span of eight feet six inches. As this king reigned 1650 years before our era, we can at once fix its date as nearly 800 years anterior to the building of Rome.* It has been said that probably the bow which the Great Architect of the Universe has placed in the Heavens, furnished to the Romans the idea of the arch in construction, if so, they soon attempted to improve on the model, by the introduction of the dropping keystone, which destroys the similitude. Or it may have been that as mathematicians assert, the circle to be the most perfect of all figures, it was desired to refute this and "relieve the eye" from its monotony, by giving a figure with a broken outline.

But, however the Romans may have arrived at the knowledge of the arch, it soon became general, and its introduction was fated to destroy, for a time, the architecture of Greece, and raise out of its ruins another style to compete with it for a share of the admiration of mankind. Long before we find any traces of the Greek orders in Rome, we see the arch in the Cloaca Maxima, which was constructed about the year 519, before our era; after this we have it at Pompeii, and in the triumphal arches and amphitheatres of the first and second centuries, when we see a striking and fatal departure from the Grecian rule, as to the width of the intercolumnia-

* Diagrams of these three arches are given in the Civil Engineer and Architect's Journal, Vol. VII., page 181, 1840.

tion occasioned by the combination of columns and arches in those structures. When in this examination we pass on to the temple of Antoninus and Faustina, we find that Palladio gives in the restoration of this edifice court in front (not now to be traced), part of which he says he saw removed, and in this restored court we have an arcade nearly similar to what he gives as that of the Corinthian order; then at the palace of Diocletian at Spalatro, we find arches springing from columns, the germ as it were of what was afterwards to be perfected in the pointed style, and produce the clustered column and the lancet arch, which in the long drawn aisle and fretted vault exhibit the glories and triumph of monastic architecture; for however that style may be indebted for some ideas to the Saracenic, imported at the time of the Crusades, yet at Spalatro we have incontrovertible proofs of its origin, even to the grotesque human heads and the zigzag ornament we erroneously call Saxon, and suppose to be peculiar to that style. Here we have also two legs of different arches springing from one column, both with and without imposts, the columns themselves raised on consols, these latter being ornamented with grotesque heads just as they are in the Gothic. When then we hold in one hand an elevation of the Parthenon, and in the other one of the Cathedral at Cologne, however startling it may appear, the style of the latter is a modification of that of the former. Some architects have drawn rather too largely on the harmony relationship might be supposed to maintain between the two styles, and have grouped them together as we see in the Duomo at Milan, and some of the alterations at Westminster Abbey.

It must be admitted that the Moorish architecture existing in Spain is very similar as regards the support of the arch to that at Spalatro, but when we consider that all the Mediterranean coast of Africa was a Roman province, and see in it the remains of an earlier and purer state of art, we may reasonably infer that Africa was also indebted to the Romans for the introduction of the method of raising their horse-shoe arches on columns.

Of Grecian domestic edifices we absolutely know nothing, except through those of Roman taste, and we may fairly conclude that those of the former differed as much from the latter as the public edifices of the two people did: however it is in vain to speculate on this point, and we must take the Romans as we find them, in the disinterred city of Pompeii. One thing very worthy of observation in the interiors of the edifices of this place in which they differ so much from those of more modern times, is that in almost every instance the hand of the architect is seen, and not the mere monotonous arrangement of a common builder. It is very true that difference of climate and habits prevent us from taking the Pompeiian houses as models for the construction of modern domestic edifices, yet much may be learned from a study of them, and the pleasing variety of character that may be given to interiors by a judicious architectural arrangement too often overlooked by us. An inspection of the house of the late Sir John Soane will show what can be done in this way even in an edifice of ordinary size and exterior, and in this point of view, independent of the models and treasures of art which it contains, the legacy of it to the nation is a bequest that can scarcely be too highly valued. It is curious to observe the similarity in the ground plans of the domestic edifices of the Chinese and those at Pompeii; and also between the temples of the same people and those of Egypt, the details indeed have nothing in common in either case, but the plans are much more similar than anything to be found of a modern date either in Italy or Egypt, are to the ancient buildings of those countries.

Both the Elizabethan and the Italian villa style are modifications of the Greek; and it is remarkable that when once we leave the fountain head, the farther we go from the source the clearer the stream runs, *i. e.*, when the modification ceases to bear that kind of resemblance that a caricature has to the original, it presents something original in itself, and ceases to be offensive to the eye. Perhaps the great merit of these styles when used for domestic purposes consists in their pliancy and freedom from strict rules. When well designed they present pleasing compositions, but never can aim at anything higher.

The Greek style has suffered much from its professed admirers and restorers, and it has now to sustain an attack from its avowed enemies; for in our own times and country the senseless cry of no Pagan, no Heathen, is now raised against it; as if the style which the short-sighted bigots have selected to supply its place were not equally obnoxious to the charge. Do these anti-Pagans not recollect that many of the sacred writings from which they profess to draw their religion, were written in a Pagan tongue; and that to acquire a knowledge of it and enable them to teach their religion to others, they store their minds with the history of all the abominations of Paganism? Whether the Greek style be more suitable than the one they have selected for the erection of *their* temples we do not pretend to decide, but we do maintain "that things which are equal to the same are equal to one another"—and further, that the Christian dispensation was not intended to overturn any of the practices, inventions, or institutions of mankind which were not repugnant to its own laws and precepts. According to some the great temple of Jehovah at Jerusalem, was in the Egyptian style, and to others in the early Greek of Pæstum: in either case the style must have been the same as that employed in the construction of Pagan temples. The Rev. James Dallaway, in his DISCOURSES ON ARCHITECTURE, has fallen into an error in saying that "the Basilica of St. Paul's, at Rome, erected by Constantine, had the earliest instance of arches constructed on columns instead of piers," and may have led his reverend brethren (unintentionally, we believe), into the error of hence supposing that form to be of Christian invention; but they cannot continue to hold this opinion after examining Adam's View of Diocletian's palace at Spalatro.

With the exception of the form of the cross in the ground plan, the mullions of windows, the rose or wheel windows, and the spires, (important features no doubt, yet insufficient in themselves to constitute a style), we know of no other characteristic that can be said to be exclusively of Christian times or countries; for all else we are more or less indebted to the Pagan or the Moslem.

It was admitted, in a former part of this essay, that difference of climate and habits may require different descriptions of edifices, both public and private, from those that were erected by the inventors of the Greek style; but it cannot be too strenuously urged, as before stated, that if it be desired to preserve the character of a style in its purity, we must adhere strictly to the principles that guided its inventors, although, from circumstances, we may be constrained to modify the style in its application. A Greek composition is not a thing of shreds and patches, with a portico stuck on its front; nor is it a receptacle for groups of mock pediments, a retreat for a pigmy ordinance, nor yet an asylum for columns out of place. Simplicity of the most bewitching kind, an air of repose and completeness, and the most perfect harmony, pervade every part. It would be impossible to lay the finger of criticism on any ornament and say that it could be dispensed with, or its place more appropriately supplied by any other: such are the examples which the architects of the age of Pericles have left for our instruction, and when we attempt to modify them to suit our present wants, the great difficulty is to preserve their evanescent spirit; still it appears to be within the range of possibility to do so, but only by those who are thoroughly imbued with the idea that these models contain in themselves the elements of perfection sufficient for a new creation of the art if all else were lost. On that feeling the success of our adaptation depends; without it, an edifice may have a verbal resemblance to the model without possessing its expression; may be ornate, but not ornamental; convenient, but not symmetrical; well constructed, but ill designed; the work of a skilful builder who understands his trade, but not the production of an accomplished architect who aims at the highest walk in his profession; it may induce the groundlings to stare, but it may also force the judicious to grieve.

With the sublime works of the ancient masters for our guidance in the three orders we have sufficient materials to work upon, to modify, combine, and adapt for our present requirements, and the instruction of future ages. As soon as we shall have these examples, not only in distant lands and geometrical elevations, but realised before our eyes in our own country, then they must effect an improvement in our taste, and then we shall be better able to invent and make new combinations on the same unerring principles exhibited in our models; in short, we must first have a pristine—not a *cinque*—but a *novocento* revival; and it would appear that such was the opinion of the Institute of British Architects in proposing the subject of the present essay. Let us commence then by discarding, *in toto*, the emasculated Doric, and when we compose in the Doric itself let us recollect that our conceptions must be the works of giants, and not the efforts of pigmies; and in the Ionic and Corinthian, that the ornate capitals require ornamented shafts, and that sculpture adds much to the beauty of the frieze in all the orders. We must also guard against breaking up the entablature, and in the treatment of porticoes bear in remembrance that those which are wanting in depth must be deficient in beauty. Let us also remember that although windows be necessary evils, yet it is not necessary to increase the evil by incongruous ornaments; and that our designs must have unity and be one whole, not a collection of separate and distinct parts.

For ourselves, although in various countries we have seen "cloud-capp'd towers, gorgeous palaces, and solemn temples," of christian, pagan, heathen, and moslem construction, yet we remain convinced that (as has been well said) "for all the higher effects which architecture is capable of producing, a Greek peripteral temple of the Doric order is UNRIVALLED."

THE PRINCIPLES OF CHURCH RESTORATION.

Those who can distinguish between the revival of the ancient principles of pointed architecture and a mechanical imitation of ancient forms, have no difficulty in recognising the propriety of restoring the numerous ecclesiastical and civil edifices bequeathed to us by our mediæval ancestors. An important distinction between the renewed appreciation of pointed architecture now, and the Renaissance of classic architecture in the fifteenth century—and one greatly in favour of modern taste,—is that no effort is now made to reconcile styles which depend on opposite causes for their beauty. The modern revival, on the contrary, is marked by an anxiety to purge our churches of the barbarisms of the Debased and pseudo-classic revivals, and to render our national architecture as free as possible from foreign admixture.

If we define the principle of church restoration to be the removal from our churches of everything that is absolutely *incongruous* with their architecture, and if we apply this principle consistently, we shall have no difficulty in ascertaining what is to be retained, and what is to be rejected where several styles of architecture are exhibited in the same edifice.

It is necessary that this definition should be established, because restorers have frequently contented themselves with the object of ascertaining and carrying out the *original idea* of the building restored. Now, what we look upon as a fatal objection to this principle is, that in the majority of cases it is incapable of a practical application. We suppose that there is no one, really zealous for the advancement of pure architecture, who would not rejoice to see every one of our glorious cathedrals thoroughly and efficiently restored; and yet, if the task were to be set about with the view of realising exclusively the intentions of the first founders of these vast piles, which are the growth of successive ages, the most enthusiastic lover of mediæval art most oppose a work which tended rather to destruction than restoration.

Supposing, for instance, it were determined to perfectly restore Ely Cathedral, and suppose ample funds existed for this purpose, so that there were absolutely no restrictions whatever on the efforts of the architect except those imposed by his own taste and judgment—would any one be insane enough to attempt to restore Ely Cathedral to one uniform style? Or, supposing that one style only ought to be retained, by what rule should the selection be directed? Should all the cathedral be destroyed except those parts which exhibit the Norman architecture of the Prior's Entrance?—or, all except the Early English similar to that of the presbytery? —or, all except the Decorated of the choir?—or, all except the Perpendicular of Bishop Alcock's Chapel? Is it not obvious that it would be impossible to retain any one style exclusively?

By what principle then ought the restoration to be directed in the instance supposed? Obviously by this,—of removing all the additions and repairing all the mutilations by which the church has been defaced since the Reformation, and of *retaining the whole of the genuine architecture*. If the different styles adopted by our ancestors had been so essentially discordant as to be absolutely irreconcilable to the same principles of beauty,—if it were impossible that forms successively developed in Christian architecture could be combined harmoniously,—if, in every case where the same building exhibited more than one style, the variety appeared harsh and offensive to the eye,—then, indeed, there might be some pretext for the advocates of uniformity. It is a matter of fact, however, and one that speaks loudly for the merit of Christian architecture, that it *is consistent with itself*, and that different forms of it may exist together without producing a discordant effect. When, indeed, we come to the Debased period, we find contrasts repugnant to pure taste, because arising from the combination of pointed architecture with a style diametrically opposed to it—the Classic. The effect of Grecian mouldings introduced in the woodwork (and sometimes, alas, as in Westminster Abbey, in the masonry) of an English cathedral, is monstrous and insufferable. But the case is altogether different where Norman architecture is combined with Early English or Decorated with Perpendicular: for here, the very fact that each style grew out of the preceding—that there was in each case a Transition style—proves that there cannot be incongruity or discontinuity in these successive developements of mediæval art.

There is moreover a tacit homage paid to the principles of our ancestors by the very act of restoring their architecture, which is inconsistent with the destruction of any part of it. Without adopting a vague admiration of old things simply for their antiquity, independently of their excellence, we yet must concede thus much:—that, in destroying the additions made to our churches after the Reformation, we, in fact, give our adhesion to the architectural principles of those who preceded the Reformation. We say, in fact, this, by our preservation of the existing monuments of Norman and Pointed architecture, that those edifices exhibit merits totally overlooked or mis-apprehended by the classic innovators. Now is it not palpably absurd and inconsistent, when we have made this profession, to destroy any portion of the genuine works of the mediæval architects? Must we not, to speak plainly, condemn this destruction as sheer Vandalism—a Vandalism, too, which is inconsistent with itself, and works all the more fatally because disguised by a profession of reverence for antiquity?

The *restoration* of St. Sepulchre's Church, at Cambridge, was disgraced by this reckless and irremediable desecration. The ancient Perpendicular architecture of the fifteenth century was destroyed in the western part of the building by those who, by a singular perversity, erected at the east a chancel in the Perpendicular style of the *nineteenth* century! And this destruction, under the name of restoration, was the work of those who take to themselves κατ' ἐξοχὴν the character of guardians of English church architecture. Well might M. Didron complain that the injury which modern restorers have, in their self-sufficiency, done to our ancient monuments is far more irreparable than the ravages of time and neglect.

In a recent number of the *Ecclesiologist* we find a complaint of the destruction of the old gateway of the British Museum. This complaint is founded, not on the consideration that the structure has any merit in itself, —it is not attempted to be denied that it is a hideous specimen of bastard architecture,—but simply on the ground that *the architecture is "genuine!"* Senseless inconsistency! A vile mass of brickwork, decorated with some contemptible imitations of Grecian mouldings, is to be preserved, *simply* because it is old; and yet these blind admirers of mere antiquity cannot consent to the preservation of that which is much more ancient, and possesses moreover the merit of architectural beauty and the claim of reverence for sacred places.

It is well nigh time that some effectual means were taken to prevent injuries which once effected are irremediable. We speak thus boldly of them because there is a growing spirit for tampering with ancient architecture in England and France which has already produced the most pernicious effects and tends to produce more. The injuries that have been committed in the cathedral of St. Denis, near Paris, under the pretense of restoration, ought to move the indignation of every lover of Pointed architecture. At Rouen, too, and Amiens (we believe) also, the same work of destruction has been commenced, and under the same pretext. One zealous and uncompromising denouncer of these innovations—M. Didron—has, indeed, been able, in many instances, by the respect attached to his profound antiquarian learning, to restrain the progress of the mischief—and, in a country where the reparation of public monuments is in the hands of the government, his voice must have effect; but here we have no such general supervision, and can only trust to the slow progress of public opinion for the protection of our churches.*

If there must be a destruction of ancient architecture it ought, at least, to proceed on principles which are consistent with themselves, but even this is not the case. Before taking a step which cannot be retraced, the least exercise of prudence is to lay down a general plan of our future progress; and yet, in church-restoration this has been hitherto impossible.

* We do not mean to assert absolutely that it is impossible for a case to arise where the partial demolition of ancient work is justifiable, but we certainly are quite incapable of foreseeing such a case. It may be as well to allude here to to an instance where a laudable work of restoration is likely to be marred by indiscretion in the particular noticed in the text. One of the proposed alterations of Jesus College Chapel, at Cambridge, is the substitution of an Early English east window for that of ancient Perpendicular architecture, at present existing in the choir. On what principle this demolition is commenced it is not very easy to see: it is not even pretended that it will be possible to adopt lancet architecture throughout the entire building, for the Perpendicular windows in the transepts and nave are not to be removed. In fact, a destruction of all the chapel except the lancet architecture would almost involve the rebuilding of the whole edifice. Besides, there is no more reason to retain parts anterior than those posterior to the lancet period, and, to be consistent, the piscina and the Norman gallery in the north transept ought to be destroyed—or rather, if the principle be to carry out the original idea of the edifice, then the Norman ought alone to be retained. If the great east window be, as we believe, the work of Bishop Alcock, the founder of the college, to whom the present institution is chiefly indebted for its existence, respect for his memory should be an additional motive for preserving one, and not the least, of the records of his munificence.

The modern science of mediæval architecture is at present an immature science; every day is adding to our stock of knowledge or correcting false impressions. It is not many years since Rickman introduced the classification and nomenclature of the different styles now in use. How is it possible then that in so brief a period we can have learned all of the science that is worth knowing—that we have now learned so much that we may venture to correct the errors of our teachers, the mediæval architects? At least, there is no harm in waiting awhile till we be *quite* sure that our corrections are not the result of imperfect knowledge.

Of this there will be no debate, that no mischief can arise from confining our endeavours, for the present, to careful reparation. The removal of flat plaster ceilings, of Grecian or Elizabethan screens, of the defilements of stucco, paint and whitewash, and the other inventions of churchwardens and parish architects, are works that may be undertaken without the chance of their propriety being hereafter disputed. Add to these, the repair of parts which have decayed by process of time or been mutilated by violence, the restitution of adornments where clear traces of them remain, and the *scrupulous preservation of every portion of the genuine mediæval architecture*, and we have done all that the present, or, probably, any future, state of our knowledge can justify.

BLAST FURNACE.

Observations on the more recent Researches concerning the Operations of the Blast Furnace in the manufacture of Iron.

By Dr. J. L. Smith.

[From *Silliman's Journal* for March, 1846.]

The great difference existing between metallurgical operations of the present day, and those of a former period, is owing chiefly to the ameliorations produced by the application of the science of chemistry to the *modus operandi* of the various changes taking place during the operations, from their commencement to their termination.

Copper and some other metals are now made to assume forms in the chemist's laboratory, that formerly required great artistical skill for their production—the chemist simply making use of such agents and forces as are at his command, and over which he has, by close analytical study, acquired perfect control. Our object, at present, is only to advert to the chemical investigations more recently made on the manufacture of iron, treating of those changes that occur in the ore, coal, and flux, that are thrown in at the mouth of the furnace, and in the air thrown in from below. For most that will be said on this subject, we are principally indebted to the recent interesting researches of M. Ebelman.

The importance of a knowledge of the facts to be brought forward in this article, will be apparent to every one in any way acquainted with the manu- of iron. It will be seen, that the time is not far distant when the economy in the article of fuel will amount in value to the present profit of many of the works. The consequence must be, that many of those works that are abandoned will be resumed, and others erected in localities formerly thought unfit.

It is well known that the blast furnace is the first into which the ore is introduced, for the purpose of converting it into malleable iron, and much therefore depends upon the state in which the pig metal passes from this furnace, whether subsequent operations will furnish an iron of the first quality or not.

In putting the blast furnace into operation, the first step is to heat it for some time with coal only. After the furnace has arrived at a proper temperature, ore, fuel and flux, are thrown in alternately, in small quantities, so as to have the three ingredients properly mixed in their descent. In from 25 to 48 hours from the time when the ore is first thrown in, the entire capacity of the furnace, from the tuyer to the mouth, is occupied with the ore, fuel, and flux, in their various stages of transformation.

In order to explain clearly, and in as short a space as possible, what these transformations are, and how they are brought about, we may consider:—1. The changes that take place in the descending mass, composed of ore, fuel, and flux.—2. The changes that take place in the ascending mass, composed of air and its hygrometric moisture, thrown in at the tuyer.—3. The chemical action going on between the ascending and descending masses.—4. The composition of the gases in various parts of the furnace during its operation.—5. The causes that render necessary the great heat of the blast furnace.

1. *Changes that take place in the descending mass, composed of ore, coal, and flux.*—By coal is here meant charcoal; when any other species of fuel is alluded to, it will be specified. In the upper half of the fire-room, the materials are subjected to a comparatively low temperature, and they lose only the moisture, volatile matter, hydrogen, and carbonic acid, that they may contain; this change taking place principally in the lower part of the upper half of the fire-room.

In the lower half of the fire-room, the ore is the only material that undergoes a change, it being converted wholly or in part into iron or magnetic oxide of iron—the coal is not altered, no consumption of it taking place from the mouth down to the commencement of the boshes.

From the commencement of the boshes down to the tuyer, the reduction of the ore is completed. Very little of the coal is consumed between the boshes and in the upper part of the hearth; the principal consumption of is taking place in the immediate neighbourhood of the tuyer.

The fusion of the iron and slag occurs at a short distance above the tuyer, and it is in the hearth of the furnace that the iron combines with a portion of the coal to form the fusible carburet or pig-iron. It is also on the hearth that the flux combines with the siliceous and other impurities of the ore. This concludes the changes which the ore, coal, and flux undergo from the mouth of the furnace to the tuyer.

If the fuel used be wood, or partly wood, it is during its passage through the upper half of the fire-room that its volatile parts are lost, and it becomes converted into charcoal. M. Ebelman ascertained that wood, at the depth of ten feet, in a fire-room twenty-six feet high, preserved its appearance after an exposure for 1¾ of an hour, and that the mineral mixed with it preserved its moisture at this depth; but three and a half feet lower, an exposure of 3½ hours reduced the wood to perfect charcoal, and the ore to magnetic oxide. The temperature of the upper half of the fire-room, when wood is used, is lower than in the case of charcoal, from the great amount of heat made latent by the vapour arising from the wood. In the case of bituminous coal, Bunsen and Playfair find that it has to descend still lower before it is perfectly coked.

After the wood is completely charred, or the coal become coked, the subsequent changes are the same that happen in the charcoal furnaces.

2. *Changes that take place in the ascending mass, which is composed of air and hygrometric moisture.*—The weight of the air thrown in at the tuyer in twenty-four hours is twice that of the ore, coal, and flux, thrown in at the mouth during the same time.

The air, as soon as it enters the tuyer and reaches the first portion of coal, undergoes a change—its oxygen is converted into carbonic acid, and its moisture decomposed, furnishing hydrogen and carbonic oxide—after ascending a short distance (12 or 18 inches,) the carbonic acid is converted into carbonic oxide—between this point and the upper part of the boshes it undergoes but very little change, having added to it a further small amount of carbonic oxide. So the ascending column at the top of the boshes is composed of nitrogen, carbonic oxide and hydrogen—from this point it begins to undergo a change; the carbonic oxide diminishes, carbonic acid appears, and goes on increasing for about half the way up the fire-room; after which the carbonic acid, carbonic oxide, and nitrogen remain the same, when the hydrogen increases, and moisture begins to appear and augment up to the mouth. The ascending mass, as it passes out of the mouth, contains the vapour of water, carbonic acid, carbonic oxide, hydrogen, and nitrogen. The nitrogen undergoes no alteration in its passage through the furnace, and the same is true of the hydrogen formed at the tuyer.

If wood be used, the gases passing out of the mouth are the same as those just mentioned, with an increased quantity of moisture, and the addition of those pyroligneous products arising from the dry distillation of wood.

In case of the use of bituminous coal, the gases, first alluded to, have added to them ammonia, light carburetted hydrogen, olefiant gas, carburetted hydrogen of unknown composition, and sulphuretted hydrogen.

3. *The chemical reaction occurring between the ascending and descending masses.*—From the foregoing statements we can at a glance see what are the materials to be met with in the different parts of the furnace, and can therefore readily study their reactions upon each other.

In the upper half of the fire-room little or no chemical action is taking place, the ore, flux, and coal, as already stated, simply losing their volatile parts. In the bottom of the upper half and the entire lower half of the fire-room a reaction is taking place between the ore and the carbonic oxide of the ascending column; iron or magnetic oxide of iron and carbonic acid being the result. It must be borne in mind that the coal has played no part in this reduction down to the commencement of the boshes. Between the boshes, and in the hearth, no reaction appears to take place between the ascending and descending masses, but the reduction of the ore is completed by the direct action of the coal upon the remaining portion of the undecomposed ore; carbonic oxide being formed;—and here is the first consumption of the coal in its passage downwards.

According to M. Ebelman, the ore loses in the fire-room $\frac{9}{13}$ of its oxygen by the reaction of the oxide of carbon, and the remaining $\frac{4}{13}$ disappears in the boshes and hearth, in the manner already stated, at the expense of from $\frac{8}{100}$ to $\frac{12}{100}$ of the entire amount of charcoal used.

The ore being now completely reduced, unites with a portion of carbon in the hearth, melts at about 13 inches from the tuyer, and descends into the crucible; and here also the flux, combining with the impurities of the ore, forms the slag, which melts.

The coal and the air react upon each other most powerfully, just in the neighbourhood of the tuyer, where the most intense heat is produced; the oxygen becomes converted into carbonic acid, which acting upon a portion of the ignited coal, is almost at the same moment reduced to carbonic oxide; the moisture of air acting on the ignited charcoal undergoes the decomposition already mentioned, hydrogen and carbonic oxide resulting therefrom.

When the ore is easy of reduction, the gas at the boshes is represented by 100 nitrogen and 52·5 carbonic oxide, *plus* the quantity of carbonic oxide and hydrogen afforded by the moisture.

It must be clearly understood, that these rules do not apply to every variety of ore. They are especially applicable to the hemetites and such ores as are either naturally porous or become so in their passage through the fire-room of the furnace, thus increasing the surface of contact exposed to the action of the reducing agent (carbonic oxide), so that when it has reached the boshes the reduction is nearly complete.

The specular, magnetic, and siliceous ores, are reduced with much more difficulty; most of the ore, in these cases, reaching the boshes but slightly altered, they being principally dependent upon the direct action of coal for their reduction. This circumstance largely increases the consumption of coal when any of these ores are employed; and the amount of caloric made latent, in consequence of the reduction requiring the direct action of the coal, is very great; whereas in the reduction of the ore by carbonic oxide no heat becomes latent, for the heat rendered latent by the oxygen of the ore becoming gaseous, is compensated by the sensible heat produced by the combination of the carbonic oxide with the oxygen. Where the reduction is produced by the carbon, with the formation of carbonic oxide, 1598 unities of heat are made sensible, while 6216 are rendered latent, giving a difference of absolute loss of 4618.

It should be the object of the metallurgist to reduce as much of the iron as possible by the oxide of carbon. Magnetic, siliceous, and other hard ores, should be reduced to smaller fragments than those softer and more easily managed. Were it possible to reduce them to powder without the danger of choking the furnace, it would be all the better, as the great object is to have a large extent of surface exposed to the carbonic oxide. The different capacity of different ores for reduction shows the necessity of having furnaces of different dimensions for them respectively.

The matter which covers the melted metal in the crucible, and that which adheres to the interior of the hearth, contains silicate of iron and charcoal in a pasty state, and there is consequently a constant reduction of the oxide of iron, which gives rise to carbonic oxide; this gas bubbles through the slag, which, if drawn off at this time, will, when cold, present a porous structure,—a sure indication that the furnace is not working well, and that the slag itself contains much of the ore in the form of a silicate.

4. *Composition of the gas in various parts of the furnace during its operation.*—The analyses lately made by Ebelman are the most accurate and best detailed that we are in possession of. What follows has reference to a furnace worked with charcoal.

Gas taken from the mouth of the furnace and dried:—

Carbonic acid	12·88
Carbonic oxide	28·51
Hydrogen	5·82
Nitrogen	57·79

The vapour of water in a hundred volumes of this gas, varies from nine to fourteen volumes. Examinations made at different times show the proportion of hydrogen and nitrogen to be nearly uniform, and that the sum of the volumes of carbonic acid and carbonic oxide is constant, but that there is a variation in their respective proportions.

Gas taken from the interior of the fire-room at 5 *to* 10, *and* 13 *to* 17 *feet from the mouth (fire room* 36 *feet).* From five to ten feet the proportion of moisture diminishes, the other ingredients remaining about the same. From 13 to 17 feet the proportion of carbonic oxide increases, while the carbonic acid and hydrogen diminish.

Gas from the bottom of the fire-room and top of the boshes:—This is remarkable for the constancy of its composition, and for the absence of carbonic acid and watery vapour. Composition:—

Carbonic oxide	35·01
Hydrogen	1·92
Nitrogen	63·07

Gas from the bottom of the boshes and commencement of the hearth:—

Carbonic acid	0·31
Carbonic oxide	41·59
Hydrogen	1·42
Nitrogen	56·68

Gas from the neighbourhood of the tuyer:—

Carbonic oxide	51·35
Hydrogen	1·25
Nitrogen	47·40

The two last statements would appear to contradict the rules previously laid down, as regulating the operation of the blast furnace; for, according to them, the proportion of carbonic oxide, at the top of the boshes, should be a little greater than in the hearth, whereas the reverse would appear to be the case by the analyses here given. Besides, from a glance at the composition of the three last gases alluded to, it would appear that the gaseous products, as they ascended the furnace, lost completely a portion of the carbonic oxide, without a replacement by carbonic acid or other compound; in other words, a portion of it would appear to be completely annihilated, which of course is an impossibility. This apparent anomaly is easily accounted for, when it is stated how the gas was collected.

In order to obtain the gas from different portions of the furnace, holes were bored into the side, and a tube inserted, by which it was drawn off. Allusion has already been made to the fact that a pasty mass adheres to the sides of the hearth, containing silicate of iron and charcoal, in which there is a constant reduction of the iron, with the formation of carbonic oxide. Now it is evident that the gas drawn off by a hole bored into the side of the hearth, will be largely mixed with this carbonic oxide forming in the immediate neighbourhood of the opening, and that it cannot serve as an index to the character of gas passing through the centre of the hearth. M. Ebelman was aware of this fact, but he was not able to overcome the difficulties in the way of obtaining the gas under the proper circumstances.

Gas taken at the tuyer.—Here it is little else than atmosphere mixed with a few per cent. of carbonic acid.

From these results it will not be difficult to admit, that the oxygen of the air is converted immediately into carbonic acid, which is rapidly changed into carbonic oxide, under the influence of an excess of carbon and the high temperature developed near the tuyer.

5. *The causes that render necessary the great heat of the blast furnace.*—The weight of the ore, flux, and combustible, which enters the furnace, being only one-half that of the ascending column, and as the specific heat of these three materials is very much below that of the gas of the ascending mass, it is not the heating of them that explains the necessity of the very great heat of the blast furnace. But the principal cooling causes are,—

1. The drying of the ore, flux, and coal, and the expulsion of carbonic acid from the flux, &c., rendering much of the heat latent; for what was solid is now transformed to the gaseous state.

2. The reduction of the ore, or in other words, the transformation of the solid oxygen of the ore into gaseous oxygen. If the ore has been deprived of its oxygen by the action of carbonic oxide, with the formation of carbonic acid, the heat rendered latent by the oxygen, is compensated for by the heat developed by the reaction between the oxygen and carbonic oxide; which is the character of the operation that principally takes place in the lower part of the fire-room. If the ore has been deprived of its oxygen by the direct action of the coal, the amount of heat rendered latent is enormous, as already stated; for carbonic oxide is the result of this reaction, and the amount of heat developed by it falls far short of that rendered latent by the oxygen that has entered into its formation, assuming the gaseous condition,—this is the character of the reduction taking place in the boshes and hearth.

3. The conversion of the carbonic acid near the tuyer into carbonic oxide has a powerful influence in cooling the upper part of the hearth; for of the 6260 units of heat formed by the first action of the air upon the coal, 4662 are rendered latent by the conversion of this carbonic acid into carbonic oxide.

This terminates what it was proposed to treat of; it is little else than a sketch of the chemistry of the blast furnace, sufficient to show its importance.

In a future article, some remarks will be made upon the amount of combustible lost in the operation of this furnace, the recent methods employed to prevent this loss in the complete combustion of coal, the action of the hot blast, theory of the refining furnace, charring of wood, and other points of interest.

STEPHENSON'S TUBULAR BRIDGE.

Mr. Fairbairn's Report.

Abstract or short Summary of Results from Experiments relative to the proposed Bridge across the Menai Straits, addressed to Robert Stephenson, Esq. By. W. Fairbairn.

After a series of experiments undertaken at your request, for ascertaining the strongest form of a Sheet Iron Tubular Bridge across the Menai Straits, I have been induced, in order to meet the requirements for such a structure, and to ensure safety in the construction, to call in the aid and assistance of my friend Mr. Hodgkinson.

The flexible nature of the material, and the difficulties which presented themselves in retaining the lighter description of tubes in shape gave exceedingly anomalous results; and having no formula on which dependence could be placed for the reduction of the experiments, I deemed it necessary, in a subject of such importance, to secure the co-operation of the first authority, in order to give confidence to the Chester and Holyhead Railway Company, with whom you are connected, and the public generally.

It will be observed, that the first class of experiments is upon cylindrical tubes;—the second upon those of the elliptical form;—and the last upon the rectangular kind. Tubes of each sort have been carefully tested, and the results recorded in the order in which they were made; and moreover, each specimen had direct reference to the intended Bridge, both as regards the length and thickness, as also the depth and width.

In the first class of experiments, which are those of the cylindrical form, the results are as follow:

CYLINDRICAL TUBES.

No. of Experiments.	Distance between the supports. ft.	in.	Diameter in Inches.	Thickness of Plate in inches.	Ultimate Deflection in Inches.	Breaking weight in lb.	Remarks.
1	17	0	12·18	·0408	·39	3,040	Crushed top.
2	17	0	12·00	·0370	·65	2,704	Ditto.
3	15	7½	12·40	·1810	1·29	11,440	Torn asunder at the bottom.
4	23	5	18·26	·0582	·56	6,400	Ditto.
5	23	5	17·68	·0631	·74	6,400	Ditto.
6	23	5	18·18	·1190	1·19	14,240	Ditto.
7	31	3¼	24·00	·0954	·63	9,760	Ditto.
8	31	3¼	24·30	·13601	·95	14,240	Ditto.
9	31	3¼	24·20	·0954	·74	10,680	Ditto.

With the exception of the first two, nearly the whole of the tubes were ruptured by tearing asunder at the bottom through the line of the rivets.

Finding the cylindrical form comparatively weak, the next experiments were upon tubes of the rectangular shape, which gave much better results. For the present it may, however, be more convenient to take the elliptical kind, as being the nearest approximation, as regards both form and strength, to the cylinders recorded above.

ELLIPTICAL TUBES.

No. of Experiments.	Distance between the supports. ft.	in.	Diameters, transverse and conjugate in inches.	Thickness of Plates in inches.	Ultimate Deflection in inches.	Breaking weight in lb.	Remarks.
19	17	0	14·62 / 9·25	·0416	·62	2,100	Crushed on top.
20	24	0	21 66 / 13·50	1·1820	1·86	17,076	Broke by extension.
21	24	0	21·25 / 14·12	·0688	·45	7,270	By compression.
22	18	6	12 ·00 / 7 ·50	·0775	·95	6,867	By compression. This tube had a fin on the top side.
24	17	6	15·00 / 9·75	·1430	1·39	15,000	Both sides were ruptured.

It will be observed that the whole of these experiments indicated weakness on the top side of the tnbe, which, in almost every case, was greatly distorted by the force of compression acting in that direction. It is probable that those of the cylindrical form would have yielded in like manner, had the rivetting at the joints been equally perfect on the lower side of the tube. This was not, however, the case, and hence arise the causes of rupture at that part.

The next experiments, and probably the more important, were those of the rectangular kind; they indicate a considerably increased strength when compared with the cylindrical and elliptical forms: and, considering the many advantages which they possess over every other yet experimented upon, I am inclined to think them not only the strongest but the best adapted (either as regards lightness or security) for the proposed Bridge.

RECTANGULAR TUBES.

No. of Experiments.	Distance between Supports ft.	in.	Depth in inches	Width in inches.	Thickness of Plate in inches. top.	bottom.	Ultimate Deflection in inches.	Breaking Weight in lb.	Remarks.
14	17	6	9·6	9·6	·075	·075	1·10	3,738	Broke by Compression.
14	17	6	9·6	9·6	·272	·075	1·13	8.273	(Reversed.) Extens.
15	17	6	9·6	9·6	·075	·142	0·94	3,788	Compression.
15	17	6	9·6	9·6	·142	·075	1·88	7.148	Extension.
16	17	6	18·25	9·25	·059	·149	0·93	6,812	Compression.
16	17	6	18·25	9·25	·149	·059	1·73	12,188	Ditto.
17	24	0	15·00	2·25	·160	·160	2·66	17,600	Ditto.
18	18	0	13 25	7·50	·142	·142	1·71	13,680	Ditto.
23	18	6	13·00	8·00	·066	·066	1·19	8,812	Compression. Circular bottom, fin at top.
29	19	0	15·40	7·75	·230	·180	1·59	22,469	Sides distorted. Corrugated top.

On consulting the above table, it will be found that the results as respects strength are of a higher order than those obtained from the cylindrical and elliptical tubes; and particularly those constructed with stronger plates on the top side, which, in almost every experiment where the thin side was uppermost, gave signs of weakness in that part. Some curious and interesting phenomena presented themselves in these experiments,—many of them are anomalous to our preconceived notions of the strength of materials,—and totally different to any thing yet exhibited in any previous research. It has invariably been observed, that in almost every experiment the tubes gave evidence of weakness in their powers of resistance on the top side, to the forces tending to crush them. This was strongly exemplified in experiments 14, 15, 16, &c., marked on the drawings and the table. With tubes of a rectangular shape, having the top side about double the thickness of the bottom, and the sides only half the thickness of the bottom, or one-fourth the thickness of the top, nearly double the strength was obtained. In experiment 14, (marked in the margin of the above table,) a tube of the rectangular form, 9½ inches square, with top and bottom plates of equal thickness, the breaking weight was 3,738 lb.

Rivetting a stronger plate on the top side,
the strength was increased to .. 8,273 lb.

The difference being 4,535 lb.,—considerably more than double the strength sustained by the tube when the top and bottom sides were equal.

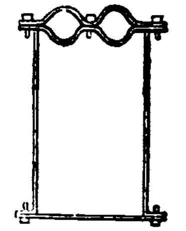
The experiments given in No. 15 are of the same character, where the top plate is as near as possible double the thickness of the bottom. In these experiments, the tube was first crippled by doubling up the thin plate on the top side, which was done with a weight of .. 3,788 lb.

It was then reversed with the thick side upwards, and by
this change the breaking weight was increased to .. 7,148

Making a difference of .. .. .. 3,360 lb.

or an increase of nearly double the strength, by the simple operation of reversing the tube, and turning it upside down.

The same degree of importance is attached to a similar form, when the depth in the middle is double the width of the tube. From the experiments in No. 16, we deduce the same results in a tube where the depth is 18¼, and the breadth 9¼ inches. Loading this tube with 6,812 lb. (the thin plate being uppermost), it follows precisely the same law as before, and becomes wrinkled, with a hummoc rising on the top side so as to render it no longer safe to sustain the load. Take, however, the same tube, and reverse it with the thick plate upwards, and you not only straighten the part previously injured, but you increase the resisting powers from 6,812 lb. to 12,188 lb. Let us now examine the tube in the 29th experiment, where the top is composed of corrugated iron, as per sketch, forming two tubular cavities extending longitudinally along its upper side. This, it will be observed, presents the best form for resisting the "puckering," or crushing force, which, on almost every occasion, was present in the previous experiments. Having loaded the tube with increasing weights, it ultimately gave way by tearing the sides from the top and bottom plates, at nearly one and the same instant after the last weight, 22,469 lb., was laid on. The greatly increased strength indicated by this form of tube, is highly satisfactory, and provided these facts be duly appreciated in the construction of the bridge, they will, I have no doubt, lead to the balance of the two resisting forces of tension and compression.



The results here obtained are so essential to this enquiry, and to our knowledge of the strength of materials in general, that I have deemed it essential, in this abridged statement, to direct attention to facts of immense value in the proper and judicious application, as well as distribution, of the material in the proposed structure. Strength and lightness are desiderata of great importance,—and the circumstances above stated are well worthy the attention of the mathematician and engineer.

For the present we shall have to consider not only the due and perfect proportion of the top and bottom sides of the tube; but also the stiffening of the sides with those parts, in order to effect the required rigidity for retaining the whole in shape. These are considerations which require attention: and till further experiments are made, and probably some of them upon a larger scale, it would be hazardous to pronounce anything definite as to the proportion of the parts, and the equalization of the forces tending to the derangement of the structure.

So far as our knowledge extends,—and judging from the experiments already completed,—I would venture to state that a tubular bridge can be constructed, of such powers and dimensions as will meet, with perfect security, the requirements of railway traffic across the Straits. The utmost care must, however, be observed in the construction, and probably a much greater quantity of material may be required, than was originally contemplated before the structure can be considered safe.

In this opinion Mr. Hodgkinson and myself seem to agree: and although suspension chains may be useful in the construction in the first instance, they would nevertheless be highly improper to depend upon as the principal support of the bridge. Under every circumstance, I am of opinion that the tubes should be made sufficiently strong to sustain not only their own weight, but in addition to that load, 2,000 tons equally distributed over the surface of the platform, a load ten times greater than they will ever be called upon to support. In fact, it should be a huge sheet iron hollow girder, of sufficient strength and stiffness to sustain those weights; and, provided the parts are well proportioned, and the plates properly rivetted, you may strip off the chains, and leave it as a useful monument of the enterprise and energy of the age in which it was constructed.

In the pursuit of the experiments on the rectangular as well as other description of tubes, I have been most ably assisted by my excellent friend Mr. Hodgkinson; his scientific and mathematical attainments render him well qualified for such researches; and I feel myself indebted to him for the kind advice and valuable assistance which he has rendered in these and other investigations. I am also deeply indebted to yourself and the Directors for the confidence you have placed in my efforts, and for the encouragement I have uniformly received during the progressive development of this enquiry.

But, in fact, the subject is of such importance, and the responsibilities attached to it are so great, as to demand every effort to demonstrate, calculate, and advise what in this case is best to be done. Both of us have therefore laboured incessantly at the task, and I am indebted to my friend for the reduction of the experiments which I would not attempt to weaken by a single observation.

Wm. Fairbairn.

Mr. Hodgkinson's Report.

Summary of Results offered, in conjunction with one by William Fairbairn, Esq., M. Inst. C. E., *to* Robt. Stephenson, Esq, M. Inst. C.E., &c., &c., *for the Directors of the Chester and Holyhead Railway, on the subject of a proposed Bridge across the Menai, near to Bangor.—By* Eaton Hodgkinson, F.R.S.

Having in the month of August last year been requested to render assistance, principally in a scientific point of view, with respect to the experiments to ascertain the practicability of erecting a Tubular Bridge across the Menai Straits, of sufficient strength for railway trains to pass through it with safety, I attended twice in London for that purpose: and as the experiments made there were on tubes of various forms of section, including several elliptical and circular ones, I investigated formulæ for reducing the strength of the leading ones. It appeared evident to me, however, that any conclusions deduced from received principles, with respect to the strength of thin tubes, could only be approximations; for these tubes usually give way by the top or compressed side becoming wrinkled, and unable to offer resistance, long before the parts subjected to tension are strained to the utmost they would bear. To ascertain how far this defect, which had not been contemplated in the theory, would affect the truth of computations on the strength of the tubes proposed to be used in the bridge,—and also to show whether the principles generally received could be applied with certainty in reasoning as to the strength of the bridge from that of models comparatively very small,—for these two purposes I urged the necessity of a number of fundamental experiments, which, besides supplying the wants above mentioned, might enable me to obtain additional information to that from Mr. Fairbairn's experiments, with respect to the proportions that the different parts of the section of such a bridge ought to have, as well as what form it should be of, in order to bear the most.

Feeling that there might be objections against allowing me to follow the courses I proposed, however necessary it might appear to myself, I suggested a much more limited series of experiments than now appear to me to be necessary; and, as the time consumed in getting the plates rolled and the tubes prepared, caused the experiments to be delayed till the beginning of the year, the time given me has beeen too limited to obtain all the facts which the few experiments proposed would have afforded.

I will now give the results, so far as they have been obtained and seem worthy of reliance, subject to correction from future experiments; beginning with the reduction of Mr. Fairbairn's experiments on the strength of tubes of wrought iron made of plates rivetted together.

Cylindrical Tubes.—The strength of a cylindrical tube, supported at the ends, and loaded in the middle, is expressed by the formula

$$w = \frac{\pi f}{a\,l}\,(a^4 - a'^4).$$

Where l is the distance between the supports; a, a' the external and internal radii; w the breaking weight; f the strain upon a unity of section, as a square inch, at the top and bottom of the tube, in consequence of the weight w; $\pi = 3{\cdot}14159$.

From this formula we obtain

$$f = \frac{w\,l\,a}{\pi\,(a^4 - a'^4)}.$$

As it will be convenient to know the strain f per square inch, which the metal at the top and bottom of the tube is bearing when rupture takes place, this value will be obtained from each of Mr. Fairbairn's experiments: the value w being made to include, besides the weight laid on at the time of fracture, the pressure from the weight of the tube between the supports, this last being equal to half that weight. Computing the results we have, from

$$\left.\begin{array}{ll} \text{Experiment } 1, & f = 33456 \\ \quad\;\; ,, \quad 2, & f = 33426 \\ \quad\;\; ,, \quad 3, & f = 35462 \\ \quad\;\; ,, \quad 4, & f = 32415 \\ \quad\;\; ,, \quad 5, & f = 30078 \\ \quad\;\; ,, \quad 6, & f = 33869 \\ \quad\;\; ,, \quad 7, & f = 22528 \\ \quad\;\; ,, \quad 8, & f = 22655 \\ \quad\;\; ,, \quad 9, & f = 25095 \end{array}\right\}\ \text{Mean 29887 lb.} = 13{\cdot}34 \text{ tons.}$$

Fracture in all cases took place either by the tube failing at the top, or tearing across at the rivet holes; this happened on the average, as appears from above, when the metal was strained 13½ tons per square inch, or little more than half its full tensile strength.

Elliptical Tubes.—The value of f in an elliptical tube broken as before, (the transverse axis being vertical), is expressed by the formula

$$f = \frac{w\,l\,a}{\pi\,(b\,a^3 - b'\,a'^3)}.$$

Where a, a' are the semitransverse external and internal diameters; b, b' the semi-conjugate external and internal diameters; and the rest as before, w including in all cases the pressure from the weight of the beam.

Computing the results from Mr. Fairbairn's experiments we have from

$$\left.\begin{array}{ll} \text{Experiment } 20, & f = 36938 \text{ lb.} \\ \quad\;\; ,, \quad 21, & f = 29144 \\ \quad\;\; ,, \quad 24, & f = 45185 \end{array}\right\}\ \text{Mean 37089 lb.} = 16{\cdot}55 \text{ tons.}$$

Rectangular Tubes—If in a rectangular tube, employed as a beam, the thickness of the top and bottom be equal, and the sides are of any thickness at pleasure, then we have

$$f = \frac{3\,w\,l\,d}{2\,(b\,d^3 - b'\,d'^3)}.$$

in which d, d' are the external and internal depths respectively; b, b' the external and internal breadths; and the rest as before.

Mr. Fairbairn's experiment No. 14 gives by reduction

$$f = 18495 \text{ lb.} = 8{\cdot}2566 \text{ tons.}$$

This is, however, much below the value which some of my own experiments give, as will be seen further on.

The value of f, which represents the strain upon the top or bottom of the tube when it gives way, is the quantity per square inch which the material will bear either before it becomes crushed at the top side or torn asunder at the bottom. But it has been mentioned before, that thin sheets of iron take a corrugated form with a much less pressure than would be required to tear them asunder; and therefore the value of f, as obtained from the preceding experiments, is generally the resistance of the material to crushing, and would have been so in every instance if the plates on the bottom side (subjected to tension) had not been rendered weaker by rivetting.

The experiments made by myself were directed principally to two objects:—

I.—To ascertain how far this value of f would be affected by changing the thickness of the metal, the other dimensions of the tube being the same.

II.—To obtain the strength of tubes, precisely similar to other tubes fixed on,—but proportionately less than the former in all their dimensions, as length, breadth, depth, and thickness,—in order to enable us to reason as to strength from one size to another, with more certainty than hitherto, as mentioned before. Another object not far pursued, was to seek for the proper proportion of metal in the top and bottom of the tube. Much more is required in this direction.

In the three series of experiments made, the tubes were *rectangular*, and the dimensions and other values are given below.

Length.		Depth.	Breadth.	Distance between supports		Weight.		Thickness of Plates.	Last observed Deflection.	Corresponding Weight.	Breaking Weight.	Value of f, for crushing Strain.

The tube placed first in each series, is intended to be proportional in every leading dimension, as distance between supports, breadth, depth, and thickness of metal,—and any variations are allowed for in the computation. Thus the three first tubes of each series are intended to be similar; and in the same manner of the other tubes, &c.

Looking at the breaking weights of the tubes varying only in thickness, we find a great falling off in the strength of the thinner ones; and the values of f show that in these—the thickness of the plates being ·525, ·272, ·124 inch—the resistance, per square inch, will be 19·17, 14·47, and 7·74 tons respectively. The breaking weights here employed, do not include the pressure from the weight of the beam.

The value of f is usually constant in questions on the strength of bodies of the same nature, and represents the tensile strength of the material, but it appears from these experiments that it is variable in tubes, and represents their power to resist crippling. It depends upon the thickness of the matter in the tubes, when the depth or diameter is the same; or upon the thickness divided by the depth when that varies. The determination of the value of f, which can only be obtained by experiment, forms the chief obstacle to obtaining a formula for the strength of tubes of every form. When f is known the rest appears to depend upon received principles, and the computation of the strength may be made as in the Application de la Mécanique of Navier, Part 1st, Article IV.; or as in Papers of my own in the Memoirs of the Literary and Philosophical Society of Manchester, vols 4 and 5, second series. I have, however, made for the present purpose, further investigations on this subject, but defer giving them till additional information is obtained on the different points alluded to in this report; and this may account for other omissions.

In the last table of experiments the tubes were devised to lessen or to avoid the anomalies which rivetting introduces, in order to render the properties sought for more obvious. Hence, the results are somewhat higher than those which would be obtained by rivetting as generally applied.

The tube 31 feet 6 inches long, 24 cwt. 1 qr. weight, and ·272 inch in thickness of plates, was broken by crushing at the top with 22·75 tons. This tube was afterwards rendered straight, and had its weak top replaced by one of a given thickness, which I had obtained from computation; and the result was, that by a small addition of metal, applied in its proper proportion to the weakest part, the tube was increased in strength from 22·75 tons to 32·53 tons; and the top and the bottom gave way together.

If it be determined to erect a bridge of tubes, I would beg to recommend that suspension chains be employed as an auxiliary, otherwise great thickness of metal would be required to produce adequate stiffness and strength.

EATON HODGKINSON.

TIDAL HARBOURS.

Second Report of the Commissioners.

A more extended inquiry has fully confirmed the views which the limited examination of last year led us to submit to your majesty. Not only is there a general want of control over the management and revenue of the ports, but there is not a single exception among the numerous cases which have come before us in which such a control might not have been the means of saving unnecessary outlay; of preventing encroachments that can now scarcely be remedied; or of stopping works that must be removed in order to secure the objects to which the attention of the commission is directed.

The necessity of such supervision has also become more apparent since the publication of the returns to the orders of the House of Commons of August last, from which we learn that the income of the various ports of the United Kingdom considerably exceeds the sum of £800,000 a year—the whole levied by charters and acts of Parliament, or otherwise, from dues on shipping, and on goods borne by shipping, but over the expenditure of which Parliament has not at present the slightest control.

That much of this money has been and is misapplied will excite no surprise, when we find that several harbours are governed by numerous self-elected, irresponsible Commissioners, (in some places exceeding even 100 in number), often conducting their proceedings in private, auditing their own accounts, publishing no statement of income or expenditure, and laying out large sums of money without the advice of an engineer; and that these commissioners are frequently landed proprietors, sometimes non-resident, and occasionally a shipowner, but rarely a sailor among them. Such, however, is the constitution of many of the harbour boards of this country, acting under authority conferred by Parliament.

Since the date of our first report we have, in compliance with that clause of her Majesty's Commission which directs us to visit and personally inspect all the harbours and shores of the United Kingdom, examined the chief ports on the east coast of England, from the river Thames to the Tyne, thus including Yarmouth, Hull, and the principal coal ports of Durham and Northumberland, which, owing to the extraordinary increase in steam navigation, are daily rising into greater importance.

On the west coast we have personally inspected the rivers Lune, Wyre, Ribble, and Dee; and the ports of the Isle of Man, which, although of small extent as harbours, become of consequence from their position in the centre of the Irish Channel, and as the head-quarters of an extensive and increasing fishing trade.

In Ireland we have been enabled to visit most of the ports and fishing-piers around the coast, and have been strongly impressed by a sense of the great value of its natural harbours, their depth and capacity, and the extent and capability for improvement of its fisheries, which, even in their present state, and with the fishery-piers often in ruins from neglect, afford employment to 19,880 vessels and boats, and 93,000 hardy fishermen.

But these natural advantages are very far from having been turned to the best account.

The harbour of Dublin and the river Liffey offer an instructive example of the correctness of this statement. Within the last 30 years many improvements have taken place. The depth of water over the bar and up to the city quays has been increased several feet, by dredging, and by the bold measure of running out the great north wall. The traffic and consequent revenue of the port have more than doubled, and the latter has risen to £34,000 a year. Yet the evidence shows that the foundation of the quay is generally so imperfect that they will not, in their present state, admit of the river being further deepened; that the south quay, the resort of three-fourths of the shipping of the port, is encumbered at its foot by heaps of mud; that the entrance into the grand canal dock is all but blocked up by sand-banks; that there is a great want of graving docks; that there is but one public crane; that the port charges are very high; and that the ballast, of which, by Act of Parliament, the ballast-office has a monopoly, and for which it charges about double the market price, is in many cases bad.

The Isle of Man occupies an important position in the Irish Channel, directly in the track of communication between Liverpool, Glasgow, and Belfast, and of the coal trade from Whitehaven and Maryport to the whole of the east coast of Ireland. It has been aptly termed the "Beacon of the Irish Sea," and as such everything that care and skill can suggest, as to lights, beacons, and improvement of its harbours, would be well bestowed, and tend to prevent that recurrence of the numerous wrecks that have taken place around its shores. Yet such is far from being now the case; on the contrary (with the exception of the coast lights maintained by the Board in Scotland), marked neglect prevails throughout; and here the evils of irresponsible, self-elected authority are but too manifest, the commissioners meeting only once a year to go through the form of auditing their own accounts, keeping no regular minutes of their proceedings, and practically leaving the whole power and authority in the hands of a single person.

On the north-west coast of England, the river Lune and the port of Lancaster are capable of much improvement.

The river Ribble and port of Preston offer a proof also of the value of skilful engineering, as applied to navigable rivers. Only five years since, spring tides rose but six feet, and neap tides not at all, at Preston quay, so that vessels were obliged to unload their cargoes at Lytham, near the mouth of the river, and send them up to Preston in lighters or flats drawing but six feet of water; whereas now, by means of straightening the channel, and deepening its bed, spring tides rise ten feet, and vessels of 200 tons, drawing eleven feet of water, come up to the quay.

It appears from the Parliamentary returns that the aggregate debt of the several ports of the United Kingdom, exclusive of docks in the port of London, exceeds £4,000,000 sterling; one-fourth part, therefore, of the whole harbour income of £800,000 a year must be annually appropriated to pay the interest of this debt, which will consequently materially cripple the means for future improvements. This large sum, although borrowed with the sanction of the Legislature, has been laid out entirely by the several local boards, without the slightest control being exercised over it either by Parliament, or by any other power specially charged to watch over the interests of the public.

Among the numerous cases of the misapplication of the harbour funds, to which we have already had occasion to refer, the sum of more than £28,000 expended last year in Parliamentary and legal expenses connected with bills for the improvement of harbours, seems to your commission to be a most impolitic unnecessary outlay, and one which might be entirely prevented by the establishment of a Harbour Conservancy Board, such as we have humbly ventured to submit for your Majesty's consideration.

From the competition already commenced between railroads and the coasting shipping, we fear that unless immediate measures be taken to improve the harbours and navigable rivers of this kingdom, and, where practicable, to lessen the dues, a large portion of the goods which these vessels now carry will soon be conveyed by the railroads rapidly extending to almost every part of the coast. We would, therefore, strongly urge such assistance, not only on economical but on political grounds of the highest importance to the maritime interests of the kingdom, as the coasting trade has ever been the best nursery for the hardy race of seamen who have so ably maintained the honour and power of the country.

We alluded in our first report to the obstructions and shoals which so seriously impede and endanger the navigation of the Thames, between Gravesend and London-bridge; all the additional information and evidence we have received since that report was presented, fully convince us of the correctness of the opinions we then expressed, and we feel confident that, if the various and frequently conflicting authorities to whose guardianship the conservancy of this noble river is entrusted, could be induced to co-operate cordially in its improvement, and to carry on their operations jointly on one sound and uniform system, the impediments which now discredit the local administrations and endangered the commerce of the metropolis, might be speedily and cheaply removed. And in strong corroboration of our own view of this subject, we subjoin the following extract from the report of a select committee of the House of Commons in the year 1836, specially appointed to inquire into the state of the port of London:—

"That this committee are of opinion that the various conflicting jurisdictions and claims of the Admiralty, the Trinity House, and the Corporation of the City of London over the river Thames below the bridges, have had a most injurious effect upon the interests of navigation; that it is desirable they should be consolidated and vested in some one responsible body, and that means should be found to provide for the removal of shoals and obstructions in the bed of the river."

All these facts and considerations induce us most earnestly to repeat the recommendation, which we ventured dutifully to submit to your Majesty in our former report, that all the tidal harbours in the United Kingdom be placed under the special care of a board of conservancy, to be formed under the authority and provisions of an act of Parliament, being fully convinced that any less stringent and decisive measures will be found wholly inadequate for the accomplishment of the great national object which your Majesty has been graciously pleased to direct us to consider and examine.

All which we humbly certify to your Majesty,

W. Bowles, Rear-Admiral, M.P., Chairman.
J. J. Gordon Bremer, Captain R.N.
Joseph Hume, M.P.
Aaron Chapman, M.P.
Edward R. Rice, M.P.
Thomas Baring, M.P.
F. Beaufort, Hydrographer.
G. B. Airy, Astronomer Royal.
John Washington, Captain R.N.
Richard Godson, Q.C. and M.P., Counsel to the Admiralty.

London, March 20, 1846.

The Value of Smoke.—A striking instance of economic talent came to our knowledge in the district of Alston Moor. From the smelting earths of one "house," an arched tunnel conducts the smoke to an outlet at a distance from the works, in a waste spot, where no one can complain of it. The gathering matter or "fume" resulting from the passage of the smoke is annually submitted to a process, by which at that time it yielded enough to pay for the construction of a chimney. A similar tunnel chimney three miles in length was erecting at Allendale. Its fume will yield thousands of pounds sterling per annum. Truly, here it may be said that smoke does not end in smoke.—'British Quarterly Review.'

PAINTING ON GLASS.

There are three kinds of paintings on glass: paintings with the different colours on separate pieces of glass, painting on uncoloured glass, and painting on crystal. The first two methods are frequently combined so as to constitute a fourth kind of painting on glass. The first kind of painting is incontestably the most ancient. Glass is prepared in sheets, blue, violet, yellow, green, and red, and after being divided into pieces of the proper size and shape, the separate portions are put together by glaziers' lead.

The preparation of purple glass has fallen into such disuse, that till very recently, the art was considered to be entirely lost, but this is not the case, for there still exist printed receipts which describe all the details of the operation. Baptiste Porta, who was born in the year 1540, has given one of the receipts in his *Magie Naturelle*, and he has taken care at the same time to warn us of the difficulty of obtaining a successful result. Other receipts are found in the compilations of Néri, Merret, and Kunckel, and have been transferred to the encyclopædia. No information, however is given respecting red glass. It is not prepared with the purple of gold, for this substance gives neither a scarlet red nor the red, of clear wine: Instead of oxyde of iron, the protoxyde of copper is used. But as this last produces an exceedingly deep colour which deprives the glass of its transparency, the usual plan is to cover white glass with a thin layer of red glass, so as to form a kind of plated glass. The process is as follows—there are placed in the furnace two crucibles, of which one contains common glass, the other glass of the same composition, but coloured with protoxyde of copper, to which is added protoxyde of tin. This last body tends to prevent the oxydation of the protoxyde of copper which would have the effect of colouring the glass green. A small addition of protoxyde of iron gives a scarlet red or flame colour. If the glass take a greenish tint a little bi-tartarate of potash will renew the colours by restoring the bi-oxyde of copper to the state of a protoxyde. The workman commences by taking on his "blowing-iron" a small quantity of red glass; he then plunges the tube into the white glass, of which he takes a much larger quantity, and he then blows it out according to the ordinary method of making "tables" of crown glass. This method was employed for the ancient glass of church windows; at the present day this glass is manufactured at Hoffnungsthal, in Silesia, by the Tyne Company in England, by Bontemps in France, and at Besançon.

The glass, as has been said, is cut up into coloured plates. The tints and half tints are applied by means of coloured enamels on one face or the other of the glass, which is exposed to heat, and the different pieces are joined by glaziers' lead according to the pattern or design. If the paintings be small, and designed to be viewed close, plated glass, and not glass coloured throughout its thickness, is employed. Parts of the coloured layer are removed at the requisite places, and on the white glass thus laid bare, the colours required for the painting are applied. In this way designs are obtained of which the colours differ altogether from the ground-colour. Instead of removing the coloured layer by mechanical means, it may be destroyed by fluoric acid.

The effect of the weather insensibly alters the colours of ancient paintings on glass.

Painting on glass properly so called, that is to say, the application of coloured enamels to uncoloured sheets of glass was little known to the ancient artists, and it is only in our own day that the progress of chemistry has advanced this art to any degree of perfection.

Painting on uncoloured glass was executed in 1800 by Dihl; it consists in tracing the same design on two sheets of plain glass, which are submitted to the action of fire, and then the faces on which the designs are drawn are laid one upon the other.

To fix by heat the colours on glass without altering its form, or fusing it, it is necessary to add vitreous matters, which are readily fusible, fluxes, which vary according to the nature of the colours.

Silicate of lead is employed with or without borax, minium and very fine sand are fused together, and different proportions of calcined silex and quartz. For instance, take

Quartz	.. ..	3 parts	or	Borax calcined	..	5 parts.
Minium	.. ..	9 „		Quartz	.. ..	3 „
Borax calcined	..	1½ „		Minium	.. ..	1 „

The quantity of flux required for each colour, so that it may have the required fusibility and clearness is very variable, the necessary proportion is in general three or four parts. All colours are not adapted for the same flux; the purple of gold, the blue of cobalt, require an alkaline flux; the minium injures these substances, while other deep colours are not injured by fluxes into which lead enters.

Some substances require to be vitrified with the flux proper to them, before they can be employed in painting, as the feeble heat to which they are subsequently subject is not sufficient to develop the colour properly. The deutoxyde of copper, and the yellows, blues and violets, are among these substances. With purple of gold and oxyde of iron on the contrary, great precautions are necessary to prevent the injury of the colour by too great heat. The coloured enamels when prepared are reduced to powder, and preserved from the action of moisture.

All kinds of glass are not suitable for painting. Excess of alkali is destructive; preference is therefore given to the hardest glass, which contains a great deal of silex, and which does not attract moisture, as the Bohemian glass for instance.

Before applying the colours with the brush, they are mixed on a palette with turpentine. When the painting is finished the colours are fixed by heat, an operation which requires great care and experience. Pots of fire-clay closed by a cover of the same substance are placed in a support of iron, so that they can be enveloped on all sides by the flames; the method adopted in France for cooling the glass is to put it in separate furnaces heated by charcoal. The plates of glass are laid one upon another on clay slabs, supported on props of the same material. The heat is judged of by trial-pieces, which are introduced with the rest of the glass into the furnace, and are withdrawn with a spatula. When the colours are well vitrified, the plates are put in the annealing oven and gradually cooled. It is necessary that this last operation should be conducted very gradually, to ensure the permanence of the colours.

The colour communicated to glass by the protoxyde of copper is, as has been observed, too intense to be employed alone, for it causes the "metal" to appear opaque of a deep brown. It is necessary for procuring a transparent red that the glass should be extremely thin. Consequently, the only means of getting red glass of a proper thickness is by covering plain glass by a thin layer of red. The plated glass has the advantage of allowing the partial removal of the red layer in order to obtain white figures or add other colours. The glass of the Middle Ages shows that this method was adopted by the ancients.

In order that, when the red and white glass are blown together, they may be well united and do not separate during cooling (as happened in some of Engelhardt's first experiments), the "metal" of both must be the same, or at least analogous. It is best to make the red a little weaker than the white; the latter must not contain any oxydising substance, which would injure the red colour.

Great care is required to avoid air bubbles in the glass. The red and white must be ready at the same time, in order to work together well. The beauty of the glass depends also materially on the skill of the workman, for it is easy to understand that the coloured glass is always thicker near the orifice of the blowing-iron than at a distance. It is on this account that the glass is seldom of a uniform colour, except in the middle of the plate: at the extremity of it the red layer is sometimes so thin that all trace of colour is lost. Dr. Engelhardt has preserved several ancient specimens, in which this gradation from a deep colour to a light one, has been made use of in a very happy manner to produce striking effects. After a certain degree of practice, the workman is able to obtain a tolerably uniform colour, and Dr. Engelhardt expects to effect this object completely in a glass manufactory where he has directed attention to this particular branch of the art.

It is sometimes necessary, when the glass has once been painted and the colours fixed by baking, to add a second coat of painting; and as it is then necessary that the glass should be again subjected to heat, the colouring matter must be rendered so fusible by an additional proportion of flux as to avoid all risk of fusing the colours first painted.—*Translated from the Revue Scientifique et Industrielle.*

CLERESTORIES IN MODERN CHURCHES.

Christ Church, Plymouth.

Sir,—I am really most reluctant to intrude myself again upon your pages; the more so, as "Candidus" has so kindly and (of course, as *I* think) so ably defended the principles on which I have acted. The answer, however, which you have made to "Candidus" seems to require from me a word or two in explanation. In the first place, Christ Church, Plymouth, is *not* lighted by "clerestories *only*." There are windows at the east ends of the aisles on the gallery floor, besides the two great east and west windows, which literally *do* make the main body of the interior as "cheerful as the day;" and in the darkest seats beneath the galleries, on a gloomy day, you can see perfectly well. There is *no* part "useless" or even "inconvenient," "by its darkness." The body of the church is so wide, and the gallery recesses so comparatively shallow, that the "defect" which you say "*must* exist" does *not* exist. Though a positive *sun-beam* cannot "shine round a corner," it is equally certain that where there is a great central reservoir (if I may use the expression) of daylight, it will expand its illumination even into corners which the sun's immediate rays can never reach. Again, "the extent of unbroken surface of the north and south walls" is not so great as you seem to imagine. There are recesses for seats where, under other circumstances, there would have been windows; and these (had our means allowed it) might have been rendered highly ornate. At all events, here are admirable localities for mural monuments.

You are, likewise, under a misconception as to the reference made by "Candidus" to the octagon of Ely Cathedral. The "lower windows," as you term them, are only "lower" than the *lantern*. They are the *clerestory* *windows* of the *octagon*, above the arches opening into the aisles, and ranging with the clerestory of the nave.

In assuming it to be an "essential principle of Pointed architecture that the north and south walls of a church should have windows, because you find this to have been universally the case in ancient examples of the art practised by its inventors," you, in fact, deny the applicability of Pointed architecture to any church that is not insulated; or, in other words, you declare that no circumstances can warrant the construction of a church in immediate contact with other buildings on either hand. This may, or may not be. All I desire of my critics is a fair consideration of the *conditions* under which my church has been built. They were imperatively these:—*the Gothic style*, and *no north or south windows;* the latter resulting from the economy which required a *maximum* building on a *minimum* space, and therefore precluded any north or south area. The question was, whether a certain number of Christians should remain without church sitting-room, or whether a church without north or south windows (in the Gothic style) should be built?

I shrunk not from the attempt to reconcile the demands of my employers with the limits of my means; and considered, that no "essential principle" of architecture (be it "Pointed" or otherwise) would be compromised by the *modification* of ancient example to modern purposes. I did as I conceived the old architects would have done under the different necessities of protestant worship and other peculiar circumstances of means and situation; and I am not aware that any, who have *seen* the result of my endeavours, have pronounced them unsuccessful.

I am, Sir,

Yours truly,

George Wightwick.

[The difference between Mr. Wightwick's opinion and our own respecting the subject of the letter which he unnecessarily apologises for sending, is, probably, less than he himself imagines. Where the question arises, as he has stated it, "whether a certain number of Christians should remain without church sitting room, or whether a church without north or south windows (in the Gothic style) should be built," we must answer at once that the attainment of the main purpose of the building should be preferred to all considerations of architectural beauty.

It is conceded, however, by the phrase "modification of ancient example," that the mode of construction suggested is modern. The only question between Mr. Wightwick and ourselves is, whether the ancient architects could have been induced to adopt this mode. We think not, and will give the reasons of our opinion consecutively.

I. Ancient precedent is universally in favour of this opinion. In *all* ancient churches, *without one single exception*, the aisle or nave windows are an essential part of the edifice. We do not mean to strain the argument of precedent beyond its proper limit, or to advocate the imitation of the practice of our forefathers without examining the correctness of their principles. But the plea of precedent is at least valuable thus far—that the universality of it indicates something more than the uniformity of mere routine. It seems obvious that if the mediæval architects, under whatever different circumstances they constructed churches, whether isolated in villages, or among the crowded buildings of large towns, or within the walls of fortresses, colleges, or abbeys,—whether the site were on a plain or on the precipitous declivities of a feudal fastness,—under conditions the most varied and frequently the most difficult, adhered to the principle of building nave windows, we have at least a presumptive proof that the inventors of Pointed architecture, who may be supposed best acquainted with its essential nature, considered this principle of paramount importance.

It is to be remembered that the ancient architects frequently built churches under the same difficulties, arising from the contiguity of secular buildings, which embarrass modern architects. In the old cities of Normandy and Flanders the careful observer will notice cases of churches to which large additions had been made after the site was closely hemmed in by other edifices; and it is frequently very instructive to observe the skilful means adopted to procure access of light to the lower part of the added portions of the building.

II. The light of the clerestories was always subordinate to that of the aisles until Pointed architecture began to decline. In Early English and Decorated architecture, clerestories are not nearly so large as in Perpendicular buildings. In the former styles the clerestory is in by far the greatest number of examples omitted altogether; and where it exists, the windows are always small, and the light from them greatly subdued. In churches these windows are trefoils or quatrefoils or other single-light apertures: clerestory windows of more than one light are confined to cathedrals or very large churches. In the Perpendicular architecture, however, especially in the latter and worst part of it, the fatal principle of enlarging the clerestories was first introduced, and became a powerful cause of the debasement of Christian architecture. To the very last, however, the construction of nave windows was universally retained, even when the art exhibited that sure and certain mark of decay—the substitution of elaborate details for simplicity and excellence of design.

The preceding arguments are of the nature of historical considerations. We wish, however, to guard ourselves against the supposition that we over-estimate the value of precedent. We trust that we shall never be accused of irreverence for antiquity; but, at the same time, it is mere pedantry to affect ancient rules which have no intrinsic merit to recommend them. Precedent always furnishes *presumptive* evidence, but there are three causes from which it may become valueless. First,—an ancient practice may have originated in prejudice or accident and not in fixed principles. Secondly,—the fixed principles which influenced the ancients may be proved, by subsequent knowledge, to be erroneous or insufficient. And lastly,—principles which were perfectly sufficient when first acted upon, may, by time and change of circumstances, become obsolete. It is therefore necessary, for the completeness of our argument, to show that none of these causes operate in the present case to destroy the value of the precedent. We proceed, therefore, to the arguments derived from general considerations of the nature of Pointed architecture.

III. The clerestory admits light in that part of the church which appears most beautiful by a subdued light. The solemnity then of the appearance of a church is derived in a great measure from the comparative obscurity of its roofs. The dark shadowy roofs of Pointed architecture have been favorite subjects of admiration with those who are excellent judges of general architectural effects—the poets. In questions like these, one example is worth a folio of dissertation, and if those who are really anxious to get at the truth in this matter will take the trouble to observe the difference between the mode of lighting the interior of the nave of Westminster Abbey and Henry VIIth's Chapel, they will have no difficulty in arriving at a conclusion. In the former case, the great body of light (notwithstanding that much of it is unhappily obstructed by preposterous monuments) comes from the aisles, and produces the most beautiful effect by the shadows of the piers and arches. The light of the clerestory is comparatively small, and must have been still less when the windows were filled with stained glass. Let the reader, when he has carefully observed the effect of the light in the nave, especially at the western end of it, proceed to Henry the Seventh's Chapel—a building belonging to the very last period of which the Pointed architecture continues to claim our respect. In this chapel he will find enormous clerestory windows, admitting a flood of light near the roof. The lower windows give but little light, and that little is almost entirely obstructed by the stalls. Here, therefore, the observer has one of the best instances which ancient churches afford of the effect of light admitted by clerestories. We have never heard any difference of opinion among unprejudiced persons as to the *solemnity* of this effect. It is not solemn—it is scenic—theatrical—the glare thrown from the upper part of a stage when the foot-lights are lowered. Compared with the effect of the nave of the Abbey, there cannot be a doubt which exhibits the "dim religious light" of a Christian edifice. The gorgeous multiplication of ornaments which profusely decorate Henry the Seventh's Chapel dazzles the eye, but produces nothing like a *solemn* impression, and the judicious observer goes away satisfied that the design and general arrangement of this structure is incapable of that stately grandeur which imposes a feeling of awe and reverence. Westminster Abbey is by no means the most favourable instance which we could have selected, but it was the most familiar. But imagine some of the more magnificent cathedrals of the continent lighted by the clerestories alone—Antwerp, or that of Cologne, or Rouen! Suppose, if it be possible, the dim obscure roofs of these glorious edifices suddenly illuminated by a flood of light;—where would be the solemnity of the "long-drawn aisles" then? Suppose the windows of these aisles darkened and every shadow reversed,—will it be denied that the effect would be absolutely hideous? Or if it be objected that the question in dispute refers to a church and not to a cathedral, we will cite the well-known instance of Great St. Mary's Church, at Cambridge, where the dazzling light of the clerestory is not only destructive of all solemn effect, but actually painful to the eye by its violent contrast with the comparative darkness of the aisles.

IV. By the undue enlargement of the clerestory, the piers and arches become subordinate parts of the structure. This result is produced not so much by the actual diminution of the size of these members as by the prominence given to the clerestory by the light proceeding from it. Now the consequence of this is, a violation of the rules of "apparent construction," for the greatest weight to be supported being that of the nave-roof, the arches and piers should be treated as of primary importance: the architectural effect of them is destroyed directly they become subordinate, and accordingly in the best churches the piers of the nave have great strength, and the weight of the roof appears directly imposed upon them. Where, however, the wall above the arches is perforated by numerous windows (sometimes so numerous as to give this part the appearance of a huge lanthorn), the roof never seems adequately supported: there is an appearance of instability produced, which is directly opposed to the canons of architecture. And this instability is not always merely apparent. It is frequently a matter of observation that the walls of the clerestory, where they have been weakened by the size of the perforations, are thrust outwards by the pressure of the roof. This deviation from the perpendicular is especially observable in cases where a Perpendicular clerestory is a subsequent addition to a Decorated or earlier church.

V. A church is not a mere façade. That word *façade* is Italian in its origin, and both the word and thing signified belong exclusively to Italian architecture. The Christian architects viewed their churches not as mere surfaces or fronts, but as possessing the dimensions of length, breadth, and height. The *superficial* style of architecture is a modern invention, doubtless derived from that habit of *making up elevations* on the Italian principle which characterized the last century.

Of the reversal of the shadows where the light is obtained from a clerestory *exclusively*, it is not necessary to speak at large, because we have elsewhere spoken of it. We may observe, however, that in the mouldings of nave-arches and the deep undercut capitals of pillars the shadows must be exactly reversed when the light is obtained from a clerestory, instead of the aisles: in the one case these shadows are thrown downwards—in the other upwards. Consequently the architect, if he have a due sense of constructive propriety, will never dream of using ancient mouldings in churches built on the new plan—he must devise new mouldings suited to the novel disposition of the light. This point is not one of speculation but observation, as any one familiar with ancient mediæval mouldings may satisfy himself by examining the result of introducing them into some of the new London churches, windowless aisles.

The breaking the continuous surface of the north and south wall by recesses instead of windows, is an expedient which by no means removes the objections here assigned. We have, in a previous number, guarded ourselves against the conclusion that churches are necessarily to be isolated. There are many cases where chapter-houses, cloisters, &c. abut on churches without marring their architecture. If however we be asked whether a church built in the line of a street, between adjacent houses, and only distinguished from them by having its gable instead of its parapet turned towards the street, and by the display of a few stock-in-trade Gothic ornaments, satisfies the essential principles of mediæval architecture, we answer emphatically and unhesitatingly—No. By no means—if the laws of style are to be interpreted by the spirit instead of the letter—by the general artistic effect of a design, and not by minute resemblances of detail.

We know that architects have much to contend with in the injudicious wishes and erroneous taste of those who employ them; but we are also convinced that they may frequently get over these difficulties by firmness, and by explaining the reasons which fortify their own opinions.

Of course when an architect is told to build a *maximum* church on a given area, or a church of given cubic contents on a *minimum* area, the question becomes one of simple geometry—all idea of architectural propriety must be given up. In less hopeless cases, however, we would venture to recommend the architect to leave a little space, if only of two or three feet, between the walls of the church and those of the adjacent houses,—to provide at least enough space for the construction of buttresses. It will require some additional expense to render the north and south walls uniform in architecture with the rest of the church, and the architect will have to practise some self denial, since he will not have so much money to expend on the more conspicuous western end. But this self denial will be well rewarded, for though there will not be so much to attract the eyes of mere lovers of show, the homage paid to the principles of pure taste will claim the admiration of the judicious observer, "the censure of which one must, in your allowance, outweigh a whole theatre of others."

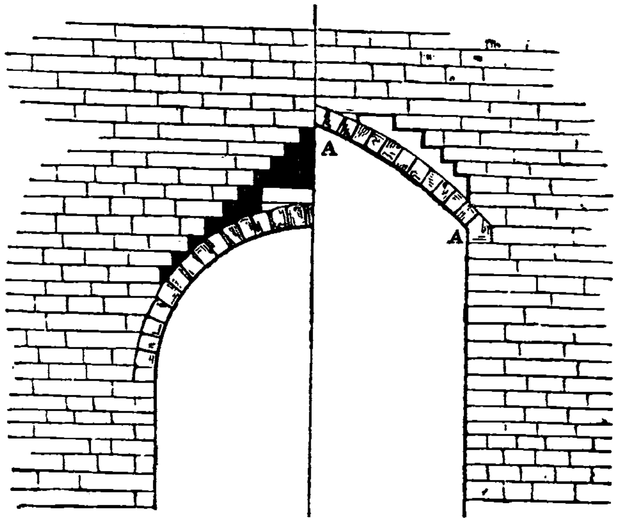
Of course this advice is given on the most unfavourable supposition, namely, that there are not funds to purchase the adjacent buildings. In this case it may be well left to the munificence and good-feeling of future benefactors to contribute the means of removing these obstructions, and displaying in all its dimensions, the edifice which then, and not till then, will exhibit the character of a Christian Church.]

THEORY OF THE ARCH.

Sir—In our last letter we endeavoured to show that your review of our pamphlet was written under a misconception of the principles therein advanced, and hence the wholesale condemnation with which you were courteous enough to favour us.

You have challenged us to show where the standard writers on the theory of the arch have failed in their reasoning. We should consider it presumptuous to entertain any doubt of the accuracy of the statements of Professor Moseley, neither does his theory of the arch, and the method by which he arrives at the line of resistance and the line of pressure, militate against the observations which we have ventured to bring forward.

We maintain that the voussoirs of an arch, of any form, have only to support that portion of the superstructure where the corbelling ceases to



exist (represented by the shaded lines in the accompanying diagram). Now, if the "two-centred pointed arch"—not the plate bond, which you have erroneously put forward as our proposition,—shown at A, A, is substituted for the semicircular, segmental, or elliptical, is it not manifest that there is greater strength obtained, with less amount of material? The beds of the voussoirs being nearly parallel, and the key stone of the arch being the only portion at all affected (in a downward direction) by the superincumbent weight, it appears to us to possess advantages co-equal with the "merit of novelty."

We do not consider it worth while to occupy your pages with any remarks respecting the title of our tract; if we have demonstrated that a stronger arch at less cost is obtained by our method of construction, we shall consider our labours amply repaid.

We are, Sir,
Your obedient servants,

Blair and Phillips.

ARCHITECTURAL COMPETITION.

Sir—The recent award of premiums of competitors for the Leeds Industrial Schools, affords another source of *encouragement* to young architects, and is too good an example of what professional men have to contend with, to pass unnoticed.

The Committee was composed of one respectable innkeeper, a fourth-rate manufacturer, a maltster, a drug dealer, a house painter, a leather dealer, a grocer, and an apothecary. The Plans were hung up for the private inspection of the committee and friends by a joiner, who gave the names of the competitors to the parties, but to appear decent, they called in a reputable architect, from a neighbouring town, to decide upon the merits of the designs, and on his decision this Committee professed to act.

Among the competitors were some four or five architects (one of whom took care, with all due *northern foresight*, to describe by letter his *pertickler* plans to his friends on the Committee, lest they perchance might favour those of *older* and better rivals); another competitor was a joiner, preacher, and conventicle builder; another, a pot-house keeper, who began his career as a joiner, and perfected himself as a toll clerk of a market-house.

The Judge made a just award, upon which the committee did *not* act, but contrary to all reasonable expectation, they gave the first premium to their friend whose *brandy-and-water* and *pennyworths of tobacco* had oft regaled the majority after closing their shops.

Much more might be said, but this suffices to show the state of art in this great manufacturing place, and how hopeless is the chance of any young or old architect to erect a public building here, unless expressly commissioned by some of the few men of education and taste who remain to us of the *ancien regime*.

I remain, Sir,
Your obedient servant,

Leeds, April 18, 1846. VIATOR.

REGISTER OF NEW PATENTS.

If additional information be required respecting any patent, it may be obtained at the office of this Journal.

MOTIVE POWER.

DAVID WILKINSON, of Potters Bury, near Stoney Stratford, Gent., for "*improvements in obtaining motive power.*"—Granted October 10, 1845; Enrolled April 9, 1846.

This invention consists in a mode of combining heated air with steam, instead of using air or steam separately. In carrying out this invention the patentee proposes to apply an air pump of about half the cubic contents of the cylinder, by means of which air is to be forced through tubes or other suitable apparatus, such apparatus being heated externally, so that the air may become highly heated, which is afterwards admitted into the steam boilers or generators, that the heated air may combine with the steam and go together into the working cylinder of the engine. This invention is more particularly intended for high pressure engines, notwithstanding, the patentee states the same is equally applicable to low pressure or condensing engines.

The claim is for forcing air through pipes or other suitable heated surfaces and then mixing the same with steam, and working the steam and heated air conjointly.

SLIDE VALVES OF LOCOMOTIVE ENGINES.

ROBERT BEWICK LONGRIDGE, of the Bedlington Iron Works, near Morpeth, Northumberland, for "*an improved locomotive engine.*"—Granted January 13; Enrolled March 13, 1846.

This invention for improvements in locomotive engines relates to the slide valves and mode of working the same. The accompanying figure shews a

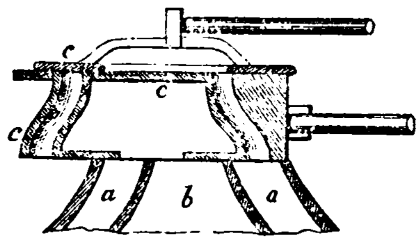


Fig. 1.

transverse section of the slides and steam ports leading to the cylinder. *a a* are the induction ports leading to the cylinder; *b* is the eduction port; *c c* is a slide valve for opening and closing the ports in the cylinder, and is worked by an arrangement of levers and excentric, which latter is capable of being moved upon the shaft say 30 degrees on each side the centre of the crank, for backward and forward movement of the engine. The induction ports of the valve pass through to the back thereof, at which place there is a second slide *c'* for cutting off the steam at any required part of the stroke. This latter valve or slide is worked by an excentric, keyed fast on the shaft,

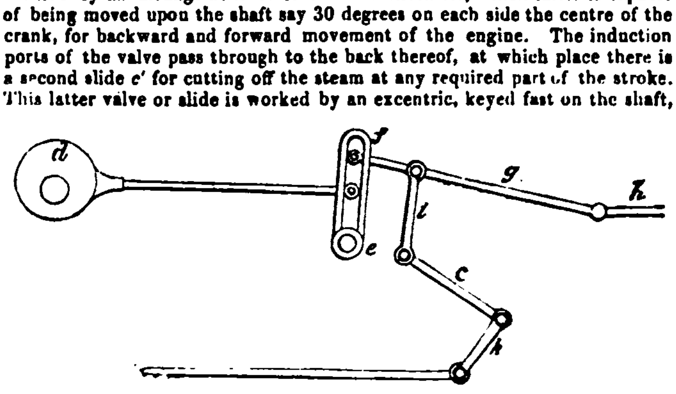

Fig. 2.

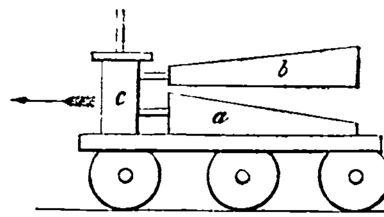
and an arrangement of levers shown at fig. 2. *d* is the excentric rod, the outer end of which is connected to a lever keyed on the weigh shaft *e*; upon this shaft is keyed a slotted lever *f*, which receives a stud attached to the end of a link *g*; the opposite end of the link *g* is attached to the valve rod *h*, so that by raising or depressing the stud in the slotted lever *f*, the amount of motion imparted to the valve rod *h* and valve or slide *c'* can be varied at pleasure. The end of the link *g* is raised or depressed in the slot by means of a rod *i*, attached to the end of a bell-cranked lever *k*; to the opposite end is attached a rod *l*, actuated by a lever placed near the engine-driver. Another improvement consists in heating the water supplied by the feed pumps previous to entering the boiler. For this purpose the inventor proposes that the water, after leaving the feed pumps and before entering the boiler, shall pass through a chamber or series of pipes exposed to the action of heated vapours, which pass through the tubes into the smoke box, so that the water may become highly heated before entering the boiler.

LOCOMOTIVE ENGINES.

HENRY SAMUEL RAYNER, of Ripley, Derby, Gent., for "*certain improvements in locomotive engines.*"—Granted September 4, 1845; Enrolled March 4, 1846.

The object of the inventor is to construct a locomotive engine, which is to be propelled by the pressure of the atmosphere acting upon the exterior surface of a vessel or vessels exhausted of air. The annexed diagram shows a side elevation of Mr. Rayner's locomotive, which may be termed a perpetual locomotive, being of that class of machines when once started will continue its course so long as the parts of the apparatus will hold together! *a* represents a rectangular or oblong vessel of a wedge-shape form mounted upon



the carriage framing; above this vessel is fixed another (marked *b*) of the same construction, but in a reverse position; the object of reversing the two vessels being for the backward and forward movement of the apparatus. Each of these vessels are made hollow and perfectly air-tight, and are connected, by means of a pipe, with an air-pump *c*, also fixed upon the framing of the carriage. Now, in order to start the locomotive, Mr. Rayner gravely proposes to exhaust one of the two vessels *a* or *b*, when the locomotive will be propelled either backward or forward as may be required. For the inventor states, if the vessel *b* be exhausted of air, a certain amount of pressure will be exerted on the whole of its exterior surface; that is to say, there would be a vertical pressure on the upper or inclined surface, which the ingenious Mr. Rayner supposes would propel the locomotive; in order therefore to counteract this propelling power, he proposes to have the "wheels, rails, and axles" at an angle, so that the locomotive under such circumstances would remain motionless. He then states that the sides of the vessels being equal to one another, the pressure would be equal; that is to say, the pressure on one side of the vessel would be counteracted by that of the other. Now, the pressure on the under surface, the inventor states, is counteracted by the *gravity* of the carriage (this would not have been a bad idea for Hanson's ærial machine). Again, the pressure on the ends of the vessel is also the same per square inch as the other parts of the vessel; but one of the ends is double the area of the other, consequently, there will be double the pressure on the larger end of the vessel *b* when exhausted, tending to propel the carriage in the direction of the arrow; and in order to reverse the motion of the locomotive, it will only be necessary to exhaust, by means of the air-pump *c*, the vessel *a* in place of the vessel *b*. In conclusion, it would perhaps not be out of place to recommend the inventor to pay a little more attention to the study of pneumatics before he attempts to bring his invention before the public.

PROPELLING POWER.

JOHN LAKE, of Apsley, in the county of Herts, civil engineer, for "*certain improvements in propelling.*"—Granted October 9, 1845; Enrolled April 9, 1846.

This invention consists in a peculiar mode of propelling carriages on railways and common roads, and also barges or boats on rivers and canals. In carrying out this invention it is proposed to lay between the rails a continuous pipe, having a longitudinal slit or opening similar to those employed on atmospheric railways, as will be seen on referring to fig. 1, which represents a longitudinal section of a portion of a tube showing the other arrangements necessary for propelling a train of carriages upon a line of railway, between the rails of which is placed the tube *a*, and continued throughout the whole length of the line. Within this tube there are two pistons *b b*, connected together by means of a pipe *c* with a stop-cock *d*;

this pipe is firmly attached to a vertical arm that passes through the longitudinal opening and attached to the leading or driving carriage of the

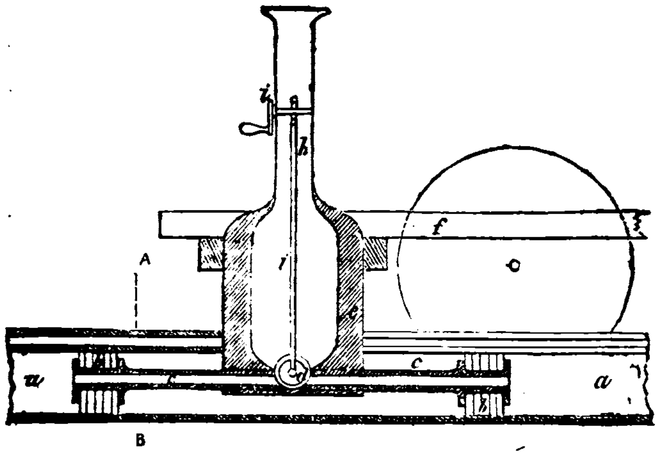


Fig. 1.

train, a portion of which is marked with the letter *f*. Fig. 2 represents a transverse section of the apparatus taken through the line A B of fig. 1, in which is shown the mode of closing the longitudinal opening by means of a valve *g* sliding edgeways into a groove or recess formed in the upper part of the tube. The operation is as follows:—At certain intervals along the line

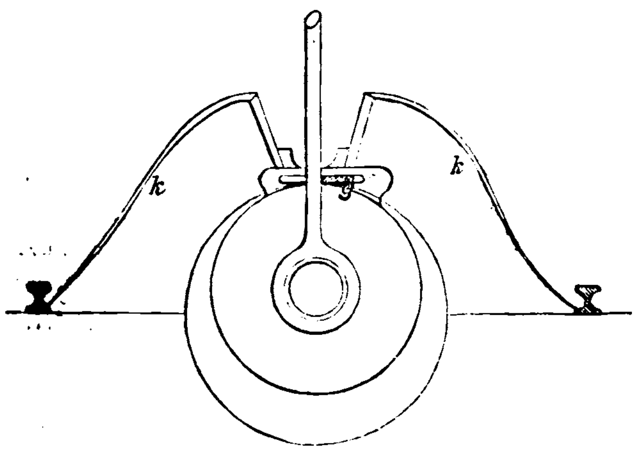

Fig. 2.

are to be erected steam boilers; and in order to propel the carriages, steam is to be admitted into the tube *a a* throughout the whole length, for the purpose of warming the tube and driving out the air. The ends of the tube and longitudinal opening being closed, a communication is to be formed with the tube and a condenser, similar to those employed in steam engines, for the purpose of condensing the steam, leaving the pipe empty or nearly so; when this is done the piston *d d* is brought near to the opening leading from the boiler, when a fresh supply of steam is admitted, which will have the effect of propelling the piston and train of carriages along the line. The specification states that the condenser may be dispensed with by opening the cock *d*, so as to let the steam first introduced into the pipe pass up the funnel *h* for the purpose of driving out the air. *i i* is an arrangement of levers for opening the valve *d*. In place of having stationary boilers, the inventor proposes to have an ordinary locomotive boiler, and instead of the steam working the engines as heretofore, such steam is allowed to pass through the pipe *c c* into the main, either from behind or in front, depending upon the direction in which the carriage or train is to be propelled. In descending inclines, the inventor proposes to fill the tube with steam, which will have the effect of a break, the motion of the carriage being regulated by opening the valve *d* so as to allow the steam to escape from the main *a a* through the funnel into the atmosphere. *k k* (fig. 2) represents a covering for the pipe, composed of felt, straw, sawdust, or other bad conductor of heat.

White Gravel.—Upwards of 7,000 tons of white gravel have been shipped from this city to London since the 15th of September last. It is taken from the beach at Long Island, and used to beautify the parks and gardens of London.—*New York paper.*

A NEW GONIOMETER AND CRYSTALLONOME.

At a recent meeting of the Chemical Society, Dr. Leeson read a paper "*On crystallography, with a description of a goniometer and crystallonome, or instrument for studying crystals, in reference to their gubernatorial axes.*" The author commenced by observing that discriminative chemical researches have not received that assistance from crystallography which might reasonably be expected from the natural distinction of form peculiar to various different substances.

The particular design of the author's present paper was to introduce greater facility and simplicity in the classification and determination of crystalline forms, both by improved methods of observation, and also by a system of classification founded on the three gubernatorial axes, for the happy discovery of which we are indebted to Weiss, by whom, however, as well as by others who have succeeded him, systems have been proposed by no means realising that simplicity and perfection of which the fundamental principle is believed to be susceptible. To prove that the nomenclature and classification of the different authors were both confused and complicated, various tables were referred to, showing the systems respectively adopted by them. By referring to which it was apparent that different authors used the same terms for totally different fundamental forms; and also that by many of them terms were employed which, having reference simply to the *number* of planes bounding a given system, were, in fact, as subsequently demonstrated, applicable to every class and order, and therefore not *discriminative* of any one in particular. Any one who may have carefully examined the first crystals depositing from solutions of different substances, will be struck by the general prevalence of the prismatic or hexahedral form, or of some modification thereof; at the same time, he will observe great variety in the *number* of planes bounding many of the crystals. Under the microscope he will not only be struck by the general prevalence of parallelograms, or sections of the prismatic forms, as well as hexagons, triangles, and other sections, resulting from hemihedral modifications, but also by the *primâ facie* similarity of the sectional forms presented by totally different substances. It is in the discrimination of these forms that the principles of classification now about to be proposed, and the goniometer subsequently described, are peculiarly applicable.

Before describing the system itself, the author requested to explain an instrument which he exhibited, and stated he had contrived some years ago, for the purpose of studying the relative character of crystals derived from different positions and lengths of the three gubernatorial axes, and for which instrument he requested to be allowed to propose the name crystallonome. The author showed, with that instrument, that whatever be the length and relative position or inclination of the three axes, a prism or hexahedron must necessarily result from a set of planes terminating the extremities of the respective axes, such planes terminating one axis, and being parallel to the other two axes. These planes were represented by a contrivance for attaching pieces of stiff paper or card-board to the extremities of the axes. The author then showed that an octahedron must necessarily result in every case from a set of planes cutting all three axes, and which octahedron might easily be built up and represented by threads connecting the extremities of all the axes. The construction of other forms was also demonstrated.

The crystallonome, although constructed with only three zones placed at right angles to each other, is nevertheless capable of showing the position of the axes in every class, even where all the axes are oblique; this was illustrated by the instrument itself. It was also shown, that whatever be the class and order of a crystal, there are always two zones in which all three axes will be found. It having been already stated, that the three gubernatorial axes form the basis of the proposed system, it will be evident that the discriminative principles of the system must be dependent on the position and length of the respective axes. Since the relative position of the axes occasions the greatest difference in the appearance and character of a crystal, it seems natural to take that as determining the class; and we shall find that as regards this distinctive character, there are but three classes to which the variation of position can give origin, viz.:—1, where all the axes are situated at right angles to each other; 2, in which one axis is at right angles to the other two, which are obliquely placed as regards each other, one rectangular axis and two oblique, being, in fact, the same as though we represented it as two rectangular axes and one oblique; 3, in which all the axes are oblique to each other.

We have thus three classes, which we term respectively:—1, rectangular; 2, right oblique; 3, oblique; and these we again subdivide into three orders, dependent on the relative length of the axes, viz.:—1, all the axes equal; 2, two axes only equal, the third being longer or shorter than the other two; 3, all the axes of different lengths. These orders we term—1, equiaxial; 2, binequiaxial; 3, inequiaxial.

With these three classes and three orders we obtain nine distinct crystalline bases, which, the author trusts, will be found easy to remember and simple to distinguish. Generally speaking, few substances will be found to crystallise in forms belonging to distinct classes or orders. Without, however, passing any opinion on the subject of dimorphism, the author showed, by reference to the native crystals of sulphur, and also those obtained by fusion, that, according to the system now proposed, sulphur cannot be considered as dimorphous, the native crystals being, in fact, modifications of the octahedrons, or the rectangular inequiaxial system; whilst those of fusion are prisms or hexahedrons belonging to the same system. Both were exhibited to the meeting, and the goniometer, subsequently described, applied to the measurement of the angles of the crystals of fusion. Whilst a chemical substance usually crystallizes in forms pertaining to the same class and order, it may nevertheless, as has been already shown, assume a great variety of forms, if reference be had only to the number of bounding planes; and these forms constitute what may be termed the genera of the author's system, which were shown by reference to diagrams, as also the symbolic notation recommended by the author.

The author concluded by exhibiting his goniometer, consisting of a double refracting prism, placed in a vernier revolving round a graduated circle, and applicable either to the microscope or to crystals placed on any convenient stand. He stated, that in most cases of crystallisation, particularly under the microscope, some crystals will be observed presenting the prismatic or hexahedral form; and knowing that the gubernatorial axes of any prism must terminate in the centre of the sides of that prism, we are at once directed to the position and length of the axes in any given crystal; whilst, by examining the angles formed by the sides of the parallelogram constituting the section of the prism with the goniometer, we may determine the inclination of the several axes. In all natural octahedrons formed by inaxial planes, the axes will be found, as shown by the crystallonome, by taking the points where four planes meet. Although octahedrons may be mathematically formed by biaxial planes—that is, by bending in the sides of the prism—it is believed that such octahedrons do not occur in nature, as it would contradict the general laws of symmetry, inasmuch as that, whilst the perpendicular axis terminated at the meeting of four planes, the middle and transverse axis would be situated in the centre of an edge bounding two planes—a state of things that could not certainly occur in the regular system; the general condition of natural symmetry being, that whatever disposition takes place at any one extremity of an axis of equal length, the same will take place at its other extremity, and also at the extremities of every other axis of equal length.

REVIEWS.

Parish Churches, *being Perspective Views of English Ecclesiastical Structures, accompanied by Plans, drawn to a uniform scale, and letterpress descriptions.* By R. and J. A. Brandon, Architects. Bell, Fleet-street, 1846. No. 1, 8vo., pp. 12; fourteen lithographic plates.

Messrs. Brandon are already favourably known to our readers as authors of the *Analysis of Gothick Architecture*, reviewed in this Journal for August 1844. The publication now before us is the first of a series intended to illustrate "such Churches as from their beauty of design and peculiar fitness for the sacred purpose for which they were reared, seem worthy of being adopted as models by those engaged in Church building." The principal distinction between the present work and the "Analysis," is, that while the latter was exclusively confined to the exemplification of architectural details, the new series gives views of entire buildings only.

Our old English Churches are so beautiful, and contain such treasures of architectural science, that we naturally commence the examination of any work, which professes to contribute to our knowledge of them, with a favourable prepossession. We cannot suggest a work which we should study with greater personal gratification than one which gave a *comprehensive, systematic, and minute* record of all that is valuable in our national church architecture. Such a work, however, to be satisfactory, must be conducted with liberal and extended views; it should be a very cyclopædia in which nothing is left out that deserves a place in it. The chief value, or to speak more truly, almost the only value of such a publication would be its *completeness*. Of course we do not mean that the work should be a confused mass of facts—a collection of knowledge so ill assorted and so crammed and crowded together, as to become, like certain modern cyclopædias, that we wot of, absolutely unintelligible. But we repeat a deliberately formed conviction that the *most* valuable contribution to architectural literature which could now be made, would be a digested and complete pandect of church architecture—not concocted hastily as a publisher's speculation to meet a transitory mania for old churches, but arranged, slowly and carefully, from a mass of information collected by pains-taking and unwearied research.

The work before us certainly does not reach this mark. The plan of it, as far as we can see, does not make any pretensions to system, and is by no means comprehensive enough. Each number of the series is to contain eight perspective views of churches, selected at random from different counties and in different styles, and the work will be completed in twelve parts: so that, altogether, we shall have ninety-six churches delineated. But what are these among so many? If Messrs. Brandon would multiply the proposed number by ten or twenty, their undertaking might assume an importance commensurate with the object in view. Not, indeed, but that the work is in many respects a valuable contribution; and if we speak of it in terms of qualified praise, it is on the score of sins of omission, not commission. The views here given are not absolutely faulty, but there are numerous drawing-books, published as first lessons in pencil drawing which frequently contain sketches which are quite as good. The letter-press descriptions, again, are not nearly copious enough, and this defect might be remedied the more easily as the authors state that they intend to visit personally every church illustrated. In the number before us, the description of each church is comprised, on the average, in thirty lines.

One other point to which we must allude is important. The authors state their intention of selecting churches which seem "worthy of being adopted as *models*." We hope they will give up this part of their plan. Nothing can be more fatal to the progress of architecture than the modern idea of model churches. Let us study the *principles* and the forms devised by our ancestors, and their modes of combining them with the zeal and reverence of learners; but let us not grow mere copyists of ancient churches. This contentment with mere reproduction marks the lowest ebb of artistic feeling—the very last stage of architectural degeneracy. The vilest modern plaster-gothic travestie is better than absolute copying; these abortions, hideous as they are, mark at least a desire to regain something of the glorious art lost among us during the Reformation; but mere mechanical imitation argues absolute hopelessness—the indolence of despair—that we have given up all endeavour to recover the ancient excellence of our national architecture, because satisfied by experience of the absolute futility of the attempt.

Besides, even supposing the copy to be fairly made, and to be a faithful transcript of the original, there are ten chances to one, that some local circumstance, an irregularity in the site, the proximity of secular buildings, or even local customs and requirements, may render it inconvenient or unfit for its purpose. Our ancestors did not design churches and stick them down *anywhere*: on the contrary, they examined the site of the new building, the nature of the soil, the particular wants intended to be supplied, the *character of the surrounding scenery*, and a thousand accidental local circumstances, before projecting the form to be adopted. A church built on a hill top would, according to their exquisite feeling of propriety, require different treatment to a church on a hill side or in a valley. A church hemmed in by woodland scenery would of necessity be different from one built on a wide open plain. Modern practice does not recognise these subtle distinctions. *We* get up a dozen or score of designs for new churches, send them to a picture exhibition to be duly admired by fashionable visitors, and duly be-paragraphed in the newspapers, and are fully prepared to execute our plans (any or all of them,) in any given spot of this island, or if need be, in the most distant quarter of the globe. They are building now, in Calcutta, a cathedral with roofs as sloping and windows as numerous and large as those suited for a similar edifice in latitude 51°.

Even if we conceded the principle of adopting architectural models, we certainly ought not to take those selected by Messrs. Brandon. A model church ought, at least, to have a uniformity of plan—a consistency of design in it. The examples before us show, on the contrary, such a remarkable diversity of style, that we might almost suppose them selected for that very peculiarity. The first church delineated, *Little Casterton, Rutlandshire*, is Early English, with Norman piers and arches, Perpendicular clerestory, and a Decorated piscina; the second, *Apston Church*, in the same county, is Perpendicular externally, with the exception of some Decorated windows; in the interior, the arches on the north side of the nave are circular. *Duddington, Northamptonshire*, the third specimen, is in the transition from Norman to Early English, with a north aisle Norman, and a Perpendicular clerestory. *Herne Church, Kent*, is apparently the most unmixed in style, being almost entirely early Decorated, with, however, some Perpendicular details. *Brampton Church, Northamptonshire*, the last example, has an Early English chancel and a Perpendicular nave; this church, by the by, has (on paper at least) somewhat too much of the prim pert look of modern Gothic.

We hope that as the work proceeds, the plan of it will be extended, and that all idea of furnishing models will be abandoned. It certainly would be preposterous to re-construct buildings which, like those here pourtrayed, are the growth of successive ages. The authors of the present work are fully capable of contributing largely to the science of mediæval architecture, and we trust will greatly extend the limits which they have assigned to their undertaking.

Reply to "Observations" of the Great Western Railway Company on the Report of the Gauge Commissioners. Vacher, Parliament-street. 1846. 8vo.; pp. 75.

This rather long "reply" is in the form of a pamphlet, which, if we mistake not, claims Mr. Wyndham Harding for its author. The style possesses the clearness, and the views are expressed with the moderation, by which Mr. Harding's dissertations on the gauge controversy have been characterised. Without involving ourselves in the discussion, we cannot help expressing an opinion that those who have read the "Observations" of the Great Western Railway Company ought certainly to examine the present pamphlet, which meets each argument consecutively, and treats the general question with great perspicuity. We wish, however, more had been said about the Intermediate Gauge. There are many competent persons—Messrs. Bury, Vignoles, and Cubitt, Col. Landmann, and General Pasley are among the number—who think the broad gauge too broad, and the narrow gauge too narrow. In the present pamphlet this opinion is dismissed in twelve lines; in the Commissioners' Report scarcely more space is occupied with it, and the view there taken is supported by very inadequate and inconclusive arguments.

Tables and Rules for facilitating the Calculation of Earthwork, &c., of Railways, Roads, and Canals. Also essays on the prismoidal formula, and on the power required upon inclined planes. By J. B. Huntington, C.E. Weale, Holborn, 1846. 12mo. pp. 286.

The object of this work in some measure resembles that of a smaller one by Mr. Hughes, reviewed in the March number of this Journal. The present treatise, however, embraces several subjects in addition to the calculation of earthworks. Tables are given for the calculation of the areas of slopes, the offsets and radii of curves, &c. The first 170 pages are occupied by the tables for the cubic contents of cuttings and embankments. Next follows a demonstration of the prismoidal formula and illustrations of the accuracy of the calculation by this method compared with that generally used by contractors. After explaining the method of using the foregoing tables, the author gives a description of a *graduated scale* for measuring earthworks, without the necessity of referring to tables. A woodcut, representing one of these scales made by Elliot, accompanies the following description:—

"I now proceed to give an explanation of a scale for measuring earthwork, which I have successfully used on the Eastern Counties Railway. The vertical and horizontal scales, and also the base and slope, must be previously determined for each scale, and then a set can be formed embracing the required slopes of the railway. My scales were made four in number, for base 34; slopes 1, 1¼, 1½, and 2 to 1; and on the back of each was properly described the slope, base, and vertical and horizontal scales to which they were applicable. All the dimensions were taken in yards lineal, superficial, or cubical, as required; the application being precisely the same as the use of the tables, and the rules being the same to find the *area*, using 2 as a co-efficient instead of 6. Owing to the fineness of the graduations, I would not advise, to insure accuracy, that the vertical scale be made less than 40 feet to 1 inch, and, generally, the larger the better. 20 feet to 1 inch vertical is a good working scale. The lengths can be made to suit convenience. There is no necessity to measure the heights or lengths previously, and the same form must be used as before described.

To Measure a Cutting by the Scale.—Apply the zero of the scale of sectional areas vertically to the gradient or formation line, and read off where the surface line intersects; put this in column 1 or 2, as the case requires: then, at the smaller end of the prismoid, upon the scale of vertical yards, with zero on the surface line, observe where the gradient intersects, then place the same point of intersection on the gradient at the other end, and read off above the zero on the scale of differential areas, where the surface line intersects; put this in column 4, and then, having measured all the lengths by the scale of horizontal yards, proceed as in the use of the tables. To save time, it is desirable to take a pair of dividers, and mark off at each division the difference of the heights in succession, and then the differential scale above zero need only be applied.

This method of computing cubic contents of cuttings and embankments is very expeditious with a little practice, and is quite as accurate, and generally more so, than the calculating by feet and the tables; because, in a working section, the points of intersection of the scale and surface line can be estimated readily by the eye; but, in using an ordinary scale of equal parts, we are compelled to neglect the fractional parts of a foot."

The above extract is followed by tables of areas required on a railway for cuttings and embankments of various heights and slopes; tables for estimating the superficies of slopes; for finding the radius of a curve of which the chord and the angle contained between the tangents to the two extreme points of the arc are known, &c.

The part of the work which refers to mensuration is followed by essays on the resistances to locomotives, and the relation of the power of the engines to those resistances. These essays, however, are not altogether satisfactory; for instance, the resistances in question are stated to be these three,—the friction of the carriages, &c., the resistance of air, and the resolved part of the weight on an incline; the author has, however, neglected the resistance due to the blast-pipe, which frequently at high velocities causes a pressure of 8 or 9 lb. per square inch on the piston. The following passage is altogether erroneous—the author is calculating "power" necessary for drawing a given load; D is the diameter of the driving wheel, *a* the area of the piston, *l* the length of the stroke:—

"Let *p* represent the pressure (60 lb. on the inch), and let the previous notation be used, then the general expression of the power is $pal \div D$ for one cylinder only. The ratio between the greatest effect of one crank, and the mean effect of two acting simultaneously at right angles to each other, is nearly as 10 to 16; and adopting this proportion, we have $1{\cdot}6 \times pal \div D =$ power of two cylinders."

This short extract contains three errors, either of which would be fatal to the conclusion arrived at. First, the pressure in the cylinder is supposed to be the same as that in the boiler, whereas the relation of these two pressures to each other depends on the velocity or number of strokes per minute; for the more frequently the cylinders have to be filled in a minute, the more will the steam be dilated in passing from the boiler. Next, the "general expression of the power" $pal + D$ is erroneous, for the relation of the pressure on the piston to that exerted by the driving wheel depends on the proportion of the distance traversed by the piston, to that traversed by a point in the circumference of the driving wheel; consequently, supposing the above formula correct in all other respects, we must substitute the length of the *circumference* for that of D the *diameter*. Lastly, the ratio 10 : 16 could not have been arrived at except by a statical process, that is, by supposing the engine not in motion; for when it is moving, the ratio will depend on excessively complicated relations between the velocity, the load, &c.; moreover, the application of this relation here is hopelessly erroneous, for (*inter alia*) it is in direct opposition to the law that in machines force is neither gained nor lost by transmission, excepting so much of it as is absorbed by friction of the mechanical organs.

It is due, however, to the author to state, that the theoretical essays are not considered as integral portions of the work, and that in the part which refers to mensuration everything has been done to facilitate calculation and to render the tables convenient for reference.

Ancient and Modern Architecture; consisting of views, plans, &c. Edited by M. Gailhabaud. Parts 43, 44, and 45; quarto. Didot. 1846.

The concluding parts of the second volume of this series, which has been before favourably noticed in this Journal, are now before us. They contain views, sections, and details of the Treasury of Atreus, at Mycenæ, a monument of Pelasgian architecture, and five plates, illustrating the Church of St. Francis, at Assisi, in Italy, built in the Pointed style of the thirteenth century. We have little to add to our former notices, except the necessity of making the plates architectural instead of pictorial seems to have been more carefully regarded in the latter parts of the work than in the commencement of it. The following extract from the description of the church at Assisi may suggest some reflections to those who advocate the universal adoption of high roofs in Pointed architecture:—

"The lofty gable which surmounts the front does not attain the object aimed at by the architects of the North in the pointed forms of their Gothic fronts. The climate of northern countries required the roof to have a very high pitch; the architectural decorations were conceived so as to harmonise with this necessity. In Italy it had always been usual to cover buildings with low roofs; and architects even in the Middle Ages should have conformed to this long establised practice. This high and useless gable, forming an isolated wall of a very unpleasing effect, and exposed to all the winds of heaven, is an anomaly that would seem to indicate the northern origin of the architect of the church of Assisi. . . . . In the upper nave, the trefoil arches, the tall openwork gables, the capitals with vegetable ornaments, all so common then in the North, are too boldly employed to be attributed to Italians, who were then novices in this Northern style. Let us add, that the mullions of the windows have the shape and outline of those executed at the same date in France and Germany; and that this edifice is the only one beyond the Alps that contains a series of painted windows so complete and so strictly in keeping with the general character of the building. The Pointed style was still a novelty in Italy at the beginning of the thirteenth century, when the church of Assisi was built; it was called *tedesco*, or German, and only a few essays had been made. At this epoch, what Italian artist could have conceived so perfect, so well-proportioned a whole, in a style then quite new to him? The isolated gable, which serves no useful purpose in the climate of Italy, though so appropriate in the North, seems to prove the northern origin of the architect, who could not allow himself to disfigure the pointed forms to which he was accustomed, by reducing them to the low pitch of Italian roofs—a modification which Niccola Pisano introduced in Gothic architecture, when he built the church of Saint Antony, at Padua; as Simon Andreozzi did in the side elevations of the Ara-Cœli, at Rome; and as many other Italian artists contemporary with the Pointed-arch period have done, but in general very imperfectly, in numerous edifices scattered about Italy, from Venice to the kingdom of Naples."

The last number contains the title-page and index of the volume. The third volume will be published in December.

NEW LAW OF COMPOUND MOTION.

At the last *soirée* of the Marquis of Northampton there was exhibited an instrument by Mr. Perigal for developing a peculiar law of compound circular motion; the following description we extract from the *Literary Gazette*. It is an instrument for "generating *retrogressive* or *recurrent* curves, by which the moving body, when it has reached the extreme points of the curve, retrogrades or returns back in exactly the same line along which it advanced; constantly moving forward and backward from one extremity to the other; and always tracing and retracing the same line as it alternately advances and recedes."

These curves were produced by a complicated system of wheel-work, which Mr. Perigal stated to be capable of generating numberless varieties of curves dependent upon the ratio of the velocities of the movements; but the instrument was, on this occasion, adjusted for the production of parabolas or hyperbolas, and a sort of figure of 8 curve, resembling a lemniscate, which he showed to be different forms of one and the same curve, just as circles and right lines are (limits or) varieties of ellipses. When the tracing-point passed through the centre, the curve was at one of its extremes or limits; and the two ovals of the figure of 8 were opened to their fullest extent of roundness; but alterations in the angular adjustment of the movements caused these ovals to become more and more flattened, till they ultimately converged or collapsed, and became in appearance a single line, terminating in points, with the form of a parabola or hyperbola; and the tracing-point travelled forward and backward from one extremity of the curve to the other repeatedly, without in the least degree thickening the line in one part more than in another; evidencing that it advanced and receded in exactly the very same path! In fact, the line of return might be considered as superposed upon the line of advance; as Mr. Perigal remarked, in reply to a very eminent mathematician, who objected that the figure of 8 curve was a line of the fourth order, inasmuch as it could be cut by a straight line in four places, while the parabola was a line of the second order, because it could be so cut only in two places; but the suggestion of its being a double line superposed seems to remove the difficulty.

Mr. Perigal informed us that one of his objects was to exhibit the parabola in the novel character of a *retrogressive* or recurrent curve of definite range; whence he inferred, that *if a comet moved in that curve* (as most of them are said to do) it *might return* after it had performed its allotted journey, *and continue to visit us periodically*, as several do, which are therefore supposed to travel in very elongated ellipses, although their apparent path more resembles a parabola.

We do not take upon ourselves to decide that this "*retrogressive*" curve of Mr. Perigal is or is not identical with the parabola of Apollonius; but we can bear testimony to its striking resemblance to the conic section; and affording at least *prima-facie* evidence of its relationship, however much its newly discovered property of "*periodicity*" may shock the prejudices of those who have hitherto thought themselves learned in such matters. Besides, it is well known that reciprocating straight lines can be produced by combinations of circular motions; and, therefore, we cannot see why it should have been deemed impossible so to produce parabolas and hyperbolas, which, being curved lines, would even appear the less unlikely. Of the importance of the discovery in reference to the cometary theory, our scientific readers can judge for themselves; and such of them as are mathematicians can, for their own satisfaction, put the question to the proof by submitting the problem to analytical investigation.

POWER TO OVERCOME INERTIA OF RAILWAY TRAINS.

Paper read at the Royal Society, on the *Investigation of the Power consumed in Overcoming the Inertia of Railway Trains, and of the Resistance of the Air to the Motion of Railway Trains at high velocities*, by P. W. Barlow, Esq.—The object of the author in this enquiry is to obtain a more correct knowledge than has hitherto been possessed of the resistance which the air opposes to the motion of locomotive engines at high velocities, and of the loss of force arising from increased back pressure, and the imperfect action of steam. For this purpose he institutes a comparison between the velocities actually acquired by railway trains with those which the theory of accelerated motion would have assigned; and his experiments are made not only on trains propelled by a locomotive engine, but also on those moving on the atmospheric railway, which latter afford valuable results, inasmuch as the tractive force is not subject to the losses at high velocities necessarily incident to locomotive engines. A table is given of the theoretical velocities resulting from calculations founded on the dynamical law of constant accelerating forces, in the case of trains of various weights, impelled by different tractive forces, moving from a state of rest, and is followed by another table of the observed velocities in Mr. Stephenson's experiments on the Dalkey line; the result of the comparison being that, in a distance of a mile and a quarter, the loss of velocity is about one-half of the observed velocity. A series of experiments on locomotive lines is next related; but the comparison is less satisfactory than in the former case, because the tractive force cannot be so accurately estimated; it is, however, sufficiently so to establish the fact, that the power lost by the locomotive engine below the speed of thirty miles per hour, is so small as to be scarcely appreciable; and that the time and power which are absorbed in putting a railway train in motion are almost entirely required to overcome the inertia of the train, and do not arise from any loss or imperfection of the engine. It appears from these experiments that above one-fifth of the whole power exerted is consumed in putting the train in motion at the observed velocity. In the atmospheric railway the author finds that the tractive force of a fifteen-inch-pipe is so small (being less than half that of a locomotive engine) that the time of overcoming the inertia must limit the amount of traffic on a single line, especially with numerous stations. When a great velocity is obtained, the tractive force of the locomotive is much reduced, and, therefore, a much greater velocity can be attained on an atmospheric railway. The inquiries of the author into the amount of resistance exerted by the air on railway trains, lead him to the conclusion that on the atmospheric railway the loss of the tractive power of the piston from friction, &c., is very inconsiderable, and that the resistance of the air is less than had been hitherto estimated, not exceeding, on an average, ten pounds per ton on the average weight of trains. A tabular statement is then given of the results of the experiments made by the British Association for the purpose of comparison with those obtained by the author. The general conclusion which he arrives at is, that the resistance of the air in a quiescent state is less than had been previously estimated, and that the ordinary atmospheric resistance in railway progression arises from the air being generally itself in motion, and, as the direction of the current is not always oblique, from its producing increased friction in the carriages. This kind of resistance will not increase as the square of the velocity; and as it is the principal one, it follows that the resistance to railway trains increases in a ratio not much higher than the velocity, and that the practical limit to the speed of railway travelling is a question, not of force, but of safety.

PROCEEDINGS OF SCIENTIFIC SOCIETIES.

ROYAL SCOTTISH SOCIETY OF ARTS.

March 23.—John Clerk Maxwell, Esq., F.R.S.E., in the Chair.

The following communications were made:—

1. *Description of a Water-wheel with Vertical Axle, on the plan of the Turbine of Fourneyron*, erected at Balgonie Mills, Fifeshire. By Joseph Gordon Stuart, Esq. The paper gave an interesting description of a Wheel on this principle recently erected by him at his flax-spinning works at Balgonie, in Fife, and a summary of its general advantages. The Turbine is, in general appearance, like an overshot wheel, laid on its side, and wrought at the bottom of the fall. The water enters it from the inner circumference of the crown, and quits it at the outer circumference, impinging on every bucket of the one, and flowing from every part of the other, at the same instant of time. The water is supplied from a reservoir rising above the wheel, in which it stands to the full height of the fall, and is discharged from the bottom of this reservoir through a cylindrical sluice, so as to be delivered not only on every bucket or curve of the wheel at the same time, but also with the full velocity due to its head. The problem sought to be solved in the construction of the curves is, that the water, which has entered without shock, should quit without velocity. On the nicety of this construction will depend the economy of power, but in general the useful effect obtained will be equal to that of the best constructed overshot wheel. The turbine has the advantage of the overshot wheel in being adaptable to any height of fall (such wheels are working on the continent on falls from 332 feet to 13 inches), in being generally cheaper in construction, and always much cheaper in maintenance,—in being little disturbed in its economical arrangement either by changes in the quantity of water supplied, or by being thrown in back water—and in going at such speed as greatly to economise the necessary connecting gearing for factory work. Mr. Stuart's paper, with the illustrative drawings and model, was remitted to a committee of the Society that they may report fully on the merits of that (in this country) novel mode of economising water power. When that committee have made their report it may be expected that the result will be laid more fully before the public, especially if it be such as to justify the expectations entertained by Mr. Stuart, of this being a most valuable improvement upon any water wheel hitherto in use.

2. *Notice of a Double Bell-Jar,—or Receiver,—for the Air Pump.* By James Tod, Esq., W.S., Sec. On a late occasion, in treating of his experiments on the relative capabilities of different gases to convey sounds, Dr. Wilson having stated that he had constructed the plate on which the bell-jar

of the air pump rests of thick plate glass, but that on exhausting the bell-jar, the pressure of the atmosphere had shivered the plate glass into pieces, Mr. Tod, in this paper, suggested a plan by which the necessary strength might be obtained, while, at the same time, all parts of the interior would be as visible as when the plate glass disc was used. Mr. Tod suggested that, by taking two semi-elliptical bell-jars, the one of which should be perforated at the bottom, and fixed in a brass or other collar attached to the pump, and the other made to fit upon its ground lip, there would then be a double bell-jar formed of great strength, able to resist the atmospheric pressure equally from above and from below; and that the galvanic wires could be introduced into the interior of the jar through perforations in the collar at the bottom and properly insulated.

3. *A Communication from Australia on a new arrangement of the Screw-Propeller.* By Mr. James Paterson, engineer. Melbourne, Port-Philip, Australia. In this new arrangement of the screw propeller, the screw is made to traverse in an angle of 30 deg., by means of a Hook's joint, and is thus intended to serve the purpose not only of a propeller but of the rudder. It is not fixed, as usual, in the dead wood, but at the outside of the stern post, just where the ordinary rudder is placed.

April 13.—Sir G. S. Mackenzie, Bart., F.R.S.E., President, in the Chair.

The following communications were made:

1. *Verbal observations on the use of the Fibres of Plants, and particularly on the use of the Plantain Fibre:* illustrated by Drawings and Specimens. By Professor Balfour, F.R.S.E.—Dr. Balfour made some general observations on the plants which furnish fibre for the purposes of manufacture. He noticed the difference in the tenacity of the woody fibre of various species of plants, such as flax and hemp, and illustrated by drawings of the form and nature of the fibre, as contrasted with the other tissues, and its distribution in the stems of herbaceous plants. Fibres, from various plants belonging to the nettle and mallow tribe, from screw pines, pine apple leaves, and palms; also New Zealand flax, Pita flax, African or Bowstring hemp, Bengal hemp, Coir, &c., were brought under consideration. Dr. Balfour then alluded to various trees, the bark of which furnished cordage, and such as the lime or linden tree, the lace-bark tree, and the East Indian sack tree or chandul (a species of Antiaris), which grows in the deep ravines of Kandalla, and in the jungle near Coorg. He then proceeded to notice various species of plants belonging to the banana and plantain tribe, as *Musa textilis, paradisaica, sapientum,* and *rosacea*, from which fibres have been prepared, the mode of preparation, the quantity yielded, and the nature of the fibre. Specimens of plantain fibres, in various states, were exhibited. In some of the specimens not fully prepared, the microscope showed, in addition to woody fibres, spiral and dotted vessels, which are by no means so tenacious as ligneous tissue. The fibres, although they bear a considerable weight, are not well fitted for the ordinary purposes of manufacture: they break easily when a knot is made on them. The communication was illustrated by fresh specimens of the leaves of many of the plants, from the Botanic Garden, and by a large drawing of the plantain.

2. *Description and Drawing of a Cabinet Lock and Key of a new construction.* By Paul S. Samuells, M.D. There are three plates in this lock, a back, a front, and a centre plate. A square hole is formed in each, but it is only the middle one which can be moved by the key; so that unless the key go down to the proper depth and no farther, the bolt cannot be shifted. There is also a back spring behind the bolt, on which two pins or studs are fixed, the one of which enters a hole in the bolt, which prevents it shifting until the spring be depressed by the key. The other pin or stud enters the pipe of the key; so that unless it exactly fits the length of that pipe, the key will not depress it far enough to relieve the bolt, or if too long, the key will not get into its place, but be caught by the outer square. Another advantage of this lock is, that on withdrawing the key, the bolt is necessarily locked.

3. *Description, with Diagrams, of a Hydro-Pneumatic Railway.* By Mr. George Clark, Edinburgh. The weight of water is made use of to compress the air, which is forced into the tube laid betwixt the two sets of rails. He then contrives an apparatus for opening the continuous valves of the tube, and for conveying the compressed air from it to the boiler of the locomotive, from which it is admitted to the pistons of the cylinders, as the steam is used, in the common method.

4. *Description of a Model of an improved method of Hanging Windows, whereby, at small expense, windows in common use can be so altered, that the Sashes can be taken out and cleaned, painted, or glazed, from the interior of the room.* By Mr. John Steven, Edinburgh. This simple method can be applied to all windows as now constructed at a very trifling expense, probably under five shillings for each window. The sashes can be taken out with ease and in about two minutes. There is nothing liable to get out of repair; and it possesses other advantages, such as allowing the upper sash to come down to the very bottom, the steps covering the pocket holes being removed to the inside frame. As a separate improvement, Mr. Steven recommends that in *new* windows the sashes should be made with a slight taper, so as to fit closely when shut, but to move freely when pulled up or down.

5. *On a Machine for Beating Carpets, Wringing and Drying Clothes, &c.* By Mr. John Baillie, Edinburgh. This consists of a broad wheel with four arms, on each of which leather is stretched—and on being turned round by a handle, these leaves strike on the carpet, while the broad leather fan drives away the dust. The wheel is then reversed, which beats the under side of the carpet, which is brought in successive parts under the beaters. By having a hook attached to the axle of the wheel, heavy clothes, such as blankets, may be easily wrung; and the wind of the fans speedily dries them when suspended within its influence.

SOCIETY OF ARTS, LONDON.

March 25.—G. Moore, Esq., V.P., in the Chair.

The first paper read was, by the Rev. Dr. Thompson, "*On the Earthquakes of Peru and Chili.*" The paper also described the peculiarities of the mountains of North and South America, and concluded with an account of the most celebrated earthquakes that have occurred in America.

The second communication was, "*On an Improved Safety Lamp for Miners.*" By Dr. Clanny. The improvement consists in preventing currents of air coming in contact with the flame; a glass, or other transparent substance, being substituted for the wire gauze at the lower part of the lamp. It is also less liable to be blown out than the Davy lamp.

April 8.—W. F. Cooke, Esq., V.P., in the Chair.

The following communications were made by Dr. Green, "*On a New Portable Stand for Telescopes with an Equatorial Movement, but without a Polar Axis.*" The subject of the improvement was introduced with an account of the telescope from the time of its discovery, and the improvements which have been made upon it up to the present time. He next alluded to the stand ordinarily used, and pointed out the peculiarities of the Herschelian, achromatic, and other stands, and the objections to them, arising either from their unsteadiness, unportability, or other causes; he then proceeded to point out the improvements which he had effected, by describing his own stand. The true principle upon which every stand ought to be constructed (observed Dr. Green) is to have the heaviest end of the telescope supported on a solid foundation, and the moving power should be placed as far as possible from the centre of motion. To effect both these conversions has been my aim in the stand which I now submit. As a triangular support is found to be the most steady, it has been adopted in this case, and pervades almost every part of the stand. The object-end of the tube containing the great mirror rests upon a circular disc, having a diameter about one-half larger than that of the tube. It is supported by three feet, which are not more than three-quarters of an inch high, so that it may be said to rest solidly on the earth. To admit of easy rotation, a second disc of the same diameter rests on the surface of the one described, and moves on three friction wheels round a pivot passed through the centre of each. Near the periphery of this upper circular disc, upon the opposite sides of it, are fixed, vertically, two flat pieces of brass, about half the diameter of the tube in height; upon these the telescope rests by means of two horizontal arms projecting from the sides. The object is to form a universal joint, and prevent the telescope rotating on its own axis. The upper end of the tube rests upon a pair of shears a little inclined towards the tube, thus the entire fabric is one large triangle, possessing the greatest steadiness. The shears are attached at their lower end to a horizontal bar, which slides in a groove. The bar is worked by means of a universal joint and rack and pinion, and by which the slow motion in azimuth is given. The shears are so constructed as to admit of being lengthened or shortened. The fine movement in altitude for finding a star is provided by a slide on the outside of the under part of the tube, to which slide the shears are attached. The slide is moved by a rack and pinion. The equatorial movement is the link of connexion between the head of the shears and the slide for the fine altitude movement, and is thus effected:—the two legs forming the shears are hinged together at the top by a circular joint, in the centre of which is inserted a piece of brass, which carries the equatorial movement slide, and is worked by a toothed-wheel and pinion. The equatorial slides are attached to the altitude slide by a universal joint. By placing the lower end with the discs it rests upon, on a tripod, this frame may be made to suit the Newtonian telescope for viewing terrestrial objects.

2. "*On a Process for the Preservation of Animal and Vegetable Substances with their forms and colours unimpaired.*" By Dr. J. Silvestri.—A number of specimens of preserved animal and other substances were exhibited.

3. "*Specimens of a new process of dulling the surface of electrotypes.*" By Mr. Colchester, and also *specimens of a new method of bronzing*, by Mr. Loope, were also exhibited.

April 15.—T. Webster, Esq., V.P., in the Chair.

The first communication was on "*Mr. Rand's inventions for the Manufacture of Flexible Metal Vessels for preserving paint and other matters.*" By W. Carpmael. Mr. Carpmael stated that Mr. Rand, who is an artist, had, from the inconvenience and waste of colour which takes place when it is put up in the bladders ordinarily used, been led to endeavour to find a substitute, and the use of metallic vessels suggested itself. After experiments he succeeded in forming them of so thin a body of metal that they are capable of being collapsed so as to shut out all air. The tubes are made of block tin the 150th part of an inch in thickness, and have at their upper end a nozzle and screw cap, and are closed at the bottom by being folded over once or twice with a pair of pincers so as to exclude all air. As the colour or other matter which they contain is pressed out, the tubes are collapsed and thus the upper part of the tube always remains full. Each tube has to go through the following process of manufacture.

A small piece of block tin is put into a die upon which a punch worked by a fly-press descends and forces the metal up, of the required thickness, between the surfaces of the die and the punch; thus by a single blow the body of the tube is formed. It is then removed to a second press, by which the screw on the neck of the tube is formed, and by a second blow, in the same press, the maker's name is stamped upon it. The cap is formed in a similar manner by a third machine. The tube when struck is placed on a lathe and cut the required length. Thus an air-tight bottle is formed without seam in a few seconds.

The second communication was by Mr. Banks, on the Cotton produced in Honduras and Yucatan, and the practicability of introducing free-labour cotton from Africa and other countries into the British market. The object of the communication was to point out the importance of our cotton manufactures—the successful competition of white and grey fabrics with those of Britain in foreign markets—the great production of raw materials by slave labour in the States—the general inferiority of the cotton imported from India—the practicability of obtaining larger supplies by free labour, from other quarters within our reach—the improvement of the staple, and consequently of the fabric, and the opening of a new market with Africa and elsewhere.

April 22.—R. TWINING, Esq., V.P., in the Chair.

The first communication was by Mr. Banks, who resumed his paper on cotton produced in Honduras and Yucatan, &c. He proceeded to show why the American white and grey fabrics maintained a higher price and so successfully competed with the British manufactures in foreign markets. He next described the peculiarities of the kinds of cotton; and means resorted to by the Americans for cleaning or freeing the cotton from the seed,—namely, the Saw Gin. The amount of cotton exported to England from America he stated to be 1,600,000 bales per annum; while that from India and other countries amounted to only 500,000 bales. He next proceeded to show that the sea-coast of Africa presents a large territory which is capable of being made to produce cotton in larger quantities, and of a quality equal, if not superior, to the American. From inquiries which had been made at the Wesleyan and Baptist Missionary Societies, he had ascertained that the missionaries of both those Societies have instructions to promote such objects as the cultivation of cotton among the natives at their several stations, which extend all along the coast of Western Africa—and he strongly urged the necessity of their introducing the saw gin, in lieu of the roller gin and hand labour, to free the cotton from the seed, and the screw-press for packing it into bales.

The second communication was by Mr. Keyse, on *an apparatus for preserving life by supporting persons when in the water.* It consists of a covering for the arms, which are made of mackintosh cloth, and are capable of being inflated, of a pair of webbed gloves, and also a pair of cork clogs, with concave bottoms. The apparatus is stated to give an additional buoyancy of 35 pounds to the body.

ROYAL INSTITUTE OF BRITISH ARCHITECTS.

Extract from the Minutes of the Ordinary Meeting, held on Monday, March 23, 1846.

Resolved,—That the Medals of the Institute be awarded next year to the Authors of the best Essays on the following subjects:—

1. On the Adaptation and Modification of the Orders of the Greeks by the Romans and Moderns.

2. On the best system to be adopted with regard to the arrangements for the thorough Drainage of a Town House, and of a Nobleman's Mansion and Offices in the Country, respectively. Comprising the general arrangement for carrying off the Waters and Sewage, the sizes and most convenient forms for the Drains or Conduits, the requisite fall, the description of material to be employed, and the several precautions for the prevention of damp, smell, and passage of vermin;—to be accompanied by block Plans and Details.

N.B. Each Essay to be written in a clear and distinct hand, on alternate pages, and to be distinguished by a Mark, or Motto, without any name attached thereto.

Resolved,—That the Soane Medallion be awarded to the best design for an Edifice, suitable to the Congregational Worship of the Church of England, and capable of accommodating One Thousand Persons, without Galleries.

The design to be Roman or Italian, expressive of its purpose both internally and externally, presenting as little obstruction to sight as possible. The Chancel to be properly marked in Plan and decoration, with reference to its Protestant uses. All the Windows to be charged with stained glass.

There must be a conspicuous Belfry, but the body of the Church is not to be surmounted by a Dome.

The Drawings of the Elevations and Two Sections, to be to a scale of one-quarter of an inch to a foot,—the Plans and Perspective View to one-eighth of an inch to a foot, and tinted with India ink or sepia only.

The competition is not confined to Members of the Institute.

DIRECTIONS FOR CANDIDATES.

Each Essay and set of Drawings is to be accompanied by a sealed letter, containing the name of the writer within, and on the outside the same motto as that attached to the Essay or Drawings; this is to be enclosed in a sealed envelope, containing an address to which a communication may be sent of the decision of the Institute, and directed—

To the Honorary Secretaries of the Royal Institute of British Architects.
Essay for Medal (or) *Drawings for Medal (Motto).*

The Packet, so prepared and directed, is to be delivered at the Rooms of the Institute, on or before the 31st of December, 1846, by Twelve o'clock at noon.

The Council will not consider themselves called upon to adjudge a Premium, unless the Essays or Drawings be of sufficient merit to deserve that distinction; and, if the best Drawings should be by a candidate who has been successful on a former occasion, the Institute reserve to themselves the power of adjudging such other adequate reward as they may think fit, and of awarding the medals offered to the second in merit. The Essays and Drawings, to which Premiums are awarded, become the property of the Institute, to be published by them if thought fit. In case of the papers not being published within eighteen months after receiving the Medals, the authors will be at liberty to publish them.

The object of the Institute is not merely to draw the attention of the Students, and younger members of the Profession, to the important theoretical and practical subjects which are annually brought forward as subject matter for the Prize Essays,—they have a still higher aim;—they would wish to enlist the experience, the judgment, and the taste of those profoundly acquainted with the several departments of the Art, whether Members of the Institute or not; in the hope of collecting a series of authoritative Essays upon every branch of Architecture, considered both as a Fine Art and a Science, so as ultimately to form an important body of information on Architecture, both decorative and constructive.

The Institute trust that this appeal to professional men will not be in vain, and when they consider the honoured names of Palladio, Chambers, Rondelet, Smeaton, Tredgold, Nicholson, Krafft, and others who have done so much, and deservedly gained so much honor in like investigations, they cannot but confidently hope that many other men of erudition, taste, and science, will be induced to add in like manner to the stores of Architectural knowledge.

April 20.—EARL DE GREY, President, in the Chair.

A paper was read by the Rev. RICHARD BURGESS, on "*The Ancient Triumphal Arches.*" The paper commenced by explaining the purposes for which those monuments were erected; that they were properly divided into two classes, arches of triumph and honorary arches. The former placed nowhere but across triumphal roads, like the Via Appia, Via Flaminia, and other great approaches: the Via Sacra, by which the procession moved to the Capitol, was distinguished by several. The honorary arches were placed where the acts they commemorated had taken place, as the Arch of Trajan at Ancona, where that Emperor had built a port, the Arch of Augustus at Susa, at the foot of Mount Cenis, where Augustus passed in journeying to or from the transalpine provinces. Mr. Burgess having established this distinction, then enumerated all the arches now existing or known to have existed in Rome or Italy, in chronological order. Before proceeding to the description of the principal existing arches, he described a triumphal procession, especially taking Vopiscus's account of Aurelian's triumph. After disposing of the provincial honorary arches, and some general remarks on such as might be termed mere gateways, the paper contained an historical account of the arches of Drusus, Titus, Septimius Severus, and Constantine in order, and to the historical account were added various architectonic observations, and illustrations of the ornaments which still exist upon those arches. Mr. Burgess pointed out the decline of Art in the arch of Septimius Severus, and the perfection of it in that of Constantine, which he showed to have been an arch belonging to the best age of sculpture, and was adopted but not erected by Constantine. In the course of the dissertation Mr. Burgess paid a tribute of respect to the memory of the late Mr. Basevi, and mentioned the Fitzwilliam Museum, at Cambridge, as a fine example of genius soaring above the little expedient of loading with ornament that which was deficient in architectural result. Mr. Burgess took occasion to compare the pageantry of the Roman triumphs with the modest deportment of our commanders, and drew some parallel between the Indian victories and those of the Romans in Asia, and the paper was concluded with a reference to the influence of Christianity in moderating the proceedings of modern warfare.

The President announced that the Académie Royale des Sciences, des Lettres et des Beaux Arts de Belgique had expressed a desire to place itself in communication with the Institute; and likewise that the Accademia Olimpica, of Vicenza, had acknowledged the receipt of the report of Messrs. Poyuter and Donaldson, the honorary secretaries, on the collection of drawings by Palladio, in the possession of the Duke of Devonshire, and as a mark of their sense of the courtesy of the Institute on the occasion, had elected Messrs. Poynter and Donaldson, Members of that Academy.

The Honorary Medal, voted on the 17th of November last, to the Chevalier Beuth, as a testimonial of the sense entertained by the members of the Institute of the benefit conferred by him on the art during the period he held the important office under the Prussian Government, from which he has retired, was presented, with an appropriate address, to the Chevalier Hebeler, who had been requested by the Chevalier Beuth to receive it on his behalf.

The Prize Medals awarded on the 23rd of February, were presented by

Earl de Grey:—to Mr. Worthington; to Mr. S. J. Nicholl; and to Mr. J. F. Wadmore.

The President announced that the Queen had been graciously pleased to bestow a further mark of favour upon the Institute, by giving annually a gold medal for the promotion of the useful purposes of the Society, and that the regulations connected with this gratifying instance of Her Majesty's continued favour, would be forthwith determined and communicated at the earliest opportunity.

DECORATIVE ART SOCIETY.

Mr. E. Cooper exhibited a process for producing a volute by means of a natural form. He had selected a shell, the *Buccinum spiratum*, or *Syracuse whelk*, and affixed it to a board; a string with crayons attached was then wound along the spiral hollow of the shell, and this, in the course of its convolutions, delineated what he assumed to be the Greek volute. He compared the result, satisfactorily, with engravings, by Nicholson, from the Ionic capitals to the Temple on the Illissus and the Temple of Bacchus at Teos, and he also had detected an exact correspondence in size in Inwood's Erechtheion, plate 21, from the Temple of Victory on the Acropolis. Mr. Cooper then explained that, in an examination of an Ionic capital in the British Museum, he observed that the eye had been fitted with a stone *similar* to the other parts; and, further, that in another instance the eye had been lost out. The orifice thus exposed, he conjectured, had been necessarily made to receive an instrument for guiding the tools used in working mouldings on the face of the volute. Its diameter agreed very nearly with that of the lower part of his shell, and he presumed that a modified cast in metal from the shell would supply an instrument suited to such a purpose, and which, at any rate, offered an inexpensive and ready mode of striking scrolls for hand-rails, &c. Mr. Tapling tested the volute described by Mr. Cooper by a notation of eight radial intersections, and he contended that the scale of expansion was different from that of the Greek volute. His remarks were afterwards sustained by a comparative experiment upon a mbbing which Mr. Cooper had in his possession. It was also said, that the engravings referred to by Mr. Cooper were incorrect.

NOTES OF THE MONTH.

One of the entire floors of the new Houses of Parliament of the building facing the river, is to be completed forthwith for the numerous committees that are likely to be called into action by railway proceedings in the Houses of Parliament.

Mr. Ambrose Poynter, the indefatigable Hon. Sec. of the Royal Institute of British Architects and the architect of numerous ecclesiastical buildings, and Mr. John Shaw, architect, of Christ's Hospital, have been appointed, under the new act, official referees in place of Mr. Higgins, who some time since resigned the appointment. We feel assured these appointments will give great satisfaction to the profession.

We regret to announce the demise of Mr. Le-keux, justly celebrated for the accuracy and neatness of his engravings connected with architecture.

Lord Mahon has been appointed President of the Society of Antiquaries. It is time that this Society commenced a revolution in its proceedings; it ought to embrace all the intentions of the two rival Societies—the Archæological Institute and Association.

The Royal Academy has announced for its architectural prize, to be awarded on the 10th December next, a silver medal for the most accurately finished drawings of St. Peter's, Cornhill; the plan, elevation, and section to be drawn from actual measurement.

The progress of the new Houses of Parliament have been greatly delayed on account of Dr. Reid's system of warming and ventilation; serious disputes have arisen with Mr. Barry, the architect, who was obliged to take his stand against the enormous inconvenience Dr. Reid's works occasioned to the progress of the building. At length Government has taken the dispute in hand; in the House of Lords, Viscount Canning announced that three gentleman had been selected to enquire into the whole subject connected with both the warming and ventilation, and to advise Government thereon. The gentlemen to whom instructions have been addressed are Mr. Hardwick, so well known as the architect of the new dining hall and library at Lincoln's-inn; Professor Graham, the Professor of Chemistry at the University of London; and Mr. George Stephenson, the engineer, a gentleman who, apart from his general scientific reputation, has given much attention to the subject of ventilation.

The ancient temple of the Knights of Malta, at Laon, has been completely restored under the auspices of Government.

A statue of Sophocles is on its way from Athens to Paris, to be placed in the Louvre. It is said to be one of the most remarkable antique works of art.

At New York, the new Trinity Church, said to be one of the best examples of Gothic architecture in that city, is nearly finished. It has a tower and crocketed spire 300 feet high; and the windows are filled in with stained glass.

M. Blouet, architect to the Arc de l'Etoile (given in the Journal, vol. II., 1839), has been elected of succeed the Baltard professor at the School of Fine Arts, in Paris.

The restoration of the works at the Chateau of Blois, by M. Duban, is making great progress.

An electrophonic telegraph, the invention of Chevalier Laskott, has been presented by Professor Jacob to the Imperial Academy of Petersburgh. It is composed of a clavia of ten keys, ten bells of different sizes, and ten conducting wires, by which the letters of the alphabet, and words which they form, are expressed by sounds and harmonics.

On the Dublin and Kingstown Railway the consumption of coke per train per mile is 26¾lb., and the total cost of power and maintenance of way 10·7 pence.

Mr. Bidder, in his report on the recent gauge experiments (detailed in the Journal for February last, p. 49), gives the following results:—

	Narrow Gauge.			Broad Gauge.		
Date of experiment	Dec. 30.	Dec. 31.	Dec. 31.	Dec. 17.	Dec. 16.	Dec. 16.
Draft in tons	50	50	80	60	80	80
Distance travelled in miles	42	85	42	101½	100½	101½
Time in minutes and sec.	72 6	108 12	56 52	112 42	117 4	121 3
Water evaporated lb.	12215	19708	9900	22596	23489	24828
Ditto do. per mile lb.	291	232	235·7	282	233½	245
Ditto do. per hour lb.	10160	11150	10480	11696	12020	12309
Cubic feet per hour	162½	178	167	198	192½	196½
Coke consumed lb.	1381		1176			
Water evaporated per lb. of Coke lb.	9·8	9·6	8·8	7·8	7·19	7·12
Coke consumed per mile lb.	31·2	24	26·6	29·6	33·6	32·6
Pressure		71	60			
Engines		A		Ixion		
Surface of fire-box feet sq.		58		97		
Areas of blast pipes in circular inches		3364¼		372½		
Contents of cylinders do.		4725		4961		

The friction of air through tubes, Mr. Bidder observes, is tolerably well ascertained; it appears that, with a pressure of ·04 lb. per inch, the velocity of the air through the long tubes of the A engine used in the narrow gauge experiments was 16 miles per hour, and through the shorter tubes of the Ixion 18 miles per hour.

ARTESIAN WELLS IN CHINA.

It is about twenty years since the report of Artesian wells in that country has reached Europe, through the medium of the French missionaries. According to these statements, one single district of the Celestial Empire, equal in size to one of the provinces of France, contains more than 10,000 (?) Artesian wells, some of which attain the astonishing depth of 8 to 900 metres. These extraordinary soundings of the earth's surface are, it is said, made by very simple means, and for various purposes, of which one, certainly, is most extraordinary, and altogether peculiar to the Chinese. Some of them discharge a water greatly impregnated with common salt, others bring to the surface a bituminous oil, others in fine, seemingly by passing through coal measures in the state of ignition, exhale constantly combustible (hydrogen) gas. These are the so-called fire-wells of the missionaries, with which the Chinese procure the gas which they use for the evaporation of the salt brine of the adjacent wells.

The importance of these statements is easily conceived, not only in a *scientific* but also a *practical* point of view, as we might be able thereby to furnish our cities, at a nominal rate, with that vast quantity of gas we now consume, but the jealousy hitherto of the Chinese authorities prevents travellers pushing to that quarter. The French Academy of Sciences has, therefore, of late inspected with great interest the specimens of bitumen and brine which the director of the French missions in China has addressed to them. The only fact of importance elicited by the chemical analysis which these substances have been submitted to is the complete absence of iodine in the brine. M. Boussingault acted as reporter in this important transaction.

J. L——Y.

THE AURIFEROUS SAND OF THE RHINE.

Some observations on the utilising the hitherto hidden riches of this river have been laid before the French Institute, by M. Daubrée, Engineer of Mines at Strasburg. It has been calculated that the amount of gold contained in the sand of the above river amounts to 25,916 kilogrammes, of the value of 114 millions of francs. M. D. has made many experiments to determine how the particles of gold detached from the Alpine rocks are distributed in the alluvion (*atterissements*) of the banks of the Rhine.

The pebbles most usually searched after for gold are those which the river deposits at a short distance from the stratum, subjected to the abrasion of the waters. It is on the upper part of banks thus formed, in the midst of large pebbles, to a depth of not more than 15 centimetres, that gold is to be met with. Out of the *actual* bed of the river, gold is also to be met with in the ancient deposits of the river, which form a band of 4 to 6 kilometres broad. In the fine sand without pebbles, such as is deposited in the hollows of the bed, no gold is to be found, any more than in the alluvial soil (slime), which, nevertheless, is of Alpine origin. The sand which is usually searched after for gold contains generally from 13 to 16 hundred millionth parts; it is rare that this richness passes 7 ten millionths. The revolutions, therefore, which the Rhine occasions, at times, in the contents of its bed changes the amount of gold from 1 to 70. The particles of gold are always very small, 17 to 22 making only a kilogramme. Compared with the sand of rivers worked in Siberia and Chili for gold, the former are 5 times, the latter 10 times richer than those of the Rhine. The gold of the Rhine sand seems to be derived from the tertiary formation, and, in the first instance, from the schistous crystalline rocks of the Alps, as is the case with most other rivers which descend from these mountains.

J. L——Y.

STEAM NAVIGATION.

Three steam vessels of war, the *Sidon*, the *Odin*, and the *Termagant*, in course of construction at Deptford Dockyard, are on the eve of being launched. The Sidon steam frigate is constructed on a plan of Sir Charles Napier's, and appears a very fine looking vessel, very strongly put together. Although only two feet longer, and two feet broader than the Odin steam vessel building in the same yard, the Sidon is intended to carry 400 tons more coals than that vessel. She was placed on blocks on the 24th of June, 1845, and in exactly 10 months will be ready to enter her future element. All the parts of her machinery above water mark are to be constructed of malleable iron, and of great power to resist injury during actual warfare; and every beam across her decks has been secured with strong iron kneedbolts to the powerful timbers of her sides.—The Odin steam frigate was designed by Mr. Fincham, master-shipwright at Portsmouth Dockyard, and the whole of her frame is put together, and she will soon be ready for launching. She was placed on the blocks on the 19th of February, 1845.—The Termagant steam-frigate, constructing from a design by Mr. White, builder at Cowes, is a vessel of the same length as the Odin, designed by Mr. Fincham; but 3 feet 6 inches greater dimensions in her extreme breadth, and will have engines of 600 horse power.—The following are the dimensions of the three vessels:—

	The Sidon.		The Odin.		The Termagant.	
Length between perpendiculars	210 ft.	9 in.	208 ft.	0 in.	208 ft.	3 in.
Ditto of keel for tonnage ..	185	9¾	183	8¼	181	0
Breadth extreme	37	0	37	0	40	6
Ditto for tonnage	36	6	36	6	40	0
Ditto moulded	35	10	35	10	39	4
Depth in hold	27	0	24	2	25	9
Burden in tons	1,328		1,326		1,540	
Horse power	560		500		600	

Launch of Two Iron Steam Ships, at Liverpool.—The Diamond—This vessel was launched from the yard of Messrs. P. Cato and Co., south end of the Brunswick Dock, and the second of two fine iron steamers built by them for the City of Dublin Company, to run between Dublin and London. She is the sister-ship of "The Emerald," (and from the same moulds). She is to be propelled (in addition to sails) by the screw, with engines on the direct action principle. The model (as of the Emerald) was furnished by Mr. John Grantham, C.E., and is well adapted for the double object of considerable stowage and rapidity of propulsion. The vessel is lap jointed, or "clincher-built," in her upper-works, as well as below the water-line, a plan which, in vessels of her comparatively small burthen, is more expensive than the flush joint, but is not only stronger, but quite as pleasing to the eye, if the workmanship be equal to that in question. The Diamond is built in the most faithful manner in every point, and does equal credit to the spirited owners in the outlay, and to Mr. Cato and those under him.—The Antelope—her model, by Mr. Grantham, is fine, and, though sharp at the extremities, of such rotundity and swell in the body, without "a lump" in any part, that she promises to carry and to sail well. She is the property of Messrs. M'Tear and Co., who have spared no expense in her construction, and the builders, Messrs. Hodgson and Son, have done ample justice to her in every respect. This vessel will have, in addition to sails, auxiliary propelling steam-power by two engines of 50-horse each, turning a screw of 12 feet diameter, on the direct action principle, patented by Mr. Grantham. The engines are by Messrs. Fawcett, Preston, and Co. She is the first of an intended line of 8 vessels of the same class, to run between this port and Rio de Janeiro, and more intimately to connect this country and the Brazils in bonds of amity and commerce, the present passage, by sailing vessels alone, being generally long and tedious. The Antelope has a finely designed billet-head and appropriate decorations, executed by Mr. Robertson. The trail-boards, gilded on a white ground, represent, in relief, the antelope pursued by the tiger, and the foliated ornaments around are rich and chaste, giving the vessel a peculiarly light and "go-ahead" appearance. The quarter-galleries are of a corresponding design, and enriched with quivers, bows, and other emblems of the chase; and the stern carving also assimilates—the whole having a peculiarly new and elegant appearance. We learn that in place of drawing so much water as was expected, she drew two inches less than was calculated, thus showing a superior degree of buoyancy.—The following are the dimensions of the two vessels:—

	The Antelope.		The Diamond.	
Length over all	190 ft.	0 in.	.. 145 ft.	0 in.
„ of keel	168	0	.. ..	
„ between perpendiculars	175	0	.. ..	
Breadth of beam	26	4	.. 21	0
Depth of hold	17	0	.. 13	6
Burthen in tons ..	600		.. 300	
Diameter of screw	..	12	.. ..	
Horse power	100	..	.. 60	

Telegraphic Communication between France and England.—Amidst the many wonderful inventions of modern days, wherein the faculties of man have overcome difficulties apparently insurmountable, and made the very elements themselves subservient to his power and use, there are none more wonderful than that now about to be carried out by the establishment of sub-marine telegraphs, by which an instantaneous communication will be effected between the coasts of England and France. The British Government, by the Lords Commissioners of the Admiralty, and the French Government, by the Minister of the Interior, have granted permission to two gentlemen, the projectors of the sub-marine telegraph, to lay it down from coast to coast. The site selected is from Cape Grisnez, or from Cape Blancnez, on the French side, to the South Foreland, on the English coast. The soundings between these headlands are gradual, varying from seven fathoms near the shore on either side, to a maximum of 37 fathoms in mid-channel. The Lords of the Admiralty have also granted permission to the same gentlemen to lay down a sub-marine telegraph between Dublin and Holyhead, which is to be carried on from the latter place to Liverpool and London. The sub-marine telegraph across the English Channel will, however, be the one first laid down; the materials for this are already undergoing the process of insulation, and are in that state of forwardness which will enable the projectors to have them completed and placed in position, so that a telegraphic communication can be transmitted across the Channel about the first week in June. When this is completed, an electric telegraph will be established from the coast to Paris, and thence to Marseilles. This telegraph throughout France will be immediately under the direction of the French Government, as, according to the law of 1837, all telegraphic communications through that country are under the absolute control and superintendence of the Minister of the Interior. Upon the completion of the submarine telegraph across the English Channel, it is stated that a similar one, on a most gigantic scale, will be attempted to be formed, under the immediate sanction and patronage of the French Administration; this is no less than that of connecting the shores of Africa with those of Europe by the same instrumentality, thus opening a direct and lightning like communication between Marseilles and Algeria. It has been doubted by several scientific men whether this is practicable, and, indeed, whether even the project between the coasts of France and England can be accomplished; but it has been proved by experiments, the most satisfactory in their results, that not only can it be effected, but effected without any considerable difficulty.—'Globe.'

The "Lunar Corrector."—Invented by Captain Andrew Thompson, consists of an instrument, the principle of which depends upon the minute variation of small spherical triangles. It is formed by the third part of a circle of brass, having an index similar to a sextant, on which is set the apparent distance. The index bar and left limb are graduated, and furnished with moveable slides for performing what is termed "Laying off" the apparent altitudes; one of the slides being graduated also to a scale proportioned to the radius of the instrument, shows at the point of intersection, a number of minutes and seconds, which is the correction required; and then, by the help of a brief table, or by working a rule-of-three sum, the true distance is at once obtained. The great advantage of this instrument is its simplicity, and the little time—which, by the use of it, is required to work a lunar observation; in fact, the time required scarcely exceeds that required to find the latitude by a meridian altitude of the sun. At Messrs. Spencers, in the Minories, the invention may be seen.

Bricks.—Return of the duties paid upon bricks in the several excise collections in England from 1839 to 1845 inclusive. The total amount collected in 1839 was 459,664*l*.; and in 1845, 558,415*l*. The amount in 1839, in the London district, was 23,911*l*.; in the Manchester district, 34,793*l*.; and in the Rochester district, 24,173*l*. In 1845, in the London district, 31,267*l*.; the Manchester district, 44,290*l*.; and in the Rochester district, 44,644*l*. Including the metropolis there are 56 separate collections; in five of which, during the last year, the amount received was less than 500*l*.

LIST OF NEW PATENTS.

(From Messrs. Robertson's List.)

GRANTED IN ENGLAND FROM MARCH 31, 1846, TO APRIL 25, 1846.

Six Months allowed for Enrolment, unless otherwise expressed.

William Henry Moggridge, of 13, Old Burlington-street, Middlesex, dentist, for "certain improvements in the plates or pieces for the roofs and gums of the mouth, for attaching thereto artificial teeth."—Sealed March 31.

John Ainslie, of Alperton, Middlesex, brick and tile manufacturer, for "certain improvements in the arrangements for the manufacture of bricks, tiles, and other similar articles from clay and other plastic substances, and in the machinery or apparatus for the manufacture of bricks."—March 31.

William Spiby, of Carrington, Nottingham, engineer, for "improvements in the construction of furnaces used for heating water and other fluids."—April 1.

Harold Potter, of Darwen, Lancaster, paper manufacturer and stainer, for "improvements in printing or staining paper."—April 1.

Henry Crossley, of King William-street, London, engineer, for "certain improvements in the manufacture of sugar, and in the machinery and apparatus employed therein."—April 3.

Ferdinand Charles Warlick, of Deptford, Kent, gent., for "improvements in the manufacture of fuel."—April 7.

William Thomson, of Kilmarnock, North Britain, manufacturer and fur merchant, for "improvements in machinery for operating upon wool and other fibrous material, intended to be wrought into felted fabrics."—April 7.

George Lewis, of High Cross-street, Leicester, locksmith, for "improvements in the construction of shutters and blinds for windows and doors, and in the construction of doors."—April 7.

James Allingham, of Dublin, gent., and James William M'Ganley, clerk, of Dublin, aforesaid, for "certain improvements in steam engines."—April 7.

Joseph Hunt, of Brixton, Surrey, chemist, for "improvements in the manufacture of soda."—April 9.

Joseph Bunnett, of Deptford, engineer, for "certain improvements in water-closets, part of which improvements is applicable to other useful purposes."—April 15.

Peter Armand le Comte de Fontainemoreau, of New Broad-street, London, for "an improved mode of constructing certain parts of the harness of horses and other beasts of burden." A communication.—April 15.

Simeon Hyde, of the Strand, merchant, for "improvements in refrigirators."—April 15.

William Tutin Haycraft, of Greenwich, doctor of medicine, for "improvements in steam engines."—April 15.

Charles May, of Ipswich, Suffolk, civil engineer, for "improvements in machinery for punching, riveting, and shearing metal plates."—April 15.

Henry Mandeville Meade, of New York, America, gent., for "improvements in preparing food for animals when Indian corn is used." A communication.—April 15.

Elijah Galloway, of Buckingham-street, Strand, engineer, for "improvements in locomotive engines."—April 18.

Joseph Clinton Robertson, of Fleet-street, civil engineer, for "certain improvements in the manufacture of pins." A communication.—April 18.

John Gillett, of Brailes, of the firm of Ward, Colbourne, and Gillett, of Stratford on Avon, and Brailes, near Shipston on Stour, Warwick, agricultural implement makers, for "an improved machine or machines, for cutting, slicing, and otherwise dividing hay, straw, turnips, and other vegetable substances."—April 18.

Peter Bishop, of Birmingham, manufacturer, for "a certain improvement, or improvements, in the manufacture of bayonets."—April 21.

William Heward Bell, of Edmondsley, near Chester le Street, Durham, for "improvements in working coal in coal mines."—April 21.

Arthur Philip Perceval, of East Horsley, Surrey, clerk, for "improvements in communicating between places separated by water."—April 23.

William Ashby, of Croydon, Surrey, millwright, for "certain improvements in the manufacture of flour."—April 25.

George Philcox, of High-street, Southwark, watch-maker, for "improvements in the construction of chronometers and other time-keepers."—April 25.

CHURCH AT SACROW NEAR POTSDAM.

(*With Two Engravings, Plates VII. and VIII.*)

Of considerable merit in itself, the subject of our engravings this month acquires additional interest from its being, besides the representation of an actual building—one moreover of very recent date—a work of Persius's, the present king of Prussia's architect, who died last summer. Relative to the individual himself we are unable to add any particulars to our notice of his death at page 348 of our last volume; for besides that he is *distinguished* by Nagler by being omitted in his tremendously comprehensive 'Kunster-Lexicon'—comprehending everybody who is of no note at all,—he is not given in the 'Conversations-Lexicon der Gegenwart,' notwithstanding that several German architects of the present day are there spoken of. Still we now know something positively both as to what he executed and what he merely designed; and sketches showing examples by him of both kinds have rather exceeded than fallen at all short of our expectations, for, to say the truth, some remarks which we had met with led us to apprehend that his works partook too much of flimsy showiness, of fantastic *spielerei*—as it was termed—and of hurried sketchiness, without due consideration as to detail and finish;—a not uncommon fault among those who study composition and general effects, while, on the other hand, those who are meritoriously attentive to beauties of detail and execution are apt to be either very indifferent to, or else negligent of, original composition and the character derived from it.

The Church at Sacrow,—one of the numerous structures with which Persius embellished the environs at Potsdam, is both picturesque in itself, and placed most picturesquely—even romantically, immediately on the Havel, where that river expands into a lake, and just over against Prince Carl's Park. We have before us a general "*situations-plan*," exhibiting the whole environs of Sacrow, as far as the Heiliger See, the Marble Palace, and Potsdam in one direction (West), and the Pfauen-insel, and Griebnitz See, in the other (East); which, map as it is, is also a picture, calling up images of landscape scenery interspersed with sinuous lakes, and enlivened by architecture—palatial residences, villas, casinos, bridges, belvederes, and what tantalizes us by its name of the Maurische Tempel. To confine ourselves to the Church of Sacrow itself,—it is charmingly placed—put just as a painter would have it, and perhaps just as a pedantic precedent-monger would not, for the latter prefers the prosaic in architecture, and leaves all touches of poetry in it to artist-architects. Taken merely by itself, the Church would be more than ordinarily striking, not on account of situation and *position*, alone, but for regularity and consistency of design, kept up throughout, since so far from consisting chiefly of a show front, or making most show just at that end, it captivates from every point of view, by its singular completeness, and also by its originality, the external arcade being a happy innovation upon the basilica character, from which class of ancient ecclesiastical buildings, the style has been borrowed,—but also freely treated, with artistlike feeling, and with many tasteful modifications—albeit the precedent gentry here may shake their heads at them. The Church, however, is only one feature in an architectural group, even the campanile only one of its accessaries; and that tower, a graceful object in itself, contributes to variety in a very unusual degree, inasmuch as by standing detached, it comes differently into combination with the main building, according to the direction in which they are viewed together. Architectural ensemble is greatly promoted by the enclosed area in front, a paved fore-court surrounded by a low parapet wall, partly forming a terrace, above river. Independently of its effect in other respects, this enclosure, simple as it is in character, is of great value, because it plainly connects the campanile and church together. In our opinion, too, such well expressed demarcation of site is a propriety which, notwithstanding our precise and affected scrupulousness in some matters of ecclesiastical architecture, is frequently most strangely overlooked by us, for we have churches in country as well as towns, that seem to have fallen down *from* heaven, alighting by road-side or street-side just as chance might direct, without any sort of interval or intermediate space between the secular and the ecclesiastical. Both this fore-court and the external ambulatory around the church may look to us like innovations; yet the one and the other hold out hints to us well worth adopting; and the one and the other afford excellent situations for monuments,—the walls of the church, for instance, within the arcade, might in time be quite incrusted with marble in monumental tablets,—but unless they were allowed only under proper restrictions—such as would ensure general symmetry as to arrangement and size, and further, preserve some keeping as to style, therefore nothing at all like the flagrant *post mortem* advertisements of quacks and charlatans which disgrace the Kensal Green Cemetry, and render it at once disgusting, and ridiculous,—embellishment of the kind would be only disfigurement.

The church at Sacrow, begun in 1842, and completed in all but its interior decorations the following year, is of very economic materials, nearly the whole of the exterior, excepting the columns of the arcade, which are of stone, being only of brick, nevertheless very ornamental, every four courses of the general brickwork being relieved by two others of coloured bricks (as shown in fig. 4), and similar ones, with a figured pattern upon them, form a sort of frieze or string-course just beneath the principal cornice. The pavement within the arcade is also of bricks of various sizes, so skilfully though simply disposed as to produce considerable richness of effect. All the other details, including those of the two cornices (that of the body of the church, and that over the arcade), are carefully studied, and manifest much clever invention as well as good taste. These minutiæ and peculiarities are, however, lost in drawings on the scale of those herewith given; wherefore it becomes necessary to observe that the capitals (fig. 3, plate VIII.) of the columns are also of novel design—partaking of Grecianism in taste, though quite dissimilar from Grecian examples,—without the name of a new order being therefore arrogated, even thought of, for them.

The interior of the church is sparingly, but tastefully, decorated: the walls are wainscoted for about the height of seven feet, and above that, are coated in imitation of pale green marble, whereby, at the same time, that offensive raw blankness of surface is avoided, the fresco-painting in the large altar or chancel tribune (designed by Professor Begas, and representing Christ and the four Evangelists,) is made to tell more effectively. The ceiling shows the timbers of the roof, which are partly relieved by colours, while the intermediate spaces are filled in with stars on a cobalt blue ground. The pavement forms a sort of mosaic work of three colours (dark green, dark red, and black) on a general ground of a pale reddish hue. The metal-work for the glazing of the windows is of ornamental pattern, the effect of which is heightened by some intermixture of coloured and ground glass; and it should be, remarked, that if they do not exactly constitute what we should call a clerestory, there is only one tier of windows in the upper part of the walls.

Taken altogether, the church at Sacrow will, we think, recommend Persius as one who thought for himself, and could seize upon and turn to account such points as opportunity and subject afforded him. For our own part, we like it very much better than some of Schinkel's designs for churches on about the same scale, which, to say the truth, are in a somewhat cramped and affected style, owing, perhaps, in great measure, to his deviating too far from, and yet keeping too close to, Greek orthodoxy. The sketch of another church by Persius, since erected at Sans Souci, shows a somewhat similar design, exclusive of the external arcade; yet, though the church itself is so far plainer than that at Sacrow, it forms only a portion of a widely-extended architectural assemblage of various buildings (some of them erected), all so happily brought together as to form quite a Poussin-like scene. His talent for combination, and his predilection for extending architectural accessories for some distance around the main building, so as to blend natural and artificial objects into one captivating *tableau*, are forcibly manifested in a design by him for altering a villa residence, which he has distributed in the most piquant masses, prominent among which is a noble belvedere tower (circular in plan), so placed as to form not only an adjunct to, but an object from, the mansion. This design, it appears, was intended for some place in the neighbourhood of San-Souci; whether it has been carried into execution we know not; but if the environs of San-Souci an Potsdam have been embellished in other instances by Persius, in a manner and taste at all similar, they must present some very charming architectural pictures, and we heartily wish that some such artist as Allom would visit—with *quantum sat* of drawing paper—Berlin and Potsdam—or, we might say, discover and explore them, for they seem to be utterly unknown to English artists.

We regret that we are unable to specify with tolerable certainty any other of the various buildings on which Persius was employed for some years previous to his death, and which, whatever their faults may be, no doubt display considerable power of fancy and warmth of imagination. It has, indeed, been said of him that he sacrificed too liberally to picturesque effect, yet, in an artistic point of view, that ought hardly to be made a reproach, provided the effect aimed at was really secured. Here, we frequently sacrifice a great deal in the shape of cost, without getting any return at all for it in the shape of art.

Before we lay down our pen, we may as well mention that we have now ascertained the exact date of Persius's death, viz., July 12th, 1845.

ON THE EMPLOYMENT OF COLUMNS AND PEDIMENTS AS WINDOW MOULDINGS.

"Why, 'tis a cockle or a walnut shell,
A knack, a toy, a trick, a baby's cap;
Away with it! come, let me have a bigger."
Taming the Shrew.

In pursuing the consistent development of the subserviency of decoration to utility in classic architecture, we come to a division of our subject, concerning which it is almost impossible to obtain information from authentic examples. Respecting the forms of windows adopted by the founders of classic architecture, we have little to guide us except mere surmise, for of the domestic architecture of the Greeks we are entirely ignorant, and their temples, as far as we know, were lighted exclusively by the doorways or from the roof.

The modern forms of window-architraves are derived principally from the architecture of the period of Revival, as it is called, in the fifteenth century. And notwithstanding the multiplicity of forms of window-decorations which this style exhibits, we may observe one general characteristic which distinguishes them from those of Pointed architecture. In Pointed architecture the sides of the window-opening, in the thickness of the wall, are splayed—that is, the jambs, the lintel, and the sill are not at right angles to the face of the wall, but inclined obliquely. In the splay are sunk mouldings, frequently of the most elaborate description, which constitute the principal, and commonly the only, decoration of the window. The decorations on the face of the external wall are comparatively unpretending—generally no more than a simple label or hood-moulding. It is true that as the art advanced, and especially in the last period of it, the square-headed windows were decorated with elaborate spandrels, &c. But still, as a general rule sufficiently accurate for our purpose, we may state that Pointed windows are characterized by the decoration of their splayed surfaces.* In buildings of Classic architecture, on the contrary, the decorations of the windows are almost universally in the plane of the exterior wall, and the jambs and lintel are seldom moulded or cut obliquely in the thickness of the wall.

Among the commonest ornaments of Italian windows are miniature pediments stuck upon the exterior wall, and apparently supported by consoles or by miniature pillars. There are several reasons for concluding that this use of pediments and pillars is contrary to the principles of pure taste. The most obvious reasons are that these members, when so applied, are factitious appendages, that they unavoidably have the appearance of being *stuck on*, and that they are dwarf imitations of members which always are, or ought to be, used constructively.

But it may be answered, that *all* ornaments of windows are subject to this latter objection, that they are not used constructively; that this objection necessarily applies to all decorations on the surface of external walls—to the hood-mouldings, for instance, of Pointed windows. This consideration certainly lessens the weight of the original objection when applied to pillars and pediments; so that it is impossible to consider the use of small pillars for the decoration of windows quite so flagrant an offence against good taste as the hoisting of full-sized columns to the upper story of buildings. But still, the minor fault is not excused by the existence of a greater one. To window columns is attached that sense of the ludicrous which is inseparable from diminutive resemblances of things noble and dignified in themselves. A dwarf may be extremely well formed, but no one can attribute to him the idea of *dignity*. A little column may be a symmetrical object, but it can never be a dignified one, simply because of its resemblance to architectural members, which, in all pure architecture, are made of great strength and size in order that they may perform their natural office.

A huge isolated column used to support a monumental statue, and a pigmy column used to decorate a window, are the opposite extremes of absurdity. The one has the hideous coarseness and exaggerated features of a giant, the other the ludicrous littleness of a mannikin: they should be transported to the kingdoms of Brobdignag and Lilliput respectively.

The real objection to window-columns is—not so much that they are not used constructively (for in that respect they resemble all other window decorations) as that they are copies of members which *are* used constructively. Simple mouldings like those of the *lower* range of windows in the Reform Club House may be extremely graceful and appropriate to their purpose, but window-columns have too much the appearance of caricatures: the resemblance to their prototypes is, to use the mildest term, extremely unfortunate. If window-dressings be—and they *must* be—merely decorative, it is at least unnecessary that their forms should remind us of what are by far the principal members of classic architecture—the gable-end of the roof and the columns which sustain its weight.

Imagine for a moment the same anomaly existing in Pointed architecture. Let us conceive the effect of diminutive buttresses or miniature spires stuck against the sides of the windows! Can anything more ludicrous be imagined? And yet it is very difficult to see why this degradation of the most majestic architectural forms to base uses should be more absurd in one style than in another.

It may here possibly be replied, that in Pointed architecture, door-ways, and arches of entrance (which, in many respects, fall under the same rules as windows), are decorated with series of shafts or slender columns. But this objection is entirely obviated by the consideration that in these cases the columns are not merely decorative—that they have an office to perform, and perform it; being, in fact, the imposts of arches which sustain the superincumbent masonry.

But even supposing the above considerations insufficient, what we look upon as a fatal objection to window-columns and window-pediments is the utter barrenness of invention which they display. By the adoption of them, we seem to say to the first great founders of Classic architecture, "You have given us full and explicit information on every point of your system but one—the treatment of windows. It is the only point on which you have left us to our invention; but we are unable to invent or think for ourselves, and therefore we copy over again some of your forms, and apply them in absolute indifference of their original purpose." Now this humiliating confession is all the more unnecessary, because the possibility of designing window-mouldings which are not only intrinsically beautiful but perfectly appropriate has been proved by actual example. The palaces of Italy exhibit a great number of these designs, and we have already instanced the exceedingly graceful forms of the windows of the ground floor of the Reform Club House.

We said that it was difficult to see why the application of architectural members to ignominious purposes should be more ludicrous in Classic than in Pointed architecture. And yet, perhaps, it may be easy to find a reason for this inconsistency. It is that in the one case we are reconciled by long custom to absurdities, which in the other, either never existed or have long been lost sight of. We have, in our own country, pure and genuine specimens of the skill of the Mediæval architects; consequently, we are able to study these great masters in their own language, so to speak, without the intervention of translations. With respect to the Greek architects, however, we have not these advantages; we take our notions at second-hand from the Romans, or at third-hand from the Italians, and, consequently, frequently make gross blunders from mistaking the meaning of our teachers. Mediæval architecture has now, happily, begun to be studied philosophically—that is, we are not now content with mechanically copying the *forms* adopted by the Christian architects; we study the *principles* which produced those forms. Why should it not be so with Classic architecture also? Why should the most monstrous absurdities be perpetrated daily, because we will not leave the beaten path of mere imitation, and think for ourselves?

Sydney Smith defines wit to be the discovery of a real and accurate relation between subjects, which to ordinary understandings, do not appear connected. All the great emotions of the mind and the idea of utility are inimical to wit. "There are many mechanical contrivances," says he (Collected works, Vol. I.), "which excite sensations similar to wit, but the attention is absorbed by their utility." The converse of this idea is also true; for when things to which the idea of utility is attached are, by accidental circumstance, rendered useless, they seldom fail to excite ludicrous emotions. It is for this reason that a man who is so fat that he is incapacitated from active exertion is usually an object of ridicule, and that a man confined in the stocks gets more laughter than pity. An extremely small model of a steam-engine frequently elicits from the observer a smile, which if he were to analyse his own feelings, is caused by a mental comparison of the obvious inutility of the model with the gigantic power of a large engine. Again, there is a story of some one, who in speaking of the rapid advance of the mechanical arts in modern times, suggested (perhaps rather irreverently) that we should soon have "cast-iron parsons." The absurdity of the notion evidently arises from the consideration that however much the machine might resemble the minister in outward form, there would be no hope of rendering it capable of performing the ministerial functions. Many other instances might be adduced in which the in-

* We are here, of course, speaking of ancient Pointed architecture. In some of the starved modern specimens the walls are so thin, that they do not admit of any splay.

capacity of things for the purposes which their forms suggest renders them absurd; the application of this theory to the subject of the present paper will not be very difficult.

Whatever is opposed to the principles of common sense must be opposed to the principles of good taste; and if architects have determined that they will not recognise this axiom, they will find out sooner or later that the *people*, at least, have done so. We have endeavoured on a former occasion to show why Pointed architecture is gradually subverting the Classic. Every day adds to the strength of our conviction that this tendency can only be resisted by studying Grecian architecture in the same spirit as Pointed architecture—that is, by investigating its genius and spirit. The greatest injury which it has received has been inflicted by injudicious admirers, for they have endeavoured to incorporate with it forms and ideas which can never amalgamate with it, because repugnant to its very nature. If it be not purged of these inconsistencies we may be quite certain that it will soon altogether fall into disuse. The taste of the people will pronounce for mediæval architecture, not on the ground of its abstract superiority, but because it is more philosophically studied and practised,—and unless architects will *lead* the popular taste, they will certainly be compelled to follow it.

Not that we wish to advocate the exclusive adoption of pure Classic architecture—this pure classicality is generally nothing better than insipid imitation—but what we contend against is, the affectation of classicality where there is no chance of its being successfully realised. Surely it is better to erect a building without columns at all, than to stick columns on the surfaces of the walls, here, there, and everywhere, and to jumble together columns of all sizes (and belonging to three or four different styles) in the same edifice. To look at some modern edifices, one would think that the architect had ordered his columns at so much a dozen, and that it was quite an after-thought where he should put them.

This indiscriminate predilection for columns and pediments (and the pigmy resemblances of them) is in the vilest taste. Is it quite impossible that a building can be beautiful without these appendages? On the contrary, we are not certain whether columns and pediments might not be entirely banished from domestic architecture with advantage. If *stuck on* to the front of a house, they are mere caricatures; if used according to their original and proper purpose, they generally obscure the light of the building and diminish its convenience.

With respect, however, to the more immediate subject of this paper—the form of windows—there are one or two things besides the bits of columns and pediments, which might conveniently be suffered to go out of fashion. There is, for instance, a poor contrivance for breaking the continuity of surfaces by bevilling the edges of the stone; it is, at the best, a wretched expedient. The architect has not skill enough to group his shadows in masses, and, therefore, to render the flatness of the unbroken surfaces somewhat less intolerable, he gives the masonry the appearance of being badly jointed. Cognate to this flimsy artifice is that of scoring in the surfaces of the stone deep irregular channels which give it the appearance of being worm-eaten. This kind of masonry receives the gentle appellation of "rustic masonry,"—we should have thought "tattooed masonry" a more appropriate term. Fancy the Parthenon thus gashed and cicatrised!

Another practice in the construction of windows is the placing them so that the architraves intrude upon the frieze of an order, the continuity of which is broken to make way for the intruders. This practice is so evidently indefensible that it is not necessary to waste argument upon it. The fault is happily not very prevalent, but if the reader require an instance, we will refer him to the cathedral church of St. Paul.

The last solecism we have here to notice, is the construction of sham-windows (and also of sham-doors, for most of the rules respecting windows are applicable to doors). These, like other shams and pretences, generally reveal their own dishonesty. The architect who makes use of these expedients reflects far more severely on himself than the strictest critic could, for he confesses that he has managed his design so badly that, for the sake of uniformity and symmetry, he ought to make more windows than the purpose of the building requires, and that he has no better way of getting over the difficulty than by building sham windows in places where it is either unnecessary or absolutely impossible to construct real ones.

With respect to these and all other artifices and make-beliefs, we have one safe and certain rule to guide us—architecture is not a system of artifices. Its claim to elevated rank among the fine arts rests on much higher and nobler principles than those of trick and show. But there is now, unhappily, in all the fine arts a fashion for imitation, which is diametrically opposed to true artistic feeling. In painting, we have minute resemblances of leaves, fruit, or the pattern of silk and embroidery. In sculpture, sublimity of general expression is thought less important than accuracy in chiselling each particular hair, vein, or wrinkle of the skin. In music, we have clattering railway overtures, crashes in the base to represent thunder, and runs in the treble to imitate the nightingale. And in architecture, we must have stone look like lace, and iron like stone; we consider it imperatively necessary that every material which we use should look like something else than what it really is—above all we prefer the foppery of sticking on a few bits of finery here and there to the harmony of composition, the due disposition of light and shadow, the adaptation of every member to its appropriate office, and that general dignity which results rather from the conscious possession of beauty than the ostentatious display of it.

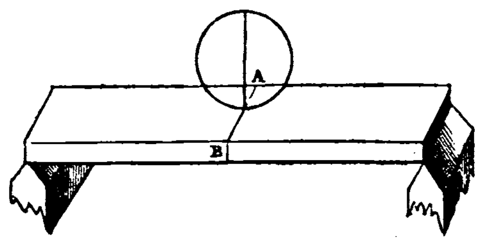
A NEW THEORY OF THE STRENGTH AND STRESS OF MATERIALS.

By Oliver Byrne, Professor of Mathematics.

I do not intend to occupy much space or time in dilating on the importance of my subject, or in giving a history of its rise and progress, or in making apologies when I differ from my predecessors, however instructive, entertaining, or judicious an opposite procedure may be; but when I do differ, I will give my reasons for doing so without a circumlocutory apology.

Theory tells us that if a uniform bar—no matter what the figure of the cross section may be, or what substance it may be composed of—be suspended by one extremity, and loaded at the other till it is on the point of being torn asunder, the weight and the corresponding transverse sectional area are proportional. The bars or rods compared requiring only uniformity and equality of texture, we may lay down a general law, *the lateral resistances* (in the direction of a perpendicular to the transverse sections) *are in proportion to the areas of these transverse sections*. This law is very evident, for if a bar or rod were conceived to be longitudinally divided into any number of equal strips, no reason could be assigned why one of these strips should support a greater portion of the weight than any of the others, so that each would support an equal part of the weight, in the same manner as an assemblage of equal parallel ropes divide the weight of an appended body equally among them. Experiments on lateral strains prove these deductions to be correct, and it affords an instance in which theory and practice may be said to coincide. The contrary is the case when the beam or bar is supported in a horizontal position, for then, the law of resistance, opposing fracture by an incumbent weight or force, is more difficult to establish, because we do not so readily see how the resisting forces exert themselves. Unlike lateral strains, the discrepancy existing between the results given by theory and by experiments is very great indeed; so much so, that very little can be relied on the theoretical results that are beyond the range of experiments. Indeed, with experiments of a range sufficiently extensive, no very great mistake can be made, however loose and uncertain the theory may be; but when we require a step far beyond our experiments, such as the determination of the best form and dimensions for a tubular bridge like that proposed by Mr. Stephenson, then the want of a theory, supported by experiment is a very great requirement.

Fig. 1.

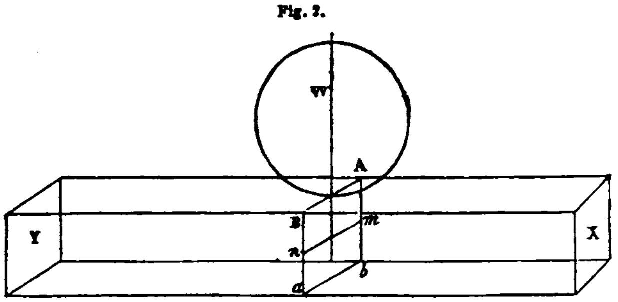


Galileo was of opinion that if a beam were supported at its extremities, as in fig. 1, and loaded by a weight at the middle, that all the fibres or filaments would exert equal resistances to prevent fracture, and that when these were overcome the whole would tend to turn about that boundary A B, in contact with the weight.

As this view of the subject supposes all the fibres to exert equal resistances, and in the direction of their lengths, these resistances will be so many equal and parallel forces and may be considered as acting together in the centre of gravity of the section, so that denoting the resistance of a single fibre by f, and supposing the section to be a rectangle of breadth b, and height h, then will $f\,b\,h$ express the sum of the resistances, and as this acts at the centre of gravity of the section, which is at the distance of $\frac{1}{2}h$ from the line A B, its moment to turn about A B will be $f\,b\,h \times \frac{h}{2} = \frac{f\,b\,h^2}{2}$.

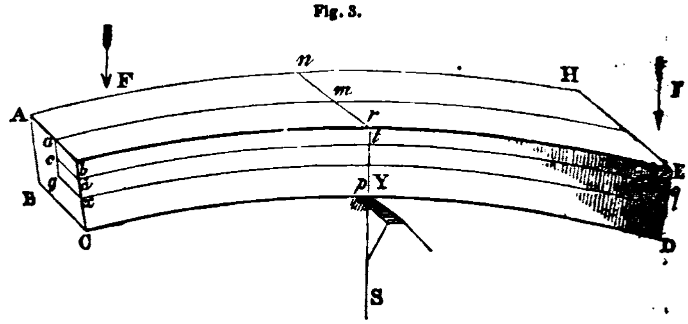
Leibnitz gave another hypothesis, which agreed with that of Galileo with respect to the position of the axis about which the segments would turn. But Leibnitz supposed the filaments or fibres to exert forces proportional to their distances from the axis; so that the middle fibre, according to the theory of Leibnitz, exerted but half the force of the extreme fibre. Calling the force of the extreme fibre f, the sum of the forces would be $\frac{f\,b\,h}{2}$; and since the centre of such a system of parallel forces is at the distance of $\frac{2h}{3}$ from the axis about which the whole is supposed to turn, hence the moment to turn will be expressed by $\frac{f\,b\,h}{2} \times \frac{2h}{3} = \frac{f\,b\,h^2}{3}$. It is easily seen, that, as far as regards the comparative strength of rectangular beams of the same material, or of similar beams whose transverse sections are rectangular, it is no matter which of these hypotheses be adopted, for both point out the law of resistance to be as the breadth multiplied by the square of the height; we shall in future use the term height or depth for the dimension in the direction of the pressure.

Fig. 2.



Galileo and Leibnitz supposed that the segments of a beam X Y, fractured by a weight W, turned about the line A B where the fracture terminates. But James Bernoulli, Mariotte, and others, were of opinion that the segments had a tendency to turn about a line, as $n\,m$, entirely within the section; the fibres on that side of the line where the fracture begins are extended, and those on the other side compressed. If the beam X Y, resting on two props at X and Y, be fractured by the weight W and $m\,n$, the line inside of the section A B $a\,b$, about which the segments of the beam have a tendency to turn, then the fibres or filaments in the space $n\,m\,b\,a$ are supposed to be extended, and those in the space B A $m\,n$ compressed. The imaginary line $m\,n$, which divides the section A B $a\,b$ into two parts—the area of compression and the area of tension—is called the neutral axis. Mr. P. Barlow laboured much to find out the true position of this neutral axis in different sorts of timber. The result of his labours and experiments may be summed up in the following words, the truth of which is very questionable:—"The centre of tension and the centre of compression each coincide with the centre of gravity of its respective area (?) and the neutral line which divides the two is so situated, that the area of tension into the distance of its centre of gravity from the neutral axis is to the area of compression into the distance of its centre of gravity from the same line, in a constant ratio for each distinct species of wood, but approximating in all towards the ratio of 3 to 1." (?) It would take up too much space to dwell on the absurd conclusions of Mr. Barlow; there are one or two things which require but little consideration to detect, first, the neutral fibres do not arrange themselves in a right line in all forms of beams, indeed, if such a line did exist, it would be a curve governed by the external form of the beam and the force applied. In the second place, the centre of gravity cannot agree in all cases with the centres of the forces of the filaments of the compressed and extended areas, and any man at first sight might suppose that the areas of compression and tension would bear a constant ratio to each other in each distinct species of wood. In the third place, I defy experiment either to confirm or contradict these conclusions of Mr. Barlow, for they have nothing whatever to do with the strength of beams. He merely says, find where MY LINE is by experiment, and I will give you something like the result of experiment from a line so determined. Let x Y Z be a portion of a beam in the locality of fracture, caused by the forces F F acting in the directions of the arrows. The same process of reasoning which points out a neutral axis in the whole A H D C, will point out a neutral axis in any portion of the body $g\,a\,b\,x\,t\,g$, no matter where it be situated; in fact, every fibre may be said to be compressed on one side and extended at the other, while the whole or each is bent round a common centre, as S, entirely outside the body. Then S Y is the radius of curvature of the arc C P D at the point p.

Fig. 3.



Now let us take $g\,c\,d\,x\,t\,y\,q$ Z, any portion of the beam, it is evident that the filaments in the upper part near to $d\,t\,q$ are expanded, and those near to x Y Z are compressed; according to this reasoning there is a set of fibres between $d\,t\,q$ and x Y Z which are neither compressed nor expanded; hence each portion of the beam is entitled to a neutral axis, which is relatively correct, but each neutral axis is itself bent round a centre in r S.

It is stated by Tredgold ("Practical Essay on the Strength of Cast Iron," page 53),—"When a rectangular beam is supported at the ends, and loaded in any manner between the supports, it may be observed that the side against which the force acts is always compressed, and that the opposite side is always extended; while at the middle of the depth there is a part which is neither extended nor compressed; or, in other words, it is not strained at all.

"Any one who chooses to make experiments may satisfy himself that this is a correct statement of the fact, in any material whatever, whether it be hard and brittle, as cast iron, zinc, or glass; or tough and ductile, as wrought iron and soft steel; or flexible, as wood and caoutchouc; or soft and ductile, as lead and tin. In very flexible bodies it may be observed by drawing fine parallel lines across the side of the bar before the force is applied; when the piece is strained, the lines become inclined, retaining their original distance apart only at the neutral axis." Now this fallacious statement (first made by M. Mariotte, which Mr. Barlow and a host of others down to Mr. Mosely have endeavoured to support by experiments, conjectures, and assertions,) may be exposed in the following descriptive manner, and afterwards by a mathematical investigation. Suppose X Y, V W, and Z T to

Fig. 4.

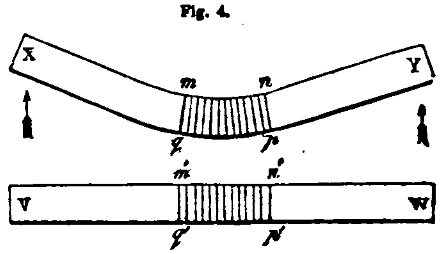


Fig. 5.

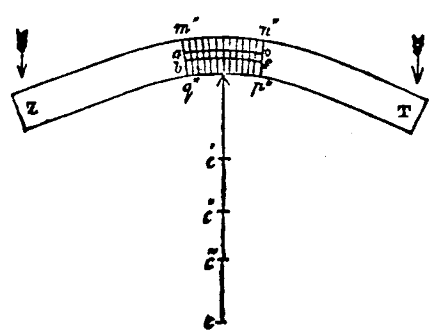

Fig. 6.

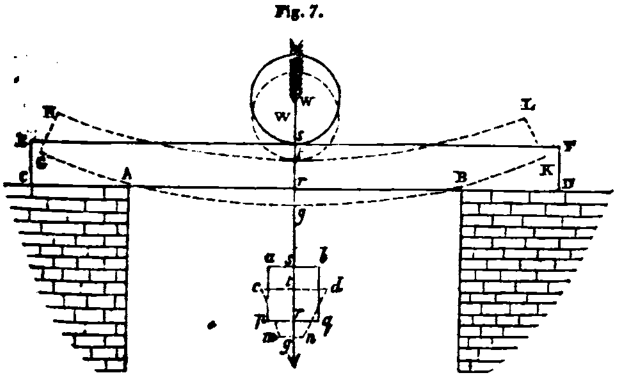
be the same beam under different circumstances. If a beam Z T be strained, with parallel lines drawn as above directed, at $m'' n'' p'' q''$, the very fact, that the line $b\,s$ being bent, shows that its particles are not in a state of quiescence, although it may be the same length as $m'\,n'$, or that one of the subdivisions of $b\,s$ is equal to one of those in $m'n'$, the position of the beam before it is bent; as Z T becomes more and more bent, the divisions will open in the upper regions near $m''\,n''$, and more contracted towards the lower near $q''\,p''$, so that the position of the neutral axis must shift towards the lower part of the beam from the top, unless the curves $m''\,n''$ and $p''\,q''$ be arcs of concentric circles, then the arc $s\,o$ in the centre will always be equal to $m'\,n'$. But it is not evident that the particles in the arc $s\,o$ or $b\,s$ are not strained at all, because either of them happen to be of the same length as $m\,n$, $m'\,n'$, or $m''\,n''$, which were all equal before the forces were applied

The conclusion we come to here is, that the whole turns round an axis, sometimes outside of the body and sometimes inside, according to the position of the centre of the circle of curvature of the curve where the greatest strain is applied. Let c' be the centre of the circle of curvature of the point in the centre of the arc $q''\,p''$, then that arc is supposed to be strained round c' as an axis. Let c'', c''', and C be respectively the centres of the circles of curvature for the points in the middles of the arcs $b\,s$, $s\,o$, $m''\,n''$; then the arc $m''\,n''$ is supposed to be bent round the centre C; $s\,o$, round c'''; and $b\,s$ round c''. When the filaments that are the most expanded—that is, those near $m''\,n''$ in Z T, and near, $q\,p$ in X Y,—become flatted at the centre, between m'', n'', or between $q\,p$, which is generally the case before fracture ensues, then the centres of the circles of curvature at these centre points, after changing from C to c''' to c'', &c., as the beam Z T becomes more bent, now returns in a contrary direction, c, c', c''', &c.; and when the fibres in $m''\,n''$ become straight, the radius of curvature becomes infinite, as in the case of the beam V W at rest, in which the particles or fibres at $m''\,n''$ are supposed to be straight.

We shall next consider the nature of the forces exerted by the filaments at different points of the cross section, in the region where fracture would ensue, when the strain exceeds the elastic limit of the body.

The beams or bars, the nature of the cross sections of which we are investigating, are supposed to be supported at the ends and loaded in the middle. In small beams, the change in the particles that we are about to describe is not perceptible; yet it will be found very considerable in large girders, such as the tubular bridge about to be constructed by Mr. Stephenson, or in small girders of a flexible nature.

Fig. 7.



The figure used in elucidating this matter is distorted, in order that the change under consideration, near the centre of the beam, may be more apparent. A very simple mode of illustrating what we shall describe relative to the molecular action of the particles in a cross section, near the centre of the beam, may be obtained by taking a rectangular piece of caoutchouc, whose cross section would be represented by $a\,b\,q\,p$; but, it is to be understood, that in point of structure we do not compare caoutchouc or india rubber with iron, brass, or wood;—but, merely to show the manner in which the particles in the cross sections of bodies, under the circumstances we have just described, endeavour to exert themselves. Let E C D F be the position of a beam before the weight W is applied,—H G A B K L its position after; the cross sections in the two positions will be represented by the figures $a\,b\,q\,p$ and $c\,d\,n\,m$. The action of the weight or force W compels the point s to move to t, and the point r to move to g, and has a tendency to lengthen the whole beam; while at the same time, the filaments in the upper part of the beam, near the middle, become compressed in the direction of the length A B, and extended in the direction of the breadth $a\,b$; that is, the breadth $a\,b$, in one position, is represented by $c\,d$ in the other. But the fibres in the lower part near r, in changing from r to g, become expanded in the direction of the length A B, and contracted in the direction of the breadth $p\,q$, so that $p\,q$ in the cross section becomes $m\,n$. From the rigidity of materials, this change may not have place, or may not be perceptible; but, in all cases, a force acting in the direction of the arrow will have the tendency to change the cross section $a\,b\,q\,p$ into one like $c\,d\,m\,n$, which if it be not able ultimately to effect, fracture must ensue.

As we have before observed, what we have just described will become clear by bending a rectangular piece of india-rubber. If the section of the rod or beam be circular, as Z, the change will differ materially from the one already described, for the circle will become, or endeavour to become, a figure like an oval. The change in the molecular particles in the cross section will arrange themselves differently, according to the external forms of the beams and the positions in which they are placed: something like the change of form in triangular beams are given in the figures X and Y. When the strain is about to exceed the limit of the

Fig. 8.

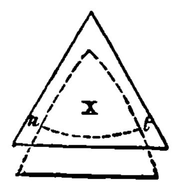


Fig. 9.

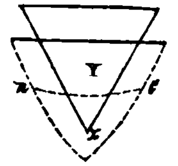
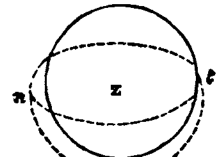
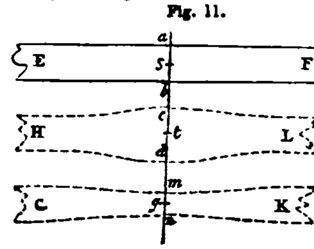


10.



elastic power of the material, the fibres which are in a state of quiescence, compared with those in the extreme upper and lower regions of the beam, will arrange themselves in a curve resembling $n\,t$ in the figures X, Y, and Z, the equation to which will be given hereafter. The behaviour of the force and filaments here stated are in themselves sufficiently simple and explicit, but, in order that none of our readers may enter upon the mathematical investigation of this important subject with incorrect notions respecting the different circumstances under which the beam may be placed, we have thought it expedient to add the following expositions and illustrations:—

Fig. 11.



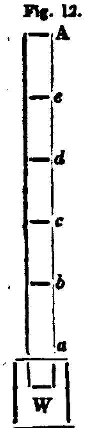
Let E s F be the upper or lower surface of the beam before the weight W is applied; H t L will represent the upper, and G g K the lower, after its application. The same parts are marked with the same letters as the figure preceding, for these surfaces are supposed to have reference to that figure. If the particles at $a\,s\,b$ in the bending process were such that they would merely become more dense, then the breadth at $a\,s\,b$ would not be changed; but it is not the case, for the harder parts of the material merely obtrude themselves into the softer, and partly become compressed and partly swell the breadth of the beam near these parts, as at $c\,t\,d$ in the upper section H t L. But in the lower surface G g K, or near it, the pariicles at $m\,g\,n$ become separated, and the breadth becomes contracted from $a\,b$, which is equal to $p\,q$ to $m\,n$.

We shall in the next place proceed to the mathematical investigation. Let W be the weight in pounds that would be borne by a beam of wood, iron, or any other material, whose cross section is an inch square, when the strain is as great as it will bear without destroying the elastic force of the body, and the direction of the force coincident with the length or axis of the bar; and let W′ be any other weight to be supported under the same circumstances. Suppose the cross section of the piece to support it to be a rectangle, whose breadth $= x$ and thickness $= y$ inches.

Then $W : W' :: 1 : xy$; or, $\frac{W'}{W} = xy$.

Strictly speaking, the lengths must be the same, or W and W′ must include the weights of their respective beams. This proportion has place from the well-known principle—abundantly proved by experiments—that "the strength of a bar or rod to resist a given strain, when drawn in the direction of its length, is directly proportional to the area of its cross section; while its elastic power remains perfect, and the direction of the force coincides with the axis."

Fig. 12.



Let d be the quantity a bar of iron, or other material, an inch square, and a foot in length, represented by $a\,b$, would be extended by the force of the weight W in pounds, which, as in the last, is supposed to be the greatest, it would bear without destroying its elastic force; and let L be the length of any other portion of the same rod in feet.

Then $1 : L :: d : L\,d =$ the extension of the rod, whose length is L. This is evident, for if we suppose the weight W to be attached at a, and to stretch $a\,b$ a quantity d it will stretch $a\,c$, $2\,d$; $a\,d$, $3\,d$; &c., because W, after stretching $a\,b$, will apply the same force to $b\,c$, and, strictly speaking, a little more, for it will have an additional weight in the length $a\,b$, a foot of the material; the same reasoning will hold with respect to any other foot, as eA for the weight W, and the weight of 4 feet of the material may be supposed to be applied at e, and act in expounding eA, but the weight of the rod is so small, that it may be neglected in moderate lengths. Strictly speaking, then W, the ultimate force must involve the weight of the bar to which it is applied. The weight W would ultimately be reduced to zero, for the bar would only be able to support its own weight without destroying its elastic force.—Example: cast iron will bear, without permanent alteration, 15,300 lb. upon a square inch; consequently, the length of a rod of cast iron that would be just able to support itself without permanent alteration would be 4,896 feet; a cubic foot of cast iron weighs 450 lb., no matter what the cross sectional area may be. Again, suppose W′ to be any other weight less than W,—

$W : W' :: d : \frac{W'd}{W} =$ the extension produced by the weight W′, supposing the length to be one foot, and the cross section an inch square; and also that the extension of a bar or rod by a force acting in the direction of its length, is proportional to the straining force; the area of the cross section remaining the same, and the strain not to exceed the elastic power of the beam, bar, or rod.

The extension for any length L, by the weight W′, $= \frac{L\,W'\,d}{W}$; for, $1 : L :: \frac{W'd}{W} \therefore \frac{L\,W'\,d}{W}$.

W′ is supposed to involve the weight of the bar, as well as W.

Let it be required to the elongation E of a bar suspended vertically, and sustaining a given strain or weight W, in the direction of its length equal L feet, the influence of its own weight being taken into account, the sectional area A square inches. Without destroying the elasticity, or surpassing the elastic limit, suppose ϵ to be the length that w pounds will elongate a bar weighing p pounds, one foot long and one square inch sectional area.

Suppose the last foot of a bar L feet long to be suspended to the second last, the effect of the last to elongate the second last will be found by the following proportion:—$w : p :: \epsilon : \frac{p\,\epsilon}{w} =$ the elongation of the second foot.

Suppose these two feet to be attached to the third foot, we have $w : 2p :: \epsilon : \frac{2\,p\,\epsilon}{w} =$ elongation of the third foot; $w : 3p :: \epsilon : \frac{3\,p\,\epsilon}{w} =$ elongation of the fourth foot; therefore the sum of the following series will give the whole elongation, the length of the bar L representing the number of terms, we have $\frac{p\,\epsilon}{w}\left\{1+2+3+4+\ldots.\ L-1\right\}\times\frac{L}{2}=\frac{L^2 p\,\epsilon}{2\,w}$. Or the elongation may be determined thus:—Let x be the length in feet measured from the lower extremity, then $w : p\,x :: \epsilon : \frac{\epsilon\,p\,x}{w} =$ the elongation of a foot in length from the strain of the weight $p\,x$. And let $d\,x$, as writers on the Calculus say, be the length which is next to nothing. $\therefore \frac{\text{foot}}{1} : \frac{\text{feet}}{d\,x} :: \frac{\epsilon\,p\,x}{w} : \frac{\epsilon\,p}{w}\,x\,d\,x =$ the elongation of the length which was supposed to be next to nothing. Integrating between the limits $x = o$ and $x = L$; that is, $\int_o^L \frac{\epsilon\,p}{w}\,x\,d\,x = 2\,w\,\frac{\epsilon\,p}{w}\,L^2$. So that a bar 1 inch square and L feet long will be elongated by its own weight $\frac{p}{2\,w}\times L^2\,\epsilon$; indeed, let the sectional area be what it may, the bar will be elongated by its own weight the same length, because the body is uniform, and each inch of sectional area is circumstanced in the same manner.

The number of pounds on each square inch of cross section $= \frac{W}{A}$, together with the weight of the bar up to that section. Then just at the point where the beam is suspended, there will be $\frac{W}{A} + p\,L$ pounds on the square inch, which must not exceed w, the elastic limit in pounds for each square inch of section. $w : \frac{W}{A} :: \epsilon : \frac{W\,\epsilon}{A\,w} =$ the elongation of each foot in length by the weight $\frac{W}{A}$ on the square inch; but as each square inch is strained by the same weight, each foot of the bar will be increased by the same length. $\therefore \frac{W\,\epsilon}{A\,w}\,L =$ the elongation of the length L, by the weight W. And hence, $\frac{W\,\epsilon}{A\,w}\,L+\frac{p\,\epsilon}{2\,w}\,L^2 = L\,\frac{\epsilon}{w}\left\{\frac{W}{A}+\frac{p}{2}\,L\right\} =$ E, the elongation by the weight W and L A p the weight of the bar.

We shall next explain certain numbers introduced by writers on this subject, and called by them *moduli*. There is the *modulus* of elasticity, the *modulus* of resilience, the *modulus* of fragility, and the *modulus* of rupture.

The *modulus of elasticity* is the strain in pounds which would be required to extend a bar, one foot long and one square inch sectional area, to double its length without altering its sectional area; or it is the trust in pounds that would compress the same unit bar into half its length, that is, till the foot becomes 6 inches, the sectional area remaining, as before, one square inch. We never could see the real use of introducing these imaginary numbers, unless for the purpose of mystifying the subject or to make it assume a very scientific appearance.

It would be a stretch of the imagination to suppose a brick to be pulled till it would become the length of two bricks. He must be a very clever man indeed who determined the modulus of elasticity of pipeclay. Mere book-makers like Hall and Moseley, of King's College, cannot be offended; but men like Barlow and Hodgkinson, who have lost their time experimenting to find them, may be a little indignant to find their favourite numbers spoken so lightly of.

Let us suppose, for argument sake, that Tredgold is right with respect to the modulus of malleable iron; he found the modulus of elasticity to be 24,920,000 lb., or 7,550,000 feet of the same matter; sectional area one square inch. Those who have made experiments will give but little credit to one who finds him wrong. Tredgold found that 17,800 lb. on a square inch of good English iron would cause no permanent alteration, and would extend a foot or any other length, not taking into account the weight of the bar, the $\frac{1}{1400}$ part of its length. $\frac{1}{1400}$ in this case would be ϵ, $17800 = w$, and $p = \frac{475}{144}$, for a cubic foot of malleable iron weighs 475 lb. nearly. Now it is evident, if the elastic limit of malleable iron were such as to allow it, and that the elongation was in direct proportion to its strain, that it would require 1400 times 17,800 lb. to extend this foot of iron till it becomes two feet long, or, which is the same thing, till it becomes a foot elongated. Now 1,400 times 17,800 = 24,920,000 lb., or, $17{,}800 \div \frac{1}{1400} = 24{,}920{,}000 = \frac{w}{\epsilon}$; this, to make the matter assume a learned appearance, or rather, a more college appearance, we shall represent by M_e; the modulus of elasticity and its reciprocal $\frac{\epsilon}{w}$ by $\frac{1}{M_e}$; so that $E = L\,\frac{\epsilon}{w}\left\{\frac{W}{A}+\frac{p}{2}\,L\right\}$ may be written $E = \frac{L}{M_e}\left\{\frac{W}{A}+\frac{p}{2}\,L\right\}$. A bar of malleable iron, one square inch of sectional area and 7,550,000 feet—nearly 1,430 miles long = 24,920,000 lb; from which circumstance 7,550,000 feet is called the modulus in feet; $24{,}920{,}000 \div \frac{475}{144} = 7{,}550{,}000$. That is, $\frac{w}{\epsilon} \div p = \frac{w}{p\,\epsilon} = M_e \div p$; in this modulus Hodgkinson differs 400 miles of iron from Tredgold, and Barlow about 250 miles of iron from Hodgkinson. So much for the modulus of elasticity.

The elongation of a bar suspended vertically, and sustaining a strain of W lb.—the influence of its own weight not being taken into account—was found to be $\frac{\epsilon}{w}\cdot\frac{W\,L}{A}$, which we shall call l:—

$\therefore l = \frac{W\,L}{M_e\,A}$ by substituting for $\frac{\epsilon}{w}$ its value $\frac{1}{M_e}$. Before we explain what is meant by the *modulus* of resilience or fragility, it is necessary to say what is meant by a unit of work. A pound weight raised vertically one foot is a unit of work done. A spring that lifts 1000 pounds $\frac{1}{1000}$ part of a foot does a unit of work. It is evident, that to elongate a bar an additional length l, the weight necessary to keep it elongated needs not be applied from the commencement of the process of elongating; for half l would be produced by half the weight, and one-third of l by one-third the weight, and so on. It is evident that $W\,l$ would be too much, for the weight W would not be actually employed in the business of elongation in moving from o to l.

Let L be the length of the bar before the weight W is applied; A, the area of its cross section; as before, $l =$ elongation consequent on W. And let x be any elongation between o and l. The weight necessary to keep L stretched to $L + x$ will be $\frac{x}{l} \times W$; this weight may be said to be fully employed while it passes through dx at the very extremity of $L + x$. $\therefore \frac{W}{l}\,x\,dx$ expresses the work done; $\therefore \frac{W}{l}\int_o^l x\,dx = \frac{W\,l^2}{2\,l} = \frac{W\,l}{2}$, the whole units of work.

We have shown that $l = \frac{W\,L}{M_e\,A}$ $\therefore M_e\,A\,l = W\,L$

$$\therefore W = \frac{M_e\,A\,l}{L} \quad \therefore \frac{W\,l}{2} = \frac{M_e\,A\,l^2}{2\,L} = \text{the units of work.}$$

Also, the work done, or the resistance overcome, expressed in units of work, $= M_e\,\frac{A\,l^2}{2\,L} = \frac{1}{2}\,M_e \left(\frac{l}{L}\right)^2 L\,A$; hence it is evident that the amount of work to be done to elongate different bars of the same material, any fractional part of its length expressed by $\frac{l}{L}$, which must not exceed the elastic limit, will vary as L A; for in every case $\frac{1}{2}\,M_e \left(\frac{l}{L}\right)$ remains constant. The work done in elongating a bar to its elastic limit,

(To be continued.)

FITZWILLIAM MUSEUM.

The following particulars respecting the site and purpose of this noble building may be interesting to those readers who are not acquainted with the topography of Cambridge.

The situation of the Museum is one of the most favourable which an architect could desire. It is near the entrance of the town from the London road, in a broad open part of the main street. When first erected the building was hemmed in by several mean and decayed tenements which have since been removed. The edifice is now perfectly isolated: on three sides are broad spaces of lawn, on the fourth or principal side is the open thoroughfare, So that the architect has had the advantage of placing his building where it may be readily seen, and where it is the conspicuous object of a place of public resort, without the architecture being marred or concealed by the adjacent houses.

The material of the masonry, pure white Portland stone, contributes much to the architectural effect—and especially in summer by the contrast of the dazzling colour of the building with the dark foliage of the trees in Peterhouse gardens. The whiteness of the stone is really extraordinary, and generally gives to strangers the impression that the building is constructed of pure marble. Those who are merely accustomed to see Portland stone of the colour which it assumes in the smoke of London, can scarcely imagine the almost startling effect produced by the brilliant appearance of the Museum at Cambridge, when seen for the first time: there are few strangers who on entering Cambridge are not impressed with a feeling akin to amazement when they suddenly come in sight of this gorgeous monument of classic architecture. The effect by night, especially, when the moon is shining, is very striking. The columns show in the moonlight as white as snow, and there is something almost magical in the manner in which they contrast with the dark shadows of the surrounding trees.

It must not be supposed, however, that the whole of the effect is to be attributed to the accidents of situation and colour: these serve only to exhibit fully the excellence of the architecture. It has been Mr. Basevi's good fortune to place his masterpiece where it will be seen and appreciated by men of taste and education; and it has successfully undergone the ordeal of their criticism. This ordeal is the more severe, because, as most of the readers of the Journal are aware, there is in Cambridge a strong and energetic party of amateur architects whose exclusive tenets would lead them to regard with little favour such a building as the Fitzwilliam Museum. Even from the hands of these, however, its architectural character has escaped safely. The most zealous of the Camdenists will generally allow (in moments of candour and liberality) that the Museum is on the whole an exception to the usual hideousness of Pagan architecture; and some of them have gone so far as to say that the building exhibits positive merits, and that they look upon the lofty columns and the sculptured pediment not only without disgust, but with a feeling very like absolute satisfaction.

But the Fitzwilliam Museum has undergone a test even surer than the judgment of the members of the Camden Society. The test is this—that the architecture appears more beautiful as the eye becomes more familiar with its character. There are many buildings which appear well at first sight, which cease to please on a second inspection; but this is by no means the case in the present instance. If on his first visit to the Museum, the stranger be gratified by the boldness and richness of its architecture, his pleasure will be only increased in subsequent examinations, when he begins to criticise the architecture in detail. Perhaps no one feels a greater admiration of it than the old Cambridge man after having been familiar with the building during the whole time of his residence, examines it afresh after the interval of several years.

That the architecture is not perfect it is useless to deny. The square mass or *hump* which rises above in the rear of the pediment sadly injures its effect, and this injury appears far greater on actual inspection of the building than could possibly be supposed from an examination of a view of the elevation. The *reason* of the injury produced probably occurs to few, though all are able to pronounce as to the reality of it. There can be no doubt that this reason is to be found in the fact that the rules of "apparent construction" are violated. The pediment, instead of being, as all pediments should be, the gable end of a roof, assumes the appearance of a factitious appendage—it looks *stuck on* and not an integral and essential portion of the structure. This effect is certainly produced by the "hump" in question, which destroys all idea of the continuity of the roof. To the same cause must be assigned the disfigurement produced by the lateral wings flanking the portico. This criticism rests not merely upon an individual opinion—the defects to which it refers are universally condemned by those who are familiar with the building. The superstructure above the apex of the pediment, and the wings to the right and left of the portico are equally destructive to its character—and from the same cause:—they show that the portico is not treated constructively, but is merely an ornament—an appendage.

There is a phrase among sculptors for a group of which the several parts are not sufficient separated—they say of such sculpture that "it does not show enough day-light," and the cutting away the marble so that limbs appear distinct and the light shines through in different parts of the group is called "letting in day-light." To apply this phraseology to a portico which like that of the Fitzwilliam Museum is flanked by wings—it excludes too much light. In pure architecture such as that of the Parthenon, the Temple of Theseus, or that of Neptune, at Pæstum, a most beautiful effect is produced by the light shining in between the extreme columns of the portico and the angles of the cella.* The relief thus given by the corner columns standing out distinctly against the sky or background is necessarily lost in the Fitzwilliam Museum.

It may also be fairly objected that the character of the street front of this edifice is not maintained in the other sides of it. Not indeed that we accuse the architect of masking it with a "show front:"—that utter violation of the rules of architecture—that hopeless vulgarity of taste, was reserved for our two national repositories of works of art, the British Museum and the National Gallery. Of these buildings the less conspicuous sides have about as much architectural pretension as a factory or union-workhouse, being in fact built of the plainest brickwork, so that the show sides, even if they were tenfold better than they really are, must be pronounced absolutely devoid of artistic value. It is however but fruitless labour to criticise these monuments of perverted taste; they display that entire want of all true architectural feeling which renders animadversion obviously useless, and we merely notice them to institute a contrast in favour

* One of the very few good qualities of the architecture of Buckingham Palace, is that the columns of the pediments at the wings stand out in this manner. The only other merits, and they are but negative merits, of this building, are that the pediments at the hump are treated as gables, that the building has not a show side, and that the materials of the masonry are all real.

of another museum of art, which though situated in a provincial town, and built neither by the national wealth nor under the auspices of the government, is the only one of the three worthy of the high purpose for which it was designed.

Of the architecture of the other parts of the building, besides those exhibited in our drawings, it must be allowed that though not absolutely bad in themselves, they by no means correspond to the elaborate magnificence of the portico. This is the more to be regretted, because from the nature of the site the sides of the Museum are quite as conspicuous as its front, and the observer can never approach it without being made aware of the disagreeable contrast. The elevation next Peterhouse Gardens has the most architectural pretension, and it, as well as the sides, are of the same beautiful stone as the front; but still the surfaces appear comparatively flat and unbroken; and what is perhaps even of more consequence, the few ornaments displayed by no means correspond in purity of taste to the character of the portico.

The interior of the building is still in a very unfinished state; the completion of it is assigned to Mr. Cockerell, and it is earnestly to be hoped that the decorations will be as *real* as possible, and that there will be no attempts to make plaster look like stone or cast iron, and deal boards look like oak. The building when completed will hold the statues, pictures, cameos and engravings bequeathed to the University by the Earl of Fitzwilliam, and also another very valuable collection of pictures at present in the Pitt Press.

ARCHITECTURAL RECOLLECTIONS OF ITALY.

By Frederick Lush.

From some ornaments taken in Italy I select the accompanying sketches for your Journal, on account of their beautiful forms, and because they might serve as a model for our English knockers, or at least suggest a more graceful and pleasing feature than that which is generally placed

Fig. 1

on our doors. Figures 1 and 2 are from Venice, but most probably of Florentine workmanship, and fig. 3 is from Verona.

Whoever has seen these small though magnificent objects abroad, must have felt how much they ennobled the entrances of the old palaces, and how delightful it was to linger on the threshold and admire them. It is strange that in England, where within the last few years so much has been done to improve every kind of decoration, these things have been neglected as though they were considered beneath the notice of the artist. The names of such men as Ghiberti, John of Bologna, Benvenuto Cellini, and others, who have left us their beautiful works, along with larger ones, could not suffer such an opinion for a moment to be entertained; but it is well known, as in the examples before us, the beauty and picturesque effect which is infused into the smallest things when genius has laboured upon them. In the design of these knockers, as well as in everything

Fig. 2.

else which passed through the hands of these cunning goldsmiths and industrious sculptors, there is an elaborate finish, of which they are quite worthy, and which for the most part challenges the closest inspection.

Fig. 3.

Leaf, flower, bird, or figure, were executed with so much feeling, and such truth to nature, that even the simplest articles of common use or ornaments in dress were real works of art; nor could a censer, salver, goblet, or a crucifix, that was fashioned by the same hand as that which wrought the Perseus, be otherwise than a gem in the collection of a prince or in the cabinet of the virtuoso.

The high opinion conceived by the Italian artists of the humblest department of art; the intense care and industry bestowed on small things as well as great; and their associating together in one common brotherhood, where none was excluded from the rest, were circumstances which acted most happily towards the development of taste and the perfection of the arts, and of which Lanzi speaks in his history of the Italian painters. The result of these ideas and the strength acquired by this union is epecially evinced in Italy. Common objects, which in Britain seldom receive any attention, there reveal some striking artistic beauty. It is sufficient in addition to what has been already referred to, to mention the famous lampholder in the Strozzi palace, Florence; the dolphins and sea-horses sculptured on the top of the tall mooring-posts in Venice; the lanterns on her canals; the ornaments of the Ca' d'oro; the pedestals to the Grecian standards in the Piazza di San Marco; or the bronze cisterns in the quadrangle of the Ducal palace.

ROYAL ACADEMY EXHIBITION: ARCHITECTURE.

We will not disturb the opinion which attributes improvement to the present Exhibition as far as the painters are concerned,—although for our part we do not perceive the slightest general advance at all,—but matters have most assuredly not mended this season with regard to architecture. However, we are tired of repeating the same complaints year after year, and that to no purpose. The Academician architects take pattern by Sir Robert Smirke, and their quality brethren take pattern by them, therefore from those who, it is to be presumed, could show us most, we get least; nor have we much from other quarters to inform us what is going on in various parts of the country. Liverpool, Manchester, and many other important places are wholly unrepresented in the present annual parliament of art in Trafalgar Square. Where are all the things whose fussy "first-stone-laying" ceremonies are recorded with such "wink o' the eye" admiration by newspapers? Where, all those drawings which have borne off five and ten pound premiums from liberal and self-enlightened competition committees? We see them not here: but to speak of what we do not see would be a much longer tale than to enumerate what we do find, that either deserves commendation or is worth mention. In an exhibition of architectural drawings we have a right to look for interest of some kind—either that attending designs adopted or proposed for particular buildings, be the talent shown in them, what it may; or else that which is produced by the intrinsic merit of the subjects themselves, though they may be merely imaginary ones. This year there is an unusual dearth of interest of either kind. There are besides a number of drawings, which though put into the architectural room hardly belong to it at all, more than the unlucky oil paintings which are stuck up there in order to be out of harm's way, till their owners send for them again. We allude to mere views and delineations of buildings, whose execution gives them no pretensions whatever as productions of the pencil, while the subjects they represent are either so exceedingly hackneyed, that their titles in the catalogue operate as a warning to pass them over; or so trivial, that we turn away from them as soon as beheld. Not a little provoking is it to find that few of those who do bring home any architectural sketches and studies from abroad, care ever to hunt out any thing fresher than such wonderful *rarities* as the Athenian Acropolis and Parthenon, and the Roman Coliseum and Forum. Does the actual capital of King Otho afford nothing whatever at all worth representing upon paper? Is his "Modern Athens" so deplorably insipid as not to have a single marked feature, or even any general physiognomy? It would seem that even our architectural draftsmen and sketchers are so infected with the "precedent-mania" that they dare not show us any building unless there is precedent for so doing by its having been represented times innumerable before. Whether it be abroad or at home that they go in quest of subjects, our architectural likeness-takers, seem terribly averse to novelty, or else they must fancy they have no right to take subjects from buildings which are so recent, that the office of showing them seems to belong exclusively to those who designed and erected them. The latter, however, do not always consider it worth their while to do so: certain at least it is that we do not find at the Royal Academy's exhibitions many of the things which are best of all suited for pictorial representation. The Colosseum in the Regent's Park, for instance, might have supplied more than one unusually striking subject, since, besides its beautiful Glyptotheca—perfectly unique as an interior—it offers many scenic architectural bits in other parts of the *place*, which would show still better in picture than they do in themselves, because in picture they would look like realities, whereas as seen in reality they are most undisguisedly only clever imitations and fictions. There might, again, have been one or two drawings of some of the apartments in the new building at Lincoln's Inn, and among them, both a general view and a partial one of the Library Yet, somehow or other,—and it may perhaps be as well not to inquire too nicely into the reason,—architects are apt to be of most stepmotherly disposition towards their own productions, begrudging what it would cost to let us behold them in pictorial effigy. Few of them take any generous interest in their art, as a fine art, and for its own sake; therefore they cannot with any sort of fairness complain of or express surprize at the indifference of the uninitiated, and the apathy of the general public;—and the latter seem to consider the architectural drawings little better than a dead weight on the Exhibition. Not a little mortifying is it to witness the hurried, listless glance bestowed on architectural subjects. If there be ever any thing of the kind among the oil paintings, it is never estimated except according to its execution as a picture. Even one of Scarlett Davis's glorious achievements of pictorial and architectural art,—one of Scandrett's fascinatingly exquisite groups of detail, or scenic views, has been known to engage attention far less than such horribly trivial subjects as swill-devouring pigs, turnip-munching boys, and strapping country wenches washing their not over and above delicate feet! How refined and poetic we English are in our ideas!

What sort of relish there is among the public for any thing relating to architecture is most disagreeably apparent from the circumstance of architecture being passed over altogether by the daily critics who profess to enlighten us in matters of art. The "big Times" has spoken of the present Exhibition without bestowing even so much as a syllable upon the architectural drawings. So that unless the "Times" be very much behind the times we actually live in, its silence as to our art is significant and expressive enough.—And what, all the while, is the Institute about?—has it done, is it doing, can it do, or does it care to do any thing, to give the requisite impulse, and bring architecture forward—and not only bring it forward, but force it upon the attention of the public? Leaving it to answer the question as best it can.

Of about two hundred and thirty subjects placed in the catalogue under the head "Architecture," barely one-half belongs to it, the rest consisting of graphic odds and ends—the very "tag-rag and bobtail" of the pictures; nevertheless the half constitute more subjects than can be properly seen, and the deficiency to be complained of is not so much that of quantity as of quality and interest. There certainly is very little of architectural interest in the solitary production contributed this season, after a couple of years' absence, by Professor Cockerell, for he makes his appearance rather as a truant from his own art, and ambitious of signalizing himself in another. This is all the more singular, because St. George's Hall, Liverpool, for the sculpture of whose pediment he here exhibits a design in No. 1254, (showing only the pediment and upper part of the columns, on a large scale), is the work of a different architect. Leaving more competent judges to determine the technical merits of the composition as one intended for sculpture, we can only say it strikes us as being so very Greek and classical as to forfeit character for originality; and at any rate there is nothing peculiar in the mode of its combination with the architecture, unless a *return* to the Greek system of placing entire statues within a pediment, can pass for an artistic conception; whereas by venturing to depart from ancient authority—as he has oft-times done in architecture—the Professor might have "initiated" a still more effective as well as perfectly new mode—produced by omitting the tympanum, and leaving the pediment quite open, except as filled in by the statues, (so fixed as to support the raking cornices); which would then tell all the more vigorously seen against the vacant space behind. Once adopted, this idea might be made to lead to other quite novel yet adequately matured effects, which we cannot now stop to point out, wherefore leaving this hint to suffice *ad interim*, we shall perhaps explain ourselves more fully at fitting opportunity. In taking leave of the Professor, we express the hope that we shall see him again next season somewhat more in *propriâ personâ*, and in his character of architect.

With the above exception—St. George's Hall—Grecian and Roman architecture does not appear to be in great request for any buildings of importance actually projected. The principal object of that kind which we here meet with is No. 1246, "Elevation of the new Theatre to be built on the east-side of Leicester-square," F. C. J. Parkinson; which, though it has been spoken of disparagingly by a contemporary, who calls it "an indifferent transcript of the Haymarket Theatre," appears to us a pleasing and tasteful composition, with some clever touches of original detail, and not only ornate but consistently so; and further, possessing more strongly marked and appropriate character than any of the existing theatres. If any resemblance can be traced between this façade and that of the Haymarket, it most assuredly does not amount to that of "transcript" or copy, much less to that of an "indifferent" one, since the "Haymarket," with its common-place straddling portico stuck up before a parcel of ordinary doors and windows, is in barbarously vile and vulgar taste. The drawing we are speaking of is not treated very happily as to colour, and we think it must be exceedingly incorrect in one respect, for according to the size of the figures, the columns must be forty feet or more in height, which is not very likely, the portico not being the centre height of the edifice. In all drawings of the kind, the only use of figures is to serve as a scale, therefore, unless they are strictly according to scale, they are neither more nor less than falsifications—sometimes even ludicrous ones, as, for instance, in the view of Sir R. Peel's new Picture Gallery, last year, where the figures in the room were only half the size of those representing the portraits on the walls; therefore, either the former were dwarfs, or the latter were colossal.

Critics differ; and it is, perhaps, but right that they should do so, since one opinion frequently helps to correct another, and where with dissent on some points there happens also to be conformity on some one other, the judgment passed in regard to the latter becomes tolerably well confirmed. Differ we do from the critic—one apparently very eager to get through his task with all possible dispatch—who, besides detecting in the preceding subject an unlucky resemblance to the Haymarket Theatre, regards with complacency such a production as No. 1174, "one of the designs submitted to the grand jury of the county of Clare for the Ennis Courts," as possessing claims on the score of originality of treatment. If not remarkably original, the treatment may be allowed to be unusual, yet hardly appropriate; neither the particular species of "Italian" adopted, nor the irregularity of the composition, befitting a public building in a town, especially one that ought to command attention by an expression of sober dignity, without playing at the picturesque. Let us hope that the design actually chosen is some degrees better than this "submitted" one. The two subjects just mentioned are almost the only designs this year for what can be called public buildings—that is, secular ones, and in other style than Gothic. We have, indeed, in No. 1214, what rather innocently calls itself a "Gothic design" for a town-hall and public assembly-room in the West of England, but as to its exact "whereabouts" we are left in most comfortable uncertainty, since it would be anything but comfort to be assured that there was any likelihood of so preposterous an affair being perpetrated anywhere. In this scarcity of designs for public buildings—except those which are evidently merely visionary ones—we may refer to No. 1217,—"The Lord Warden's hotel, &c., now erecting at Dover," (J. Beazley)—as a *quasi*-public structure, and what will certainly be a sufficiently conspicuous one—more so than it merits to be by the taste displayed in it. The main idea must, however, be a very favourite one with Mr. B., it being a repetition of what he showed us last year in what was then called a design for the Carlton Club House. What may be the differences between the two designs we are unable to say, but the principal portion is the same in both, and consists of a large Corinthian order above the ground floor, in coupled columns, with arches springing from their entablatures. (See our last Vol., p. 214.) It might have been thought that revision of the first design would have led to the adoption, for an arcade of the kind, to the more compact and legitimate combination of arches springing immediately from the capital of single columns.* The display affected by this columnar-arcade is, besides, far too pretensious for the building itself, which is so decidedly—don't print it "deucedly"—poor and unstudied in style, that the ostentatious decoration affected for it strikes as vulgar, tawdry, in *boutiquier* taste. When will architects learn to give more attention to what Cockerell calls "eurythym of quantities," and to consistency of expression, be it that of richness or plainness, or of any intermediate degree between the one and the other?

What could induce either Hopper or Railton to thrust forward into notice this year, their respective designs for the Nelson Monument, (No's. 1171 and 1313) we cannot imagine. Hardly can it have been any particular admiration which the former obtained at the time of the competition, that encouraged its author to bring it into notice again; yet, whether the drawing itself attracts notice or not, he has taken care that the subject shall not be overlooked in the catalogue, where it is spoken of more lengthily than intelligibly, it being impossible to make out how the little *tea-gardenesque* temple which constitutes the design, can possibly form part of a group of buildings for picture-galleries and exhibition-rooms. By singular coincidence, Railton's "Nelson Column"—too well known to require any remarks from us here—makes a gallant show in the catalogue, but is absolutely a nonentity in the Exhibition in comparison with his "Beau Manor Park," last season, of which mansion we should very thankfully have received an additional view this year. As to his "Riseholme Hall, adapted and enlarged for the Bishop of Lincoln" (No. 1194), it possesses no great architectural interest, though it certainly looks like a very enviable residence, and shows that bishops have no disrelish for the comforts and luxuries of this world. No. 1306, "The garden-front of Clifton Hall, Notts," (L. N. Cottingham), did not impress us at all favourably. In fact, while as to composition it is almost a nullity,—the house being a mere lumpish mass,—as to the style affected for it, it shows the worst extreme of the latest Elizabethan, when our *renaissance* had become prematurely exhausted and worn out, and had fallen into all the forced conceits and drivelling of *blasé* imagination. Whatever it has recommended itself by on this occasion, it can hardly be by its economy, since its crinkum-crankum ugliness must be of a rather expensive kind. Neither is it any advantage to this garden front that instead of being raised upon a terrace, it has a terrace rising up immediately *before* it. However, the painter has done all *he* could to command admiration by a bravely showy display of flowers and peacocks.—Infinitely more to our taste is No. 1326, "Lambourn Place, Berks, the seat of H. Hippesley, Esq., (T. L. Donaldson). If not very striking, this subject is a very agreeable and satisfactory one, both for its execution as a pictorial drawing, and for its unaffected yet sufficiently marked character as a design in the more sober style of the Elizabethan Tudor period. To say the truth, the style of house is rather that of a former period than of what any one might be likely to build at the present day, there being more of ancient gentility about it than of modern refinement.—As the immediately preceding No. is by the same architect, (almost the only member of the Institute who exhibits) we will speak of it here although it belongs to a different class of subjects. It is entitled the "Elevation of a design for an Insurance Office, being an attempt to adapt the cinque-cento style to the street architecture of the metropolis:" instead of "to adapt," the more suitable expression would have been "to introduce," because, as it seems to us, there is very little that indicates adaptation of the style to modern town-architecture in general, too much of what bears an antiquated and exotic look in it, being retained, for instance, in the form of the windows. There might have been more freedom, and less timidity and dryness of treatment; nor would it have been amiss had the drawing itself, which is now merely slightly shaded in India ink, been such as to ensure attention to the subject. Still it must be confessed that its utter want of pictorial attraction of any kind serves to distinguish it rather markedly from the subjects around it.

To return to mansions—Capernwray Hall, near Lancaster, shown in Nos. 1263 and 1340 (Sharpe and Paley), is one of the most ambitious, and shows careful attention to detail and individual parts, yet for a modern residence it looks but a gloomy sort of pile, with too much of the castle in its character. Of mansions or villas in the regular Palladian style there are none, but No. 1187, "Allenheads, now erecting on the property of T. J. Beaumont, Esq., in the county of Northumberland" (E. B. Lamb), is an application of what may be called the rural Italian villa style, that shows very great talent of a peculiar kind—the talent of accomplishing much with exceedingly limited means, for though the structure itself is simple even to plainness, it is rich in picturesque effect, and in well expressed character of an excellent kind, without artifices and affectations.—There are four designs for villas by Mocatta, small and rather showily coloured drawings, so unfavourably placed, however, that we did not give them much attention.—Of suburban villas and mansions similar to the "Kensington Garden" ones in last year's exhibition, there are none this season, although one since erected at Kensington would have furnished a subject. With respect to town and street architecture, designs for it are almost invariably confined to those for public buildings; we, however, get something so denominated in No. 1275 (W. H. Leeds), a design for a house-front, unusually ornate, though far from being violently showy, still it is what we must not hope to find the least favour with those ultra-orthodox and rigidly puritanical critics who turn up their noses at the Travellers' and Reform Clubhouses, and who look upon Barry as being scarcely a

* The church at Sacrow, shown in our present number, exemplifies such compound application of column and arch.

degree better than Borromini. By this remark it is not to be understood that the design we are speaking of is indebted to either of the two buildings just named for any of its features; on the contrary, it differs altogether from Barry's mode of composition, the middle window of the principal floor being not only distinguished from the others, but distinguished in a very eminent degree, for although the window opening is of the same size, its decoration forms a larger and loftier central compartment. There is some novelty also in introducing a bas-relief as a frieze between the principal floor and the one over it, where figures of the kind would be more distinctly seen than higher up.—We meet with subjects of street architecture for projected metropolitan improvements in Nos. 1175 and 1185 by W. J. Donthorn, and 1319 by Allom, the two former being designs for a new street in a direct line from Buckingham Palace to Westminster Abbey, and for a new Square adjoining the Abbey; and the other for improving the North bank of the Thames between London and Blackfriars Bridges. This last is a very able drawing, but the architecture is rendered quite subordinate, being treated as little more than background to the splendid and animated river view, which, as picture, would have been just as good had the present houses been represented. Perhaps it would be unfair to consider the buildings here put in as intended to do more than convey a general idea of the proposed line, for they are made up of just the same sort of showy fronts as are now in vogue for new trading streets. Were the separate elevations drawn out as usual and left to speak for themselves as designs, some of them, we fancy, would cut but a sorry figure. The same remark may serve for Mr. Donthorn's *projét*: as a street it would be a very great improvement, but as street architecture no great improvement if any, upon the samples we have got.

The transition from streets and the outsides of houses to the insides of the latter is so natural that "*Interiors*" seem to claim our attention next, almost as matter of course, but we must reserve our remarks upon them and the remaining drawings, for a second notice.

NEW METROPOLITAN CHURCHES.

St. John's, Charlotte-street, Fitzroy-square.—This church is now nearly completed. The style adopted in the more conspicuous parts of the building is Norman, or rather the modern mongrel between Norman and Romanesque. The west front exhibits two towers divided into stages; of these towers, that at the north-west angle is surmounted by a slate-covered spire. The rest of the façade consists of a gable, containing a triplet of round-headed windows, with a wheel-window above, and the west door below them. The surface of the west front is broken by small arches and columns of decoration, string courses, and a corbel-table. These members and the dressings are of Bath stone, the rest is faced with Kentish rag. As might be anticipated in a London church built in the line of a street and crammed in between the neighbouring houses, neither the interior nor the exterior of this edifice has the slightest pretensions to the *spirit* of Norman architecture, notwithstanding the imitation of some of the forms peculiar to that style. The cumbrous massive grandeur produced by the colossal proportions of the Norman era are here missed altogether. Instead of vast towers, walls of enormous thickness, and columns no more than three or four diameters in height, we have all the principal parts of a Norman cathedral comprised in the narrow space of a street elevation. The pigmy dimensions which the architect has consequently been compelled to adopt, give the idea that the building is meant rather as a sort of illustration or reduced model of a Norman church, than as a real attempt to build such an edifice in all the amplitude of its dimensions.

The church has neither transepts nor a central tower—almost universal features of ancient Norman churches. The dimensions of the interior are fully as diminutive as those of the exterior: the nave and aisles are divided by pillars and arches with wretched mouldings; the roofs are of open wood-work; the aisles are bisected by galleries, and the light is obtained from couplets of circular headed windows in the clerestory; consequently the north and south walls are blank, and the light is very unequally distributed.

The back of the church (we regret to have to apply the word "back" to a church, but the east end cannot in the present case be distinguished by a more honorable term,) is in a mews-yard, and it is needless to say that the architecture here exactly accords with that of the neighbouring stacles and coach-houses, being of the commonest brickwork. The designer seems to have been content with making a show, such as it is, in the main street.

French Protestant Church, Holborn.—The plan of this church, which has recently been consecrated, is a rectangle. The eastern end is in Bloomsbury-street, and the western in George street: the north and south sides are in the course of being blocked up by houses. The eastern elevation consists of a gable, without towers, and contains a large centre window with two lateral windows; underneath are doors, the entrance being—not at the western—but the eastern end (for the sake of facility of access, as the *Ecclesiologist* suggests, from "the more genteel street.") The great east window has five lights; but the floriation does not show much invention, being simply a number of trefoils contained within a pointed arch. The lateral windows in the same front are almost close to the central window, and in their proportions display a ludicrous contrast to it, being very narrow compared with their length, whereas the centre window is disproportionately broad. The group possesses neither the individual beauty nor the family likeness which would remind the observer of the three Graces.

The west front displays two long windows with a triangular window above, and beneath a string course, three lancets. This and the east sides of the church are faced with rag; the north and south are plain brickwork without any windows or mouldings. There has not been any absolute necessity for this nakedness, as on one side, a large open space of ground at present intervenes between the church and the neighbouring houses, and on the other side the architect himself has built a school abutting on the church. The interior of the church has of course the advantage of north and south walls perfectly blank.

At the end of the same street is another church which has recently been "done up." The style is one of which there are happily so few specimens that it has not yet received a name; we are therefore relieved from the necessity of a detailed criticism. We have only to notice, on account of their profanity, some extremely offensive ornaments with which the upper part of the exterior walls are decorated. On three sides of the building, which is bedizened in all the glories of plaster, in which it rivals most of the gin-palaces in the neighbourhood, are stucco ornaments bearing respectively the semblances of an equilateral triangle, a lamb bearing a flag, and a dove. It is needless to state what is typified by these figures, which are repeated several times in the order mentioned, so as to form a kind of frieze to three sides of the building. We trust that the incumbent clergyman will use his influence to get these profane and hideous symbols removed: as works of art they are on a *par* with the plaster images sold at fairs as toys for children.

Catholic Church, Farm-street, Berkeley-square.—This church is a very gratifying example of the rapid advances which have been made in the science of mediæval architecture during the last few years. While in Classic architecture the most barbarous perversions and absurdities—pediments surmounted by spires—columns supporting nothing—stilted bases—shafts broken by dies, &c.,—are still tolerated, our national architecture is cultivated with a purer and more philosophical taste, which is fast emancipating it from the hideous deformities of the last age. Mr. Scoles' design for the Catholic church near Berkeley-square is a satisfactory proof that our self-complacency is not without foundation.

The situation of the building is by no means advantageous; it is, indeed, almost impossible to get a good view of the exterior. From one corner of Grosvenor-square a glimpse may be obtained of the east gable, the beautiful Decorated tracery of the great east window, and the bell-turret; and another view from beside the ugly plastered church in Mount-street displays somewhat more of the new building. But still it is so hemmed in among the houses, that it can scarcely anywhere be viewed as a whole. The difficulties to be contended with in obtaining a suitable site may be judged of by the fact that the west entrance is in a mews-yard. The architecture of this part of the building will not however be made inferior to the rest because comparatively little seen: on the contrary, if there be one thing more to be admired than another in the design, it is that it displays perfect faithfulness and uniformity, and betrays no anxiety for what is colloqually termed "showing off"

The plan of the interior is nearly a rectangle (about 150 feet long) with aisles extending about half the length of the church from the east-end. These aisles are separated from the chancel and nave by piers and arches. There will be three altars—the high altar at the end of the chancel, and one at the east-end of each aisle. The side altars will be dedicated to the

Virgin and the Sacrament respectively. In the south aisle are three confessionals and the sacristy, and above the south arches in the chancel is the tribune. The light will be obtained from the east and west windows and from clerestories in the north and south walls. It is worthy of notice that the tracery of no two windows is alike, though the patterns of all of them are extremely rich: the design of the east window especially may be safely compared with some of the noblest examples of ancient Decorated architecture. With respect, however, to the absence of north and south windows below those of the clerestory, we have already given a general and distinct opinion. Our views on this subject have been so recently detailed that we need not now say more than that the examination of the church which we are describing suggested nothing which would modify our opinion. On the contrary, we can state positively that the effect of the light thrown down from above by no means harmonises with the character of the church, and that the large surfaces of blank unbroken walls are great defects. We say this the more freely because the excellence of the general design is sufficiently great to afford some drawbacks, and because the architect may justly plead the difficulties of the site as an excuse.

Parts of the interior walls will be plastered and painted with frescoes. This use of plaster is perfectly legitimate, for there is not the slightest pretension of making it look like masonry; it reveals itself honestly in its true character—that of a ground surface for the painting. No deceptive materials whatever are employed in the church. The external masonry is of Kentish rag; the mouldings, window-mullions, piers, &c., of Bath stone.

There is a temporary brick wall at the west-end: this is about to be removed for the purpose of completing the west gable, which will display three windows, with a door below the central window, and a trilateral window near the vertex of the gable. There will also be a bell-turret at this end of the church in addition to that now existing over the chancel arch. The roofs incline to the horizontal at an angle of about 60°; on the north and south sides of them are rich perforated parapets.

We hope to be able hereafter to give a more complete account of the church, and to accompany the description by illustrations.

NOTES ON ENGINEERING,
V.
MENAI TUBULAR BRIDGE.

Since the former paper (see *ante* p. 100), on the application of the theory of the strength of beams to the case of the Tubular bridge was published, a report has appeared of experiments by Messrs. Hodgkinson and Fairbairn, with reference to this particular subject. As far as analogy can be drawn between the method of those experiments and the investigation of which the present paper is a continuation, the results agree exactly. It will be observed however that the experiments had reference solely to the ultimate strength of the girders experimented upon—that is, to the extreme weight which they would bear before breaking, the present investigation however relates not so much to the *strength* of the girders as to the *strain* which they must have to bear; and as the results here arrived at are obtained from the fundamental laws of statics, and not from any assumptions respecting the nature of the bodies operated upon, the points of resemblance between this theoretical examination and the reported experiments are few. It has seemed sufficient in the present paper to point out the precise nature and amount of the forces which the metal will have to resist; leaving it to the engineer to contrive the proper means of fulfilling the requirements here pointed out.

We now proceed with the subject from the point where we left it in the former paper.

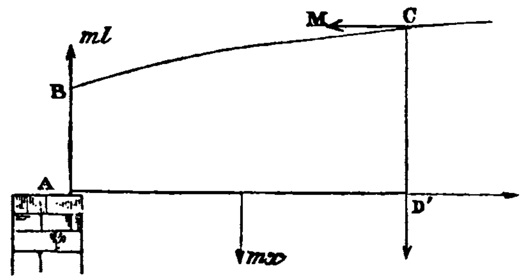
5. *Form of the Girder of uniform strength.*

When the girder is of uniform strength throughout, the strain on it is greatest at the centre for two reasons. First, from the weight of the girder itself independently of the load: for when a vertical section is made through the centre, it is seen that the molecular forces of the metal have to resist a greater moment of external forces, than when the section is supposed to be made elsewhere. Secondly, the load is a moveable one, and has the greatest moment when its centre of gravity is over the centre of the bridge. It is possible to vary the dimensions of the bridge so that the *strain on each square inch* shall be uniform throughout almost the whole length of the bridge. There are three ways of effecting this object—either by increasing the thickness of the plates towards the centre of the bridge, or by increasing the depth of the bridge towards the centre, or by combining both these methods. The second method is however the preferable one, because it does not require any considerable addition to the quantity of metal.

On narrow gauge railways the proportion of the loading of the goods trains to the length of the wagons is such that about 4 tons of load extend over about 9 feet of railway; consequently on the Menai girders (the length of which is 450 feet) we may take the extreme load to be 200 tons uniformly distributed over the length. We have now to find the law of the variation of the depth of the girder, so that its own weight, and the load together shall produce a uniform strain on the metal.

Let $2l$ be the length of the bridge, and m the weight of load and bridge together for a unit of length, and $2l\,m$ will be total weight supported. Consequently the pressure on each abutment will be $l m$.

Let a vertical section C′ D′ be supposed to be made at a distance x ($=$ A D′) from the end of the bridge. Then replacing the molecular actions by a vertical force along C′D′, and equal horizontal forces at C′ and D′; these new forces may be equated with the external forces, which are—first, the vertical pressure at the end A, which, as has been said, is equal to $m l$; secondly, the weight of the part A B C′ D′ ($= m x$), which may be supposed to act half way between A and D′. And as we



shall hereafter find that the curvature of B′ C′ is very small, it will be seen that the error arising form this supposition is quite inappreciable. Taking moments about D′ and calling the depth C′ D′, y, we have—

$$M y = m l x - m x \cdot \tfrac{1}{2} x.$$

Now y is supposed to vary so that M remains constant. Consequently, the equation to the curve B C′ will be

$$y = \frac{m}{M}\left(l x - \tfrac{1}{2} x^2\right) \text{ a parabola.}$$

It will be observed that by this equation $y = 0$ when $x = 0$ or $2l$, that is, the depth is zero at the two extremities of the beam. It is impossible, however, that this condition could be satisfied, since room must be left for the passage of the train. The height of common railway bridges usually allowed for this purpose is 15 feet, which gives a sufficiently clear space above the funnel of the engine; y, therefore, in the above equation, after it has attained the limit of 15 feet, must remain constant. The only effect of this will be that the bridge will be stronger than theory requires it to be, since, of course, if the depth towards the ends be greater than requisite, the result is an increased strength in those parts.

To determine the numerical value of m; the weight of a square foot of iron one inch thick is about 40 lb.: and since the Menai Bridge is to be 15 feet wide, the weight of one foot of the upper and lower plates together will be 1200 lb. The weight of the train we have supposed 4 tons to 9 feet, or about 1000 lb. to a foot. Consequently $m = 2200$; we will, for convenience of calculation put $m = 2240$ or 1 ton

M is to be found by determining its value at the centre of the bridge. Here $y = 30$ feet and $x = 225$ feet. Substituting these values in the equation to the curve, we find $M = 844$ tons; and since $l = 225$ and $m = 1$, the equation becomes—

$$y = \tfrac{1}{844}\left(225 - \tfrac{1}{2} x\right) x.$$

The following are some of the values of y, corresponding to given values of x:—

$x =$ 210 feet	$y =$ 29·8 feet
200	29·6
180	28·5
160	27·4
140	25·7
120	23·4
100	20·7
80	17·6.

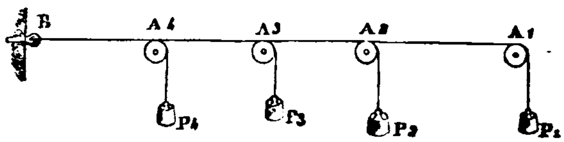
When x is between 70 and 60 feet, y will be reduced to 15 feet, and must not be farther lessened. By adopting then the form here indicated, the tension will be for 160 feet on each side of the centre uniformly equal to 841 tons, and for the 65 feet near either extremity will be less. Taking it however at 841 tons, we observe that, since the plates are 15 feet wide and 1 inch thick, and the cross section consequently contains 180 square inches, the strain per square inch on the metal plates is about $4\frac{2}{3}$ tons. Iron will bear a strain of 29 tons per square inch without breaking, and 9 tons without permanent injury; but the diminished strain here assigned to it is not too great an excess on the side of safety, when the diminution of strength at the places where the several pieces composing the upper and lower plates are welded or rivetted together is taken into consideration.

6. *Necessary strength of the vertical ribs.*

The beam of greatest strength for a given quantity of material is that in which the material is collected in two wide horizontal flanges, separated by a thin vertical rib. It has been usual to consider that no more strength is requisite in this rib than will suffice to keep the flanges apart; and the consideration seems to have been hitherto neglected in all philosophical investigations of the subject, that the longitudinal strains which the flanges exert upon the rib, render it necessary that the latter should have much more strength than what is required for the mere separation of the flanges. A very simple method may, however, be given for determining the exact amount of strength actually required in the rib by its connection with the other parts of the beam. As the subject appears to be an entirely new one, no apology is necessary for discussing it fully.

The most convenient method of determining the strains upon the vertical web or webs is to consider the vertical strains and the horizontal strains quite separately. This plan of keeping the two kind of forces perfectly distinct has been observed throughout these papers, and is by far the best for getting clear and precise notions of the subject.

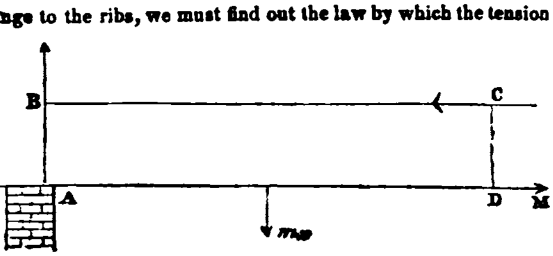
We will first consider the *longitudinal* strains which the flanges exert upon the rib. Now it is to be remembered that the upper flange is in a state of more or less compression throughout its length; and the lower flange in a state of more or less tension. We know, however, that a string stretched by two forces only, one at each end, is in a state of uniform tension throughout its length; but if forces be applied to the string at intermediate points along it, the tension will vary in various parts. For instance, suppose that a string, A_1 B, is fastened at B to a staple firmly fixed in a wall, and at A_1 passes over a pulley, and is stretched by a weight P_1, it is clear that if no weight but this act on the string, it will have a uniform



tension $= P_1$. Suppose, however, that at the points A_2, A_3, A_4, other weights are hooked on to the string and made to act upon it horizontally by means of pulleys, it is obvious that the tension of the string will now vary in various parts; between A_4 and B *all* the weights are acting on the string, and consequently the tension of this part $= P_1 + P_2 + P_3 + P_4$; between A_3 and A_4 the tension $= P_1 + P_2 + P_3$; between A_2 and A_3 the tension $= P_1 + P_2$; between A_2 and A_1 the tension $= P_1$.

Now, to apply this consideration to the lower flange of our girder—we observe that the tension of it varies in every part; this variation, therefore, arises from the action of horizontal forces at every point throughout its length, and it is certain that these horizontal forces have been communicated by no other means than by the vertical ribs.

In order to estimate the amount of the strains communicated by the bottom flange to the ribs, we must find out the law by which the tension of the



former varies. Let us first for simplicity suppose the depth of the girder uniform throughout and $= a$. Also let the whole length be uniformly loaded, and let one foot of the length of the girder with the load upon it $= m$; then if $2l$ be the length of the girder, $2ml$ will be its weight, and the reaction on the abutment A $= ml$. Also, if a section be made at any part CD and AD $= x$ the weight of the part ABCD $= mx$. Let the tension at D $=$ M. Then taking moments about C

$$Ma = mlx - mx.\tfrac{1}{2}x$$
$$= m(lx - \tfrac{1}{2}x^2).$$

Similary, if we had supposed a section made in the girder at a distance x' from the end, and that the corresponding tension was M', we should have the equation

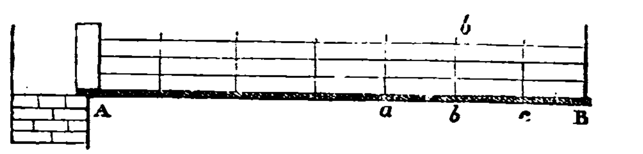
$$M'a = m\,(l\,x' - \tfrac{1}{2}\,x'^2).$$

Consequently

$$(M - M')\,a = m\,\left\{\,l\,(x - x') - \tfrac{1}{2}\,(x^2 - x'^2\right\}$$

This last equation gives the law of the variation of the tension.

We have now to see how this variation is produced by the vertical ribs. Let us first of all suppose that the connection between the upper and lower flanges is maintained—not by continuous plates—but by a *lattice* consisting of vertical and horizontal bars crossing each other. Now the upper horizontal bars will exert thrusts, and the lower, tensions. In the following figure, let A B represent a portion of the lower flange resting on the



abutment at A. Above A B are represented some of the horizontal bars of the lattice, but *those only which exert tension;* those which exert thrust as well as the upper flange being omitted in the figure. Now by this arrangement the tension of the portion of the bottom flange, between any two vertical bars is constant. For instance, the tension of that part of A B which lies between a and b is uniform, and of the part between b and c the tension is also uniform, only it is greater in amount than the tension between a and b. Call the tension between a and b, M_2 and between b and c, M_1, then it is clear that the vertical rod $b\,b'$ is solicited at the point b by two different horizontal forces, M_2, at the left of b tending to pull it *towards* the abutment, M_1 to the right of b tending to pull it further *from* the abutment. But M_1 is the greatest: therefore on the whole the rod $b\,b'$ is acted on by a force $M_1 - M_2$ tending to pull it towards the right. For the equilibrium of this rod therefore we must have equal forces tending to pull it towards the abutment. These forces are supplied by the tension of the *horizontal* bars above $a\ b$. Hence this conclusion—the aggregate tension of the horizontal bars above $a\,b = M_1 - M_2$.

Now if we suppose B the *middle* point of the beam, we know that the tension is equal and opposite on both sides of that point; that is, the tension of c B is equal to the tension to the right of B. Consequently the vertical bar at B will stand of itself without any tension of the horizontal bars above c B. The tension of these bars is therefore zero. The bars however above $b\,c$ are in a state of actual tension, the amount of which equals the difference between the tension of the portion B c of the flange and of the portion $b\,c$.

Let the successive differences of the successive portions of the flange be represented by $P_1, P_2, P_3 \ldots\ldots P_n$, then the bars above $b\,c$ are stretched by a force P_1 at c; the bars above $a\,b$ are stretched by a force P_1 at c and a force P_2 at b; the bars next to the left are stretched by a force P_1 at c, P_2 at b, and P_3 at a, and so on. Consequently the tensions of the horizontal bars are, to the left of the first upright rod, P_1; to the left of the second, $P_1 + P_2$; of the third, $P_1 + P_2 + P_3$ and so on. The tension to the left of the rth vertical rod $= P_1 + P_2 + P_3 + \ldots\ldots + P_r$.

But the forces $P_1, P_2 \ldots\ldots P_r$ are respectively equivalent to $M - M_1$, $M_1 - M_2 \ldots\ldots\ldots M_{n-1} - M_n$. Hence $P_1 + P_2 + P_3 + \ldots\ldots + P_n =$ $M - M_1 + M_1 - M_2 + \ldots\ldots + M_{r-1} - M_r = M - M_r$,

or the aggregate tension of the horizontal bars at any point is equal to the difference between the tension of the flange at that point and its tension at the centre.

But we have just shown that the tension of the flange at a distance x from the abatment

$$=\frac{m}{a}(l x - \tfrac{1}{2} x^2).$$

Putting in this equation $x=l$, we have for the tension of the flange at the centre

$$\frac{m}{a}(l^2 - \tfrac{1}{2} l^2) \text{ or } \tfrac{1}{2} l^2 \frac{m}{a}.$$

Hence finally we get the tension of the horizontal *rods* at a distance x from the end by subtracting the first expression from the second. This gives

$$\frac{m}{a}\left\{\tfrac{1}{2} l^2 - (l x - \tfrac{1}{2} x^2)\right\} \text{ or } \tfrac{1}{2}\frac{m}{a}(l-x)^2.$$

We will apply this very simple formula hereafter to show the necessary thickness of the vertical and horizontal bars, supposing the upper and lower flanges to be connected by a lattice work. For the present it is sufficient to point out that the same mode of investigation applies where the vertical ribs are not lattice work, but continuous plates. For though we have supposed the points of application of the forces which the flange exerts on the ribs to be separated by determinate intervals, it is clear from the foregoing reasoning that the result is the same whether those intervals be great or small. So that if the intervals be indefinitely diminished, that is if the rib and flange be joined at every point throughout their length, the expression for the strain which the one exerts on the other will be the same in both cases. H. C.

REVIEWS.

The Place of Egypt in the History of the World. By Chevalier de Bunsen, (Ægyptens Stelle in der Welt-Geshichte.) Hamburgh, 1845. 3 vols. 8vo. Plates.

The object of Dr. Bunsen is to *prolong* the *incipient* portion of man's history for about 2000 years, and to show, that where hitherto only an *unconnected* list of obscure names and dates was to be met, real history and chronology may be elucidated by our increased knowledge of ancient records, and the monuments of the land of the Nile. If the work before us were one relating to a country *un-monumental*, it hardly would fall within the scope of our Journal; but being one of Egyptian antiquity, we may give a brief account of its contents.

Looking over the numerous dates and names, and lists and tables of the three volumes before us, one hardly can imagine that one man's labour would suffice to construct such an array of chronological formulæ, as it were, from out of the *few* given data of such remote antiquity. But considering that we are now in 1846, and that Dr. Bunsen says that his research on Egypt began in 1812, the thing becomes plausible. Besides, there is no Egyptian scholar of the age with whom the author had not been intimately connected; and his work is a *resumé* of all what the great French expedition had begun, and such men as Belzoni, Salt, Champollion, Rosselini, Wilkinson, Col. Vyse, Perring, and last but not least, Lepsius, had brought to a pretty satisfactory close.

"To restore," says Dr. Bunsen, "the chronology of the oldest monumental nation of the world, from Menes to Alexander the Great, for an extent of at least 3000 years, would have been impossible without the perfect elucidation of those monuments and partly documents, which Manetho and Eratosthenes had before them. As geologists have endeavoured to find a *progress* in the formation of the strata of the globe, and therefrom deduce the epochs of our earth, we may accomplish a similar task, if, as is the case, the monuments of high antiquity of one of the most important worlds-nations be not wanting. To sift the chronology of these ancient times will be most feasible by the aid of *monuments*. Those monuments do not only date from much earlier times than the public in general (with exception of the *Egyptiologists*) are accustomed to expect; but they are of far greater import than even these have hitherto thought, because the chief monuments of the old reigns are the kings' sepulchres, and these sepulchres are the pyramids; and amongst them the world-famed *three* are, certainly, *not* the oldest. It is very remarkable, that we find on the field of the Pyramids (*Piramidenfelde*) almost all kings of the Memphis dynasty, but no name s-shield (*Namenschild*) which can appertain to the *thinite* kings. Those, however, may yet be discovered in the ruins of Abydos—that primæval metropolis of ancient Egypt which, notwithstanding the report of Strabo and the great import of the kings' table (*Königstafel*), has been entirely neglected by travellers. It is also remarkable that the building of Thebes is neither ascribed to the second *thinite* dynasty, nor to the first memphitic, which, as we said before, lays (according to all reports, traditions, and even historical traces) *beyond* the times historical. *A builder of Memphis*, however, *is* mentioned by Diodorus, according to a fragment of a popular tradition. According to this author, the eighth successor of Busiris II. built Memphis—then proceeds tradition: his daughter Memphis had conceived, from father Nile, a son Egyptos, a mild and just king, his successor. Busiris II. forms the concluding link of the ante-historical Thebaic traditions: he is the builder of Thebes. After him succeeded another dynasty, and the last king was the eighth of the successors of Busiris II., concluding therefore a dynasty of nine kings. His name was *Memphit*; he founded Memphis, and built a royal palace, not surpassed in after times—still, not approaching the older royal palace of Thebes." (p. 105, vol. 2.)

It was on this *very spot*—"that originated with Herodotus that part of his wonderful description of Egypt which treats of the Pyramid-epoch. Before him, the older Hecatæus had been in Egypt. What had become nearly clear by the discoveries of Belzoni, is now completely ascertained by the labours of Vyse and Perring, viz., that the regular entrances to the Pyramids were, (at the close of the original construction and the interment of the builder), shut from *inwards* by granite trap-doors, and slabs of rock; that, from that time, to their forcible opening, none had ever viewed their interior. A tablet sunk in the granite blocks of the dressing seems to have contained the hieroglyphic inscription, with the name of the buried and other particulars. The assertion of Niebuhr and Wilkinson, that the dressing was simply formed by the exterior slabs being subsequently (beginning from above) cut off at the angle of the slope, seems to be confirmed by Perring, and he adds that the surface was moreover carefully polished. The history of the destruction of these wonders of art shows, that curiosity and thirst after concealed treasures enticed the ancient caliphs, most probably, first, the son of Harun al Rashid, Mammun, to track an entrance; subsequently, especially under Saladin, the Pyramids, especially their dressing, were regularly used as quarries; in fine, the recklessness and destructiveness of the Mamelukes completed the sacrilege." (p. 149, vol. 2.)

The historical details of the building of the thirty Pyramids of Egypt, put forth by M. Bunsen, are numberless, but cannot be brought within the compass of this Journal. The biographical notice of the builders of the *two largest* pyramids will, however, interest our readers. "With the extinction of the two *Menes* lines, the southern and northern, after the death of Amchura-Bicheris the ninth king of the first Memphis dynasty,—another family, probably a memphitic one, related to the former, ascended the throne of Egypt. The first two rulers were the brother-kings *Chufu*. The elder built the second greatest Pyramid, and made a commencement of the stupendous stone wall; the largest also was probably begun during his reign. The younger brother, erected (according to Manetho) the *largest*, as a sepulchre for himself, wishing to surpass his brother by its size, as well as by the splendour and solidity of construction. He, however, disdained the dressing of the lower part with the reddish granite of Syene, which distinguishes the second largest Pyramid."

A great part of the second volume of our author is taken up with a historical disquisition on the Mœris Lake—the most stupendous, hydraulic work which has been constructed in any age. Situated at the confines of the Lybian Desert, it escaped the notice of travellers, until M. Linant, chief engineer of roads and bridges to the Pacha of Egypt, made a considerable step towards exploring it.* "Egyptian irrigation," says Dr. Bunsen, "requires two things—canals and dykes. The system of the former, in the district alluded to, may be traced out so far, that the main canal had to serve the purpose of *retaining* the water on the *upper* slope of the land, and then to distribute it to the right and left, as well as westward to the *second* slope. The canal leading on the right side to the lake, caused an immediate connection of the Bahr Jusef with the Lake, and would at least serve for the irrigation of those lands it passed through, if the waters were dammed up in it. The second system is that of dykes, for the purpose of retaining the flood-water at the height to which it had been previously raised, until the Nile slime has been deposited and fertilized the land. The irrigation of the lower parts is effected by the piercing of the dykes; and a similar system (instead of artificial sluices) we may imagine to have been resorted to during the period of Egyptian antiquity. But there were also artificial dyke gates for the same purpose." (p. 217, vol. 2.)

* "Memoir on the Lake Mœris; read before the Egyptian Society, July 5, 1842." Memoire sur le lac, etc. Alexandria, 1843; 4to., with a coarsely engraved map on stone.

What the ancients thought of this artificial *sea* may be gathered from Strabo, who says, "This nomos (*Fajum*) is the most remarkable of all, as well for its natural fertility and beauty as for the art exhibited in its construction. It comprises also the so-called Mœris Lake, almost as large as an inland sea, and of the sea-colour; its banks, also, have the appearance of sea shores. It is capable by its size and depth, of containing, at the time of the flooding of the Nile, its abundant waters, without overflowing the inhabited and fertile land; at the receding of the river, the superabundant waters return by the same channel, by one of the two embouchures; while so much as is required for irrigation, both in the lake and channel still remains." Herodotus states its circumference to be upwards of 3000 stadia, equivalent therefore to the whole extent of the Egyptian coast on the Mediterranean, an assertion which Chevalier Bunsen considers to be correct.

In this interesting locality, the tombs of Mœris and his wife, in the Fajum, north of Crocodilopolis, are yet to be adverted to. At present, only two pyramidal structures are to be seen; but the German traveller, Wansleb, had seen (1664), on these very pedestals, the fragment of a colossal statue of a king, in a sitting position. Wilkinson recognized, in these two ruins, the Pyramids seen by Herodotus; and Perring, though ignorant of the researches of Wansleb, had guessed, with great tact, the whole arrangement. He assumes the ruin to be the foundation of a truncated Pyramid. According to Pococke, the ruin with the destroyed king's statue was called by the natives *Har'm*, the Pyramid; according to Jomard, *rigl Faraun*, the feet of Pharaoh. Mr. Perring, on the other hand, told Dr. Bunsen orally, that other people still called the two pediments *Senem*, the statues; or in Arabic, *Musthamel*, the "bathed ones;" whence the former architect supposes that the pedestals, and even the lower parts of the statues, were once bathed by the floods of that fertilizing irrigation, which the great king had secured for his land and people. Our author concludes his notice of this stupendous artificial lake in the following terms;

"Thus Mœris's statue surveyed the land which, from bog and desert, he had changed into blooming fields, and converted (for thousands of years to come) into the garden of Egypt. A work lay before and around him, the equal of which for magnitude and utility the world does not know. Wall and dyke remain even now, like a work of nature, after ages of neglect; even nature seems to have been surpassed, for the Nile found, through the Lake Mœris, an efflux from his stream-bed and no longer flowed into the sea—thus supply and utilization were both calculated. This structure, nearly five thousand years' old, would alone prove the art, skill, and science of the old Pharaoh dynasty to remotest posterity, if there were no annals to testify of it."

"Such, therefore, was King Mœris's work and sepulchre. When the floods of the Nile, augmented by those of the lake, covered the land, his and his queen's statues appeared above the waters, and seemed to the beholders like the tutelary deities of the spot."

RAILWAYS. *Their Use, Progress, and Construction.* By ROBERT RITCHIE, Associate of the Institution of Civil Engineers. Longman, 1846. 16mo. pp. 444. Woodcuts.

The object of this book is to give a general historical account of the improvements which have gradually taken place in the construction of railways, and the application of the motive power *upon* them from the time of their first introduction. The work is divided into three principal parts—the construction of the railway—the motive power—and the causes of railway accidents. Under the first of these heads the writer shows how the first idea of wheel tracks of stone and iron tramways, became gradually matured and improved, till it led to the construction of railways as the universal means of land transit. This account is followed by some general views of the rigidity of iron rails, their forms and weight on different railways, and the different modes of fixing them by transverse sleepers, longitudinal sleepers, and stone blocks set at intervals; with a comparison of the merits of each system. The author generally states the arguments on each side of a controverted opinion with remarkable fairness, but in the present instance, though he has given very fully the arguments in favour of longitudinal bearers, he has not devoted quite enough space to the consideration which the advocates of transverse sleepers urge in reply.

The various shapes of the wheel flanges, the methods of passing crossings by means of points or switches, the construction of turn-tables, &c., are next detailed. Under the heads of retaining walls and viaducts, accounts are given of the size and construction of some of the principal of these works hitherto executed.

Under the head of motive power of railways, we have the history of the different improvements of locomotive engines, from the time of the experiments on the opening of the Liverpool and Manchester Railway. In considering the advantages and disadvantages of the atmospheric railways, the author is careful to state facts only and the opinions of others, without coming to any determinate opinion as to either the locomotive or atmospheric system, except that in which every impartial and competent person will concur, namely, that "it must be left to time to test their comparative advantages, for at the present time the accounts of the latter are conflicting and contradictory."

To give a better idea of the book than can be obtained from mere description, we have selected the following extract, making however a few omissions. The subject is the various forms and dimensions of iron rails:—

"Mr. Barlow came to the conclusion, that the strength of a bar should be double that of the mean strain or load. In his first report, he thought from 10 to 20 per cent. would be sufficient; that is, for a 12-ton engine, as the weight is at present distributed, a strength of 7 tons would be ample provision; and with greater accuracy of construction, a less strength would suffice; or rather, allowing the same strength, an engine of 14 or 16 tons might be passed over with greater confidence. Thus, for 12 tons' weight, with a velocity of about 35 miles per hour, 7 tons would allow a surplus strength of 16 per cent. beyond double the mean strain. The deductions from his experiments led him to recommend that the section of an iron rail for a 5-feet bearing, with strength 7 tons, should not exceed 5 inches in depth; that the head ought not to be less than 2·25 lb. per yard, and be 1 inch in depth; that the whole weight at the sections should be 67·4 lb. per yard; the thickness of the middle rib, ·85 inch; depth of bottom web, 1·66 inch; and breadth of ditto, 1½ inch; that the deflection of such a rail, with 3 tons, would be ·064 inch.

"For bearings of less width, he did not reduce the weight or size of the head, but kept it at the same section, decreasing the whole weight and depth of the rail: thus for a strength 7 tons, with a 3-feet bearing, the whole weight was 51·4 lb., whole depth 4½ inches, depth of bottom web 1 inch, breadth 1·25 inch, thickness of middle rib ·6 inch, deflection with 3 tons was ·024 inch.

"Notwithstanding that Professor Barlow expressed a strong opinion in favour of the single-flanched rail over the double,—that he could see no advantage the latter possessed to compensate for its actual and obvious defects, that he considered it inferior in strength and convenience in fixing, and that the advantage it was supposed to possess, namely, that it might be turned when the upper table was worn down, was impracticable, and that he saw no advantage in the broad bearing,—still the double-headed rail, in practice, has almost entirely superseded the single one: whether the adoption of the double one arises from affording greater convenience to the rail layer, and facilities for keying it, and the advantage of having the power of reversing it, and selecting the best side, or from the manifest advantage of a broad bearing to the rail,—this form is now generally preferred.

"The Liverpool and Manchester Railway Company has of recent years adopted a double parallel rail of a peculiar section; not admitting, however, of the power of turning it. The object to be attained in adopting this shape, is stated to be, that by having the part of the rail upon which the flanch of the wheel acts, of the same outline as the flanch itself, greater strength is given to the rail, while the other edge of the rail is lightened. These rails have been laid down at 60 and 75 lb. per yard.

"The more common and useful form of a double parallel rail, is when the segmental outline is the same at top and bottom: for although it cannot be denied that the weight of the bottom flanch does not add proportionably to the strength of the rail, nor even that the power of turning it is at all times practicable,—yet there cannot be any doubt that this form, for railways constructed on separate blocks and sleepers, presents many advantages; and besides, as the cost is nearly the same for a rail with the top and bottom flanches alike, with that where the bottom web is somewhat lighter, no hesitation can exist in preferring the former, however much theoretical deductions may mystify the subject.

"A double parallel rail, weighing 75 lb. per yard, has been laid down on the London and Birmingham, Eastern Counties, South Eastern, Edinburgh and Glasgow, and many other railways. The whole depth is 5 inches, the top and base are the same sections, 2·5 inches, the thickness of middle rib is about ¾ of an inch, or less.

"A double parallel rail has been used upon the Grand Junction and other railways, weighing 62 lb. per yard; whole depth, 4·5 inches.

"A double parallel rail, about 65 lb. per yard, of which the whole depth is about 4¾ inches, has been laid down on some parts of the London and Birmingham railway.

"A 75 lb. rail was laid down on the Edinburgh and Glasgow railway. The inner side of the chair being curved, admits of ample space for the key to wedge the rail firmly.

"The rail and chair which are now laying down on the North British railway are about 70 lb. per yard, in 12 and 16 feet lengths. The top and base are different sections, probably adopted with a view of saving in the weight, but presenting no corresponding advantages. The keys or wedges are made of oak, and are small in size.

"It seems generally agreed, that the bearing surface for the wheels to run upon, without being too heavy, or so narrow as in an additional degree to wear the wheels, should be about 2¼ inches; and hence this size of a head is generally adopted for public railways. Although, both theoretically and practically, it has been assumed, by Messrs. N. Wood, Barlow, and E. Wood, that the strongest form of rail is that of which, with sufficient depth for rigidity, the base does not contain too great a quantity of material,—and though Mr. Barlow has given a formula for calculating the section of greatest strength,—still the great object that the public are interested in, is the best form of rail for safety; and of which, while it has sufficient strength to bear upon it heavy loads in motion, the bearers should not be too far apart, to increase in the least degree the amount of either vertical or lateral deflection. When a rail possesses these advantages, its exact shape on mathematical principles is of less importance than its convenience of being easily fixed, and quickly shifted. Hence, while the single parallel rail is decreasing in practical application, the double one, from its convenience, is progressively extending. A knowledge of these facts is essentially necessary for every one engaged or connected with railways, whether he be a director or shareholder, whether an engineer or manager. With all the knowledge yet acquired, there is ample evidence of the uncertainty which still hangs around the subject; and the great expense it has already cost some of the older companies in making alterations, shows that experience to them has been dearly bought. For example, it has been shown that the Liverpool and Manchester Railway Company has had several times to alter the rails on that line; to increase the weight from 35 lb., the weight of the original rail, to 50 lb., 65 lb., and 75 lb. per yard, successively; while the London and Birmingham Railway Company, notwithstanding the advantages derived from Mr. Barlow's able report, was obliged to reduce the width of the bearings or supports from 5 feet to 3 feet 9 inches, and to increase the weight of the rails from 64 lb. to 75 lb. On other railways equally expensive alterations have been made. There is every probability, therefore, that, so long as that plan of railway construction continues, whatever may be the first cost to railway companies, a still greater weight must be given to the rails, and a still farther reduction of the width of the bearers must take place, in order to adapt the stability to increased rapidity of traction.

"It may be observed that the rails have gradually been increased in strength since steam power was introduced; the bars are usually made in 12, 15, and 16 feet lengths, with square or butt ends, and are laid end to end, the earlier complex contrivances to secure the joints being all dispensed with, and the half-lap joints now rarely used. About $\frac{1}{16}$ of an inch, at least, should be left between the ends for expansion; for it has been ascertained that a bar of 15 feet in length will expand about $\frac{1}{11}$ of an inch at 75° F. Some have, indeed, proposed to place a small piece of wood between the ends of rails, as the different expanding properties of wood and iron would fill the space, the wood expanding as the iron contracts: but such a plan is liable to objection from the wood being likely to be shaken out, and the space being left vacant. There is no part of railway construction that requires more accuracy of fitting than the joints: the squareness of the ends, and the space allowed for expansion, cannot be too carefully regulated. Instead of that, how often are seen spaces at the joints of different widths, and the ends of the bars in juxtaposition, without parallelism and uniformity of level; thus increasing the amount of friction, adding to the jolting and rocking motion, and to the risk of the wheels of carriages being thrown off the rails."

This little work contains a large quantity of information in a very small compass. The information is not perhaps quite profound or minute enough to be of great value to the experienced engineer, but the student who is commencing the subject will find here a general and compendious view of it, which will form a useful and certainly a very interesting introduction to more recondite researches.

Railway Map of England and Wales.—Messrs. Arrowsmith and Basire have recently published the large railway map of England and Wales engraved by them for the Board of Trade from plans deposited there in November last. Having only printed a few copies for the Committees of the Houses of Lords and Commons, the publishers purchased the plates from the Government, considering them interesting to the public, as giving an authentic account of all railways up to the commencement of the present time, showing those in *operation*—in *progress*—*projected*—those that failed at the Private Bill Office the end of December—and those for which petitions were not presented to the House afterwards.

A similar map of Scotland, and one of Ireland, are soon to appear. Of the map before us we can give no better encomium than by saying, that its magnificent size and the style of execution render it fully worthy of the reputation of the publishers, and of the occasion for which it was originally engraved. The size is 4 feet 9 inches by 6 feet.

OBSERVATIONS ON CAPILLARITY.

By Prof. Henry.

In 1839, the author presented the results of some experiments on the permeability of lead to mercury; and subsequent observations had led him to believe that the same property was possessed by other metals in reference to each other. His first attempt to verify this conjecture was made with the assistance of Dr. Patterson, at the United States Mint. For this purpose, a small globule of gold was placed on a plate of sheet iron, and submitted to the heat of an assaying furnace; but the experiment was unsuccessful; for, although the gold was heated much above its melting-point, it exhibited no signs of sinking into the pores of the iron. The idea afterwards suggested itself, that a different result would have been obtained had the two metals been made to adhere previous to heating, so that no oxide could have been formed between the surfaces. In accordance with this view, Prof. Henry inquired of Mr. Cornelius, of Philadelphia, if, in the course of experience in working silver-plated copper, in his extensive manufactory of lamps, he had ever observed the silver to disappear from the copper when the metal was heated. The answer was, that the silver always disappears when the plate is heated above a certain temperature, leaving a surface of copper exposed; and that it was generally believed by the workmen, that the silver evaporates at this temperature.

Professor Henry suggested that the silver, instead of evaporating, merely sunk into the pores of the copper, and that by carefully removing the surface of the latter by the action of an acid, the silver would reappear. To verify this by experiment, Mr. Cornelius heated one end of a piece of thick plated copper to nearly the melting-point of the metal; the silver at this end disappeared, and when the metal was cleaned by a solution of dilute sulphuric acid, the end which had been heated presented a uniform surface of copper, whilst the other end exhibited its proper coating of silver. The unsilvered end of the plate was next placed, for a few minutes, in a solution of muriate of zinc, by which the exterior surface of copper was removed, and the surface of silver was again exposed. This method of recovering the silver before the process of plating silver by galvanism came into use, would have been of much value to manufacturers of plated ware, since it often happened that articles were spoiled, in the process of soldering, by heating them to the degree at which silver disappears.

It is well known to the jeweller, that articles of copper, plated with gold, lose their brilliancy after a time, and that this can be restored by boiling them in ammonia; this effect is probably produced by the ammonia acting on the copper, and dissolving off its surface, so as to expose the gold, which, by diffusion has entered into the copper.

A slow diffusion of one metal through another probably takes place in cases of alloys. Silver coins, after having lain long in the earth, have been found covered with a salt of copper. This may be explained by supposing that the alloy of copper, at the surface of the coin, enters into combination with the carbonic acid of the soil, and being thus removed, its place is supplied by a diffusion from within; and in this way it is not improbable that a considerable portion of the alloy may be exhausted in the process of time, and the purity of the coin be considerably increased.

Perhaps, also, the phenomenon of what is called *segregation*, or the formation of nodules of flint in masses of carbonated lime, and of indurated marl in beds of clay, may be explained on the same principle. In breaking up these masses, it is almost always observed, that a piece of shell or some extraneous matter occupies the middle, and probably formed the nucleus, around which the matter was accumulated by attraction. The difficulty consists in explaining how the attraction of cohesion, which becomes insensible at sensible distances, should produce this effect. To explain this, let us suppose two substances uniformly diffused through each other by a slight mutual attraction, as in the case of a lump of sugar dissolved in a large quantity of water, every particle of the water will attract to itself its proportion of the sugar, and the whole will be in a state of equilibrium. If the diffusion at its commencement had been assisted by heat, and this cause of the separation of the homogeneous particles no longer existed, the diffusion might be one of unstable equilibrium; and the slightest extraneous force, such as the attraction of a minute piece of shell, might serve to disturb the quiescence, and draw to itself the diffused particles which were immediately contiguous to it. This would leave a vacuum of the atoms around the attracting mass: for example, as in the case of the sugar, there would be a portion of the water around the nucleus deprived of the sugar; this portion of the water would attract its portion of sugar from the layer without, and into this layer the sugar from the layer next without would be diffused, and so on until, through all the water, the remaining sugar would be uniformly diffused. The process would continue to be repeated, by the nucleus again attracting a portion of the sugar from the water immediately around it, and so on until a considerable accumulation would be formed around the foreign substance.

We can in this way conceive of the manner by which the molecular action, which is insensible at perceptible distances, may produce results which would appear to be the effect of attraction acting at a distance.—*From the Proc. of the American Philosophical Society.*

KENTISH RAGSTONE.

To Mr. Whichcord we are indebted for the following practical information regarding Kentish Ragstone, used by our forefathers rather largely in many of our Gothic edifices, and at the present period it is again introduced with considerable advantage; it affords, combined with dressings of Caen stone or Bath stone, an economical and, at the same time, a durable material for the construction of the walling of our ecclesiastical edifices, for which purpose it bids fair to supersede facings of white, red, and yellow bricks, and when it is judiciously introduced is very little, if any, more expensive. There is not a question as to its superior advantages in an architectural point of view.

Mr. Whichcord is an architect of extensive practice in Kent, and has had an opportunity of watching the working of Kentish ragstone, both in the quarry and in the building; he is, therefore, fully qualified to give us an opinion of its merits, which he has done in a pamphlet just published,* containing the whole of his paper, read at the Institute of British Architects, noticed in the Journal for January last, page 27, where we gave an account of the geological character of the stone, and which we now propose to follow up by adding some information regarding its practical uses.

"The larger blocks of Kentish Rag Stone of superior quality, are locally known under the name of ashlar, which comprises all work that is bedded or jointed; in fine, the stone when applied to any of the uses for which Portland or York are generally available. Stone of this description is sold by the cubic foot, and fetches a much higher price in proportion than the smaller kind.

The stone, when quarried, first has its rough projections knocked away, and for economy in transport (as the blocks cannot be sawn) is usually reduced as nearly as possible to its required dimensions. This process is technically called "skiffling," (termed "knobbling" in the neighbourhood of London, and also in the west of England,) and is performed with a heavy, double pointed hammer, such as is used in working granite. The necessity for this practice would cause great waste upon the stone, if the fragments of the better description were not available for burning into lime. The best lime, however, is usually burnt from the best stone.

Ragstone ashlar is usually dressed with the hammer, either roughly or with more care, in which state it is said to be "*roughly picked*" or "*close picked.*" In the better kinds of work it is usual to run a tooled draft round the arris of the stone, which gives to the blocks a very neat appearance; sometimes the whole face is tooled, a process which greatly increases the labour without adding to the beauty of the stone; even the best kinds are full of small hassocky spots, which show themselves upon a smooth face, turn rusty upon exposure to weather, and facilitate the decay of the stone. A building faced with tooled ashlar, even when newly erected, exhibits the appearance of bad Portland when going rapidly to decay: an evil that is not lessened by the frequency of the joints, necessarily caused by the small size of the stones, and a defect which is not so observable when the face of the work is picked. Sunk work and moulding upon ragstone should, as much as possible, be avoided, both from the great cost of executing them in so hard a material, and the rapid decay that so much wrought surface causes in this stone. The mediæval builders were well aware of this fact, and while they used ragstone extensively in the more substantial parts of their structures, preferred Caen or even fire or sandstone for the decorated portions. Caen stone is more peculiarly appropriate to be used with ragstone, on account of the small difference of the two materials in colour, a distinction entirely obliterated by time.

In using "*ragstone ashlar*" great care should be taken to have the stone laid upon its natural bed, as any other proceeding will almost certainly be followed by rapid decay; not but that I believe the stone in its soundest form to be almost beyond the influence of time or the elements, but that from the thinness of the strata, blocks of a large size can seldom be entirely freed from hassock; and even what appears to the eye as blue stone, does, for a considerable distance inward, retain the perishable nature of its enveloping crust. A block of ragstone (if the face be worked) will present, in damp weather, an appearance precisely similar to the heart and sap of timber.

When it is necessary (as in case of copings, &c.) that one bed should be exposed, care should be taken in skiffling the stone to reduce its dimensions as much as possible from the upper side, so as to expose only the soundest portion of the stone to the action of the atmosphere. In some situations, such as mullions, and door and window jambs, an unsightly appearance would be produced by too exact an attention to the beds of the stone, as the ashlar is generally too small to range with more than one course of headers. In these cases the old masons seem to have departed from their usual rule, and to have set the blocks on end so as to embrace two or three courses; but as the depth of the block required to work an ordinary jamb or mullion is not very great, it is not a difficult thing to get the whole thickness required out of the heart of stone, and where this has been done, the work will be found pretty free from decay.

Stone of the smaller layings is generally worked into headers, and used for the facing of walls, or for paving. In dressing headers for building purposes, it is common to work one side of the stone to a rough face with parallel sides, without paying much attention to the beds and joints, which often recede at an acute angle with the face, so as to bring the stones, when laid, to a closer joint. Attention, however, should be paid in building to have the stones properly pinned in behind, and carefully bonded with the work at back. Headers are generally knocked out to six, seven, eight or nine inch gauge for the height; the length and tail being determined by the size of the stone. Most headers, however, on face do not vary a great deal from the square form. No attention is paid to setting headers on their natural bed, as the appearance of the work is not so much injured by any superficial decay. It is not unusual, however, to find stones in an old wall entirely gone from this cause.

"*Coursed header work.*"—There are several modes of building with ragstone, either now in use or practised by our ancestors. That most frequently adopted in the better kind of modern buildings is the *coursed header work*, in which headers of an equal height and parallel joints are laid round in a similar manner to brickwork. There is always something stiff and formal about this kind of work, from the large size of the joints marking out each stone in distinct individuality. To make the matter worse, the work is generally finished with a raised or a sunk joint, and the mortar coloured of a deep blue colour; sometimes we see the work *even* tuck-pointed, as though it were designed to set each stone in a frame. *Coursed header work* is particularly inapplicable to the free forms of pointed architecture. If used at all, the stones should be laid in ragstone lime mortar, not *chalk lime*, and the joints simply struck. As far as appearance goes, it would be almost better that they were left rough. Chalk lime should be especially eschewed as both æsthetically and practically bad. It will not adhere to the ragstone, and the difference of colour is more offensive than when *blue* mortar is used.

"*Random coursed work*" seems to have been an improved mode of building, viz., the carrying up all the walls as nearly as possible together; this led to the practice of levelling out the work in a rough manner at every foot, or sixteen inches in height, carrying up each portion with stones of various sizes, roughly headed (as facing them is termed), and without much attention to jointing. It consequently occurred that one stone would sometimes occupy the height of two or three, while the rough sides caused continual irregularities in the joints. Great care is, however, frequently shown in fitting smaller stones to the irregularities of the larger ones, and the result of the whole is a more substantial mode of building, and greater uniformity of surface; the joints, from not occuring in straight lines, being much less observable than in header work. The bond, too, is much more complete, and an inspection of our county churches, of which most have the towers executed in this style, will convince any one of its durability.

"*Random header work.*"—There is, however, now in use a kind of approximation to "random-coursed work," that is even more objectionable than header, or rubble work; I mean "random header work." This, though only applied in inferior situations, is nearly as expensive as coursed header work, which *it is* in fact, only done in a more slovenly manner. It is executed with headers of the ordinary description, but of unequal sizes, as though attempted to be carried up in courses. The joints of the mortar are generally left *rough*; this lessens the bad effect that would otherwise be produced by the *arrangement*, or rather *no arrangement*, of the headers; but when the whole is done, the courses are only crooked, when, to all appearance, they were intended to be straight.

"*Random work*" is a style now much used in ornamental buildings, such as lodges, cottages, almshouses, dairies, &c. &c. It is commonly executed with unsquared stone, with the joints carefully fitted together and pinned in with smaller stones. When this description of work is well done, the joints never run in continuous, horizontal, or vertical lines, and every stone ought to break joint. The appearance is very good, but considerable time and much skill and nicety are required for its performance. Of course, from the mode of building in this style, it is scarcely applicable to large works, both because there is a certain littleness of appearance about it, and that it is wanting in the requisite stability.

"*Rough random work*" may be placed in the same class as that just described, but executed in an inferior manner. In this description of work it is not customary to give the stones any dressing at all, but merely lay them together with as much compactness as their irregular forms will allow; filling in between the larger stones with smaller pieces. When this kind of work is well done, it will be found very durable, and it is not an uncommon practice, where ragstone abounds, to build inclosure walls in this manner, but without using mortar or any cementing substance; and walls thus constructed will last for a considerable length of time. It is the cheapest kind of building, as there is less waste in the stone, and the expense of heading is saved, besides that a good workman will do more of it than of header work in the same time. Foundations are usually laid in rough random work, and it is applied to inclosure walls and inferior buildings.

Galleting.—It is customary in many parts of the county to "*gallet*" the joints of ragstone work; that is, to stick small "stone pinners" as thickly as possible in the pointing mortar. Galleting* is applied indifferently to every description of work, and it has the good effect of securing the joints in a great degree from the action of frost, (?) and in some situations it improves the appearance of the work.

Mention has already been made of the use of hassock as an inside lining to walls built with ragstone It is usually roughly squared, an operation that should never be neglected, as the crumbling nature of the stone

* A Pamphlet, "Observations on Kentish Ragstone as a Building Material." By John Whichcord, jun., architect. London: John Weale.

* The masons call the pieces of stone chipped off by the stroke of the chisel "galets," probably from "galette" (French) a small cake.

would endanger the security, if the work is exposed to the unequal pressure that would result from the use of irregularly shaped stones. Care should be taken not to place hassock in situations where it is exposed to very great pressure. For jambs, arches, &c., sound bricks are best to be used with it. When the work is of a superior description, and the masonry intended to show inside, as is sometimes the case, the hassock is capable of being worked to a very good surface with close joints; and as it can be procured in blocks of a considerable size, hassock is very applicable as an internal facing.

Ragstone Paving.—In Kent, ragstone is much used for paving. In most of the towns of this district the streets are laid with ragstone headers, in the same manner as granite is used in London; stables and yards also are paved with headers, which are generally preferred for these purposes to any other paving material. It is better, however, in public thoroughfares where exposed to heavy draughts, to make the kirb stones of granite.

The durability of buildings erected with ragstone depends mainly upon the qualities of the *lime* from which the mortar is made; it can only be depended upon when executed with mortar made with lime burnt from the ragstone itself; this mortar becomes in the lapse of time so very hard as to form almost one and the same body with the stone. Many buildings may be seen that have been erected a number of years that retain the original pointing in the joints, fair as when first finished, and so hard as to resist the blow of a chisel.

Ragstone lime is usually burnt in inverted conical kilns from seven to ten feet diameter at the top, such as are ordinarily used in this neighbourhood in common for burning either chalk, or ragstone lime. The process is the same in either case, but the ragstone requires more fuel for its conversion into lime. A kiln of the ordinary size will burn from one and a half to two loads per day, each load averaging 36 bushels. A load of lime requires for its production about four chords of stone, and one third of a ton of coals.

Although ragstone lime may be said to be of a very strong nature, it will not take so great a quantity of sand as most other limes; two parts of sand by measure to one lime, is the proportion generally used. If an excess of sand be employed, the mortar becomes short, and drops from the trowel. Mortar made from ragstone lime never exhibits those properties common with the chalk limes, and technically known as "fatty."

A concrete of ragstone ("Beton"), and ragstone lime, is much used in this part of the county; the stone is broken small, no piece larger than a hen's egg, with half its bulk of sand added, a quantity about sufficient to fill up the interstices of the stone. The usual proportions may be stated at six parts of stone, two of sand, and one part of lime. It is needless to say that the lime should be well burnt, ground, and used hot. A very good practice is to dispose the broken stones and sand in layers, alternately, with lime, in the proper proportions of each, then to be picked, and twice turned over, and a sufficient quantity of water added to reduce the mass to a proper consistency. In other respects the use of ragstone concrete is subject to the same regulations as concrete made from ballast.

Prices.—Subjoined is an average list of prices of stone of various kinds in the quarry, and the rate at which it can be supplied in London alongside the wharf, together with some prices paid for labour upon the stone:—

	At Quarry.			In London.		
	£	s.	d.	£	s.	d.
Rough rag, per ton		1	6		5	0
Headers, per ton		8	0		12	6
Rag for breaking, per chord		1	6		5	0
Rag for lime, per chord		2	6		6	0
Hassock, roughly squared, per chord ..		3	0		6	6
Hassock, best, per chord		4	0		7	6
Ashlar, scapled out, per foot cubic ..		2	0		2	9
Ashlar, large scantlings .. .		2	6		3	3
Lime, per load of 36 bushels ..	1	0	0	1	4	0

It would, in most cases, be cheaper and otherwise preferable to burn the lime in London.

Prices of labour on ragstone in Maidstone.

	s.	d.
Beds and joints (usually measured as plain work)		8
Plain picked face		8
Plain close picked in a superior manner		10
Tooled face	1	4
Sunk work	1	0
Sunk and tooled	1	8
Moulded	2	6
Circular plain	1	0
Circular and tooled	1	8
Circular sunk and tooled	2	0
Circular moulded and tooled	3	6

For ragstone concrete, the quantities may be stated at eleven chords broken rag, one hundred of lime, and four bushels of sand, for ten yards of concrete. Breaking the rag may be reckoned at one shilling the chord.

FICTILE MANUFACTURES—POTTERY AND PORCELAIN.

At a meeting of the Archæological Institute, May 1, a very interesting paper, by Mr. Birch, was read, on "*Fictile Manufactures, including Pottery and Porcelain of all countries and all periods.*" The subject excited great interest, and caused the table to be covered with numerous and valuable examples of the art, from the earliest to the most recent period. Specimens of Babylonian, Greek, Roman, Mediæval, Italian, and German pottery were grouped according to date; and, to continue the series to our own time, a large case presented specimens from the collection of the late Enoch Wood, and the manufactory of the Messrs. Minton, illustrative of the progress of the Staffordshire manufactories, from the time of Queen Elizabeth to the present day. Among the contributors to the exhibition were the Marquis of Northampton, Earl Spencer, Viscount Strangford, Sir Philip Egerton, Bart., Mr. Talbot, Mr. Jekyll, Mr. Bidwell, Lady Brancker, Mr. Strutt, M.P., Mr. J. W. Burgon, Mr. Dilke, Mr. Whincopp, Mr. Cole, Mr. Mayer, of Liverpool, the Rev. H. Addington, Mr. Gowen, Dr. Bromet, and Mr. Engleheart.

Mr. Birch commenced by giving a brief, but comprehensive *history of ancient Fictile Art.* He observed that the most ancient pottery extant was, probably, that found at Babylon and Nineveh; some of this was of a fine red clay, and at the latter place varnished and enamelled ware, probably of the time of Sardanapalus, had been found in the recent excavations of M. Botta. It was, perhaps, from Babylon that Fictile Art was transmitted to the Egyptians, who appear to have exercised it at the earliest known period of their history. Vases are found in the tombs in the vicinity of the Pyramids, of a date probably 2000 B.C., of baked clay, some glazed and of various colours. The ornaments of Egyptian pottery consist chiefly of flowers; with occasionally a few human and animal forms traced in black outline, but the designs are coarse, and show little taste or invention.

Mr. Birch proceeded to describe the *Fictile Art of Greece and Italy.* The vases of the archaic period are, 1. the Athenian, of a light and fine clay; the ornaments are on a fawn-coloured ground, and consist of bands and Meander borders. Animal forms occur but seldom in these designs—the human form never. 2. The black ware, ornamented with figures in relief, found throughout Etruria; and which we must consider the work of the Etruscan people, from about 660 B.C. to 416 B.C., when their power began to decline. The subjects of these vases are the most early Greek myths; some of the figures exhibiting monstrous combinations, borrowed from the oriental religions, and to be met with on the Babylonian cylinders and in the art of Persepolis. The material of this ware is black throughout. Besides this class of vases, the indigenous product of Etruria, we find in that country specimens of the Fictile Art, imported by the Greek settlers, and resembling the vases found at Corinth by the traveller Dodwell. These are known by the name of Nolan-Egyptian or Phœnician. The ground of this ware is a pale straw colour, with animals painted in maroon; the details and inner markings being given with the point of the graver, and some accessories picked out with crimson. The date of these vases is probably from 600 B.C. to 540 or 520 B.C.,—corresponding with the mythic arrival of the Greek potters, Eucheir and Eugrammos, said to have been brought to Etruria by Demaratus, from Corinth. To these earlier specimens, succeed the vases with black figures laid on a light ground. These are made of red clay, tinted with an orange-coloured varnish: the design was drawn in slight dark outline, or traced with a point, and the whole internal part of the figure filled up with black. The light inner markings of the figure were then incised on the black pigment with a graver, which cut down to the yellow ground of the vase itself; the accessories being picked out with purple and white, as in the class last described. These vases are often accompanied by inscriptions recording the name of the artist, the maker, that of the person to whom dedicated, and of the personages represented,—which are particularly valuable as evidence of the early forms of the letters.

The subjects of these vases were all taken from the most ancient Greek legends,—the Capriaca, the Iliad and Odyssey, the Hymns of Homer, and the works of Alcæus and other early Greek poets. The figures on them are still drawn in the archaic style, and resemble those on the early coins of Sybaris, Caulonia, Tarentum, and other places in Magna Græcia. This class of vases is found associated with Etruscan art and inscriptions in the tombs of the Etrurian Lucumos. They also occur in Greece Proper,—but with certain differences of fabric which forbid the supposition that they were all manufactured there, and imported thence to Etruria. It is more probable that, while those found in Greece itself are the indigenous product of that country, the Italian vases were the work of the Greeks who settled in the Etruscan cities.

Second Period.—After the above archaic period, succeed the vases of the best time of *Greek Art, from the epoch of Phidias and Polygnotus*, B.C. 470, *to the archonship of Euclides*, B.C. 404. These vases have red figures on a black ground. The material, like that of the earlier vases, is a fine red clay. The artist, having traced out the design, then filled up the whole of the background with the black pigment, following the contours of the group. The inner markings of the figures, which in the former style had been incised with the graver, were sketched in with a brush dipped in the black pigment which formed the ground. This change in the technical process gave scope to the freer and more refined treatment to which the Art of the period had attained.

The subjects of these vases are apparently suggested by the works of the great painters of the day. They chiefly represent myths; historical subjects are rare, and seldom of later date than the time of Cyrus. Representations of Crœsus on the funeral pile, Musæus, Anacreon, and the Athenian Codrus, have been found. In the inscriptions of these vases, the use of the E and O, instead of the H and Ω, affords a strong presumption that their date is earlier than the archonship of Euclides, B.C. 404,—the recorded epoch of the introduction of the double letters into the Greek alphabet. The finest specimens of this style are from Campania, Canino and Vulci. Of the Athenian school of pottery contemporary with these vases we have examples in the *lecythi* buried with the dead, and the *alabastra*, or phials for unguents, so called from the material of which they were originally made. They are of a fine red clay, covered with a white pigment, on which designs were traced in black, sienna, brown, or scarlet. The subjects of the *lecythi* are, principally, the meeting of Electra and Orestes at the tomb of Agamemnon, and other scenes from the Oresteid of the three tragedians. On the *alabastra* are represented the meetings of Athenian ladies and their lovers. Besides these kinds of pottery, the vases with red figures on black grounds are also found at Athens,—but are not so peculiarly the product of the Attic school.

The *third period of Greek Fictile Art* may be considered to range from the close of the Peloponnesian was, B.C. 404, to the time of Alexander the Great, B.C. 333. To this time belong the fine vases of Apulia,—particularly those of Ruvo, the ancient Rubastini. Among the most beautiful examples may be mentioned the vase of the potter Meidias, in the British Museum, with the subject of Castor and Pollux carrying off the daughters of Leucippus,—the vase with the subject of the Toilet of Aphrodite, belonging to Mr. Rogers,—and that with the myth of Dionysos and the Camel, the property of the Duke of Hamilton. The design, in these vases, is characterized by greater freedom and technical skill in drawing, and more complexity of grouping; the lines of the composition are more flowing and luxuriant.—This fertility of invention and dexterity of execution immediately preceded the complete decadence of vase painting. In that part of Italy now called the Basilicata, a coarse style arose after the time of Alexander the Great;—the extant specimens of which enable us distinctly to trace the progressive decline of the art. Clumsy, full forms, like those of the Flemish school of painting, were substituted for the graceful proportions of the earlier Greek style; the ornaments are crowded and ill designed, and the subjects almost limited to the Dionysiac rites,—then very prevalent in Italy. The taking of Syracuse, by Marcellus, 212 B.C., may be considered the final epoch of the art of Greek vase painting; after which time it is probable that the manufacture of them ceased.

From a survey of the history of Greek Fictile art, it appears that, in each successive period, the subjects represented on the vases were supplied from the myths commemorated in the popular poetry of the day. It is remarkable, that the epoch when the art of vase painting ceased is distinguished in the history of the Greek mind by the extinction of poetic invention, the corruption of taste, and the decay of ancient faith and regard for national tradition. It would seem that Fictile Art obeyed the general law of national decadences; and that when the subjects of the vase painter ceased to be of popular interest, his art was no longer needed.

Mr. Birch illustrated his remarks by the fine collection of Greek vases on the table before him; and, after describing the painted vases, called the attention of the meeting to three fine examples of the black Greek ware of the latest period from Benghazi, the ancient Berenice, near Tunis,—one of which had an inscription of palæographic interest. These rare specimens were exhibited by Mr. Bidwell.

Mr. Birch then proceeded to give an account of some varieties of Roman ware found in this country. 1st. The so-called Samian or red ware, apparently imitated from the fabric of the early Etruscan black ware. It is ornamented with reliefs, the whole vase being either cast in a mould, or portions of embossed work laid on the plain surface. The clay is red, and apparently an artificial compound; it is generally glazed. The reliefs are commonly hunting subjects, but are sometimes mythological. This ware is found in great abundance in Italy and throughout the Roman provinces. It is called by the Roman writers Aretine ware, from Aretium, or Arezzo,—where a celebrated manufacturer of it continued probably till the 8th century, A.D.—This ware is generally stamped with the name of the potter, who appears to have been of servile condition, and occasionally of a barbarous race. The recurrence of the same potter's name in the specimens found in England, Holland, and other parts of the Roman Empire, would lead rather to the inference that it was all issued from one or more great central manufactories in Italy; though it has been strongly maintained that the specimens found in Britain and other provinces were the product of native potteries. Specimens of this ware were exhibited by Sir Philip Egerton, Bart., from Northwich, in Cheshire,—where a Roman pottery is supposed to have existed,—and also by Mr. Talbot.—Mr. Birch proceeded to point out and compare a variety of specimens of the coarse yellow, dark blue, unglazed red, black, and light red terra-cotta Roman ware,—chiefly from the collection of the Marquis of Northampton.

Some interesting examples of *Celto-Roman ware*, recently discovered at Harpenden, Herts, were exhibited by the Rev H. Addington. Mr. Birch pointed out the distinction, in fabric and material, between these works of the Romanized Britons and the genuine British ware of ruder and coarser character, found in barrows. Excellent types of the latter were exhibited by E. Strutt, Esq., M.P., and by Sir Philip Egerton, Bart.

Among the specimens illustrative of *mediæval pottery* may be noticed a remarkable fragment from the collection of Mr. Whincopp. It appeared to have formed part of a vessel ornamented with a Gothic architectural design, in high relief, and bore a very brilliant green glaze.

The specimens of *Maiolica, or Faenza ware*, contributed by Mr. Mayer, of Liverpool, and Mr. Gowen, were numerous and good. The Secretary, in alluding to them observed, that Dr. Klemm, of Dresden, was of opinion that this ware was first made subsequently to the introduction of Chinese porcelain into Europe, by the Portuguese, in 1518. The earliest manufacture was at Faenza; but Urbino and Sienna became afterwards celebrated for it. It has been supposed that many of the designs are from the hand of Raffaelle himself; but although a letter from the great painter to the Duchess d'Urbino has been cited, stating that the drawings ordered by that princess for porcelain were in progress, it is probable that most of these subjects were furnished by engravings after the great masters. Mr. Mayer also exhibited some curious landscapes in terra cotta, which he purchased in Calabria, where they were made; but he had not been able to ascertain where the manufacture was situated, except that it was in the "interior." Mr. Octavius Morgan, M.P., with reference to these specimens, made a few remarks on the terra-cotta decorations of the Fürstenhof at Wismar, in Mecklenburg,—which he considered to be of Italian workmanship.

The discussion was closed by Mr. Cole; who observed upon the examples illustrating the progress of the Staffordshire pottery, ancient and modern, procured by Mr. H. Cole from an extensive collection made by Mr. Enoch Wood, a cotemporary of Wedgewood—and from the works of Messrs. Minton. Among the modern specimens were a copy of the Portland Vase, moulded the size of the original, and reduced by firing; a Sleeping Figure, after Dresden China, with lace introduced; Encaustic Tiles (of the revived manufacture of Messrs. Minton) of three colours, similar to those making for the new Houses of Parliament;—and other interesting specimens of this branch of our native manufactures.

Sir Philip de Grey Egerton communicated an account of the *discovery of a sepulchral urn in a tumulus on Delamere Forest;* it is of earthenware, apparently slightly baked or sun-dried. The marks of the lathe are visible in the interior; but, for want of support while the material was soft, the form of the vessel is not symmetrical. Its largest circumference is 2 ft. 11 in.; diameter of the foot, 5 inches; height, 1 ft. 1 in. It is rudely ornamented on the upper part with parallel lines drawn diagonally in various directions.—Mr. Willement sent for inspection a plaster cast from part of the iron-work which formerly inclosed the monument of Queen Eleanor, in Westminster Abbey. Although rough, it was sufficient to show the great beauty of the original. A general sketch of the whole screen is given in "Carter's Ancient Architecture," Vol. 2, pl. vii.,—in which the juxta-position of the several varieties of patterns is shown. Mr. Willement considered this work to be quite equal in design and execution to the more celebrated iron-work on the doors of Notre Dame, at Paris; and expressed a hope that, at the recommendation of the Institute, the Dean and Chapter of Westminster might be induced to restore this beautiful work of Mediæval Art to its original situation.

THE GAUGE COMMISSION.

Analysis of Evidence given before the Royal Commissioners appointed to investigate the subject of the diversity of Railway Gauges.

Robert Stephenson, Esq.: Witness's father, Mr. George Stephenson, was chief engineer of the Manchester and Liverpool Railway, completed in 1830. The gauge of 4 feet 8½ inches was adopted by his father, as it was the original gauge of the railways about Newcastle. The Manchester and Liverpool was the first line in this country worked by locomotive engines. After the Liverpool and Manchester had been established, it was considered imperative that all the lines in that neighbourhood should be of the same gauge.

It is difficult to say where a break of gauge in the northern lines could have been made with the least inconvenience, as it involves the question where is the line of minimum traffic.—When travelling on the Manchester and Liverpool Railway, before laying the gauge of the London and Birmingham, it appeared to witness, as an engine-builder, when called upon to construct engines of greater power, that an increase of three or four inches in the gauge would have assisted him materially, but since, the improvements in the mechanism of the engines have rendered that increase quite unnecessary; they have ample space and to spare. In the arrangement of the machinery, which is the main question, having reference to the width, the working gear has been much simplified, and the communications in the most recent engines between the eccentric and the slide valve have been made direct communications; whereas formerly it was made through the intervention of a series of levers which occupied the width. With reference to the increase of power, the size of the boiler is in point of fact the only limit to the power, and they have been increased in length on the narrow gauge; the power is increased by increasing their length both in the fire-box and in the tubes; in fact the power of the engine, supposing the power to be absorbed, may be taken to be directly as the area of the fire-grate or the quantity of fuel contained in the fire-box. No inconvenience results from lengthening the engines to their present extent, and their steadiness is increased; they are at present 12 feet between the front and hind axles. The increase of length between the axles renders the engines less liable to get off the rails; the short engines on four wheels were liable to violent oscillation when meeting any inequality, the front wheels being sometimes actually lifted off the rail; believes the accidents on the Brighton line and on the Brentwood inclined plane were attributable to this pitching motion. The thickness of the crank of the original engine on the Manchester and Liverpool was 8½ inches. There were various plans of reversing the engine at that time. Every engineer, in fact, at that time, had his own plan; some were extremely complicated, requiring time for the reversing to be effected; they moved in fact, the eccentric. For a long time they moved the eccentric, which slipped upon an axis, and thereby moved the eccentric from one side of the axle to the other, and consequently reversed the engine; but it required a lateral motion of something like 3½ inches; and there being two eccentrics, of course, the mere act of changing the gear occupied 6 or 7 inches of the axle, independent of the more bulky construction of the apparatus itself. The long engines, if kept within 12 feet, are not more likely to get off the rails at curves than short ones.

The resistance in passing round curves is materially affected by the width of the gauge. In the collieries about Newcastle, where the 4 feet 8½ gauge prevails, wherever they come to any mining operations where the power to be used is that of a horse or man, they immediately reduce their gauge, because they want to go out and in amongst the mines with very sharp curves, and the wide gauge would be quite impracticable amongst those. In fact, the small carriages that are used in the mining operations are upon a gauge of about 20 inches, and they go round curves under ground of about 10 or 12 feet radius; and they could only work such mines by such a gauge. It is quite obvious that the width of gauge must limit the curve. In the case of every gauge at a sharp curve, the outside and the inside rail are quite brightened by the sliding motion, because the one set of wheels has to slide forward to keep pace with the other, and the others have to slide backward. In fact, when going round a curve, both operations have to take place,—the sliding backward of the one set and the sliding forward of the other. Of course, as you increase the width of the gauge, the difference between the two becomes augmented.

Is chief engineer of the Northern and Eastern Railway, and was at its construction. Adopted the 5-feet gauge in consequence of its being brought into connection with the Eastern Counties line, which had been laid down with that gauge by Mr. Braithwaite, and with the same view he laid down the 5-feet gauge on the Blackwall, in case there should be connection between them hereafter. The gauge of the Northern and Eastern and Eastern Counties lines has recently been altered under his direction; when the extension of the Northern and Eastern was considered, and that junction with the narrow lines in the Midlands would take place, a change was thought absolutely necessary, and the same change was also decided on for the Eastern Counties, from the inconvenience of blending two gauges at the Shoreditch station; the expense of a separate carrying establishment would have been greater than the cost of alteration, which was £52,000. Of course it involved the necessity of working upon a single line of rails; the establishment was divided into two parts, one of which was retained as available for the 5-feet gauge, whilst the other half was altered to be ready to work upon the other line, which had been converted into the 4-feet 8½ in. gauge, therefore the alteration from one gauge to the other was to take place in one night, in fact, between the two trains, the last at night and the first in the morning. The whole distance was 86 miles. The operation occupied about six weeks altogether, but preparations were made beforehand. The alteration was made entirely under his superintendence, and the rails being on transverse sleepers facilitated it materially. No new rails were required, and the boilers being of the same size as those on the 4 feet 8½ in. gauge, the engines could be converted.

Considers it would be advisable to run the same carriages from Euston-square to Edinburgh and Glasgow, were a railway complete. There are men at different stations to see that nothing is wrong, and the carriages, both for passengers and goods, are now so substantial, that they may run many thousand miles without anything but greasing. Goods wagons go at less velocity, and would probably stand it better. The carriage is now much more judiciously constructed than formerly. The strength of carriages conduces very much to safety in case of accident, and the plan of making the under frames of carriages of wrought iron instead of wood, will be carried out to prevent the harm at present done by splinters. Is projector of the Chester and Holyhead Railway, and will use the 4 feet 8½ inch gauge, that carriages may run from Euston-square to Holyhead; any change would interfere with communication to Ireland. His father and he were consulted as to the lines from Antwerp to Brussels, and from Liege to Ostend, and he was connected with the Leghorn and Pisa, and recommended the 4 feet 8½ inch gauge, as it had been found in this country to answer every purpose. An inch or two, more or less, would have involved a different construction of engines, and he saw no reason for altering that which had been established by experience. Was consulted on the Belgian Railways and on the Leghorn and Pisa. When giving his opinion as to the Belgian lines, the Great Western was not opened, but in reference to the Italian line he had seen both gauges in operation.

Is not aware of any advantage the Great Western possesses, and it has several disadvantages; the additional expense of construction, as in embankments, cuttings, tunnels, bridges, and viaducts, and also in carriages, engines, tenders, workshops, and stations, everything being on an increased scale. The sliding-frame system has to be introduced instead of turn tables, so that the management of the station is more expensive. Thinks the tear and wear of the carriages on the Great Western is as much as on the narrow lines, and the resistance of the wide carriages is greater; there is more friction of the wheels on the rail to be overcome. The increased expense of the carriage department on the wide gauge would not be in the haulage per mile, but in the fixed establishment of engines. Even the increased boiler (4 feet 9 inches) of the Great Western would as nearly as possible go into the narrow gauge. While he thinks the Great Western has no advantages by the wide gauge, its introduction has involved the country in great inconvenience; if a meeting of gauges takes place in the midst of great traffic, canals would have a decided advantage over railways; the system of boxes and loose-bodied wagons for the transfer of coals has been tried and failed. The loose-box system involves the necessity of increasing the number of carriages on the railway very materially. At Erewash the coal-owners could not avail themselves of the railway, and sent the coals by canal. Coal-owners would prefer transferring their coals from railway to canal, to moving them from one railway to another, on the loose-box system, as by the latter they would lose control over their boxes; they would prefer the transfer by hand, from one railway to another, to loose boxes. The American railways are universally of the 4 feet 8½ inch gauge. There is a railway from Basle to Strasbourg of 6 feet 3 inch gauge, but parties there deeply regret the alteration, as they look forward to a transfer at each end. There is a line laid down by Deridder, from Ghent to Antwerp, of 3 feet 9 inch gauge; travelled with him on part of that line from Brussels. Has seen at the Paddington terminus the modes proposed to supersede the necessity of removing goods and passengers at the junction of different gauges, and believes it would answer the purpose as far as machinery could, but seeing one or two transferred does not convey the amount of inconvenience incident to transferring 100 coal wagons. The other mode of transferring by running the train on another set of trucks, would increase the dead weight to be drawn, so as to be highly objectionable, and the increased height would prevent some classes of goods from getting through the bridges and tunnels. The London and Birmingham goods-wagon, properly laden and placed on the Great Western truck, could not pass under their bridges. The expedient at the Great Western terminus for diminishing and widening their gauge of wheels may be safe, but being complicated, he thinks it would not keep in good order; it would also be an expensive arrangement. A modification of the sliding axle was tried on the Newcastle and Carlisle, and soon abandoned. Has not been able to think of any expedient to avoid a transfer; he has seen various ones contrived; the one by Mr. Harding, of the Bristol and Gloucester, is as good a mechanical expedient as any, but that would be so objectionable as to lead to the actual transference of goods in preference. An arrangement at the Birmingham termini for lifting goods wagons from one level to another is the simplest operation, but if they had to be put on different wagons, the evil would be very much aggravated; even with regard to Birmingham, the inconvenience of the lift is so great, that it is to be abandoned, and an inclined plane substituted.

Is still a locomotive engine-maker, and is of opinion that the 4 feet 8½ inch gauge gives ample space to get the utmost power necessary for working ordinary trains; at present there are, he believes, more powerful engines working on the narrow than on the broad-gauge lines. The cylinders of those engines are 16 inches in diameter, the length of stroke is 24 inches, and the wheels vary from 4 feet 6 to 4 feet 9 in diameter. They are all six coupled; and those engines are as heavy as the present rails will bear. They weigh from 22 to 23 tons; I believe the same weight as the Great Western engines. There is now as great a weight upon six wheels upon the narrow gauge as ought to be put upon 6 wheels; and that will be hereafter the limit of power, not the width of gauge; engines may be built upon the wide gauge, no doubt, heavier and larger in dimensions, and more powerful, but then you must make a road to support it on purpose. The weight of the rails is 75 pounds to the yard; 65 have been used. The width between the bearings varies from 3 ft to 2 ft. 9. Thinks the narrow-gauge lines best calculated for carrying weight without injury to the road, and the transverse-sleeper system is better for keeping the rails in order than the longitudinal bearings. The expansion and contraction of the iron tend to disturb the action of the sleepers. Instance on the Peterborough line, where the rails had been laid too close, and acted on by the heat of the sun, raised the sleepers three feet into the air. Locomotives can be manufactured for the narrow gauge capable of attaining as high velocities as those on the broad; they are now running upwards of 50 miles an hour, with engines not made for maximum speed. No difficulty in making a narrow-gauge engine to take 40 tons at 60 miles an hour, or more; the engines on the Great Western were made for greater speed, but the average on it was the same, or a little under the Northern and Eastern.—The average speed of the Great Western is greater than on the London and Birmingham, except for mail trains, which are precisely alike.—Has worked the express trains on the narrow lines with as much economy of coal &c., as on the Great Western. The express engines on the Birmingham are smaller than others, weighing only 12 or 13 tons, and costing about £1300.—Should recommend those weighing 17 or 18 tons, and costing about £1650. Thinks the public safety would be endangered by having the bodies of the passenger carriages moveable at a change of gauge; any slight collision, not otherwise dangerous, would throw them off, besides the risk of porters neglecting the fastenings of each.—Would never incur the responsibility of having the bodies separate from the under frames, as, besides other objections, the under frames would be more liable to derangement.—The complexity of the broad and narrow gauges in the same station would be great; the turn-table, a most invaluable machine, must be abandoned.—Combining two gauges, by laying the rails of one centrally within the other, would get rid of some of the difficulties, but not at stations. Turn-tables could be used, but already in the wide-gauge system they are beyond the pale of turn-tables, from the distance between the fore and aft axles of wagons.

In changing from a narrow to a broad-gauge line, believes the least evil is to transfer everything, changing the carriages and moving the goods by hand; with reference to general merchandize, has heard Mr. Brunel express the same opinion. Thinks it would be better to have two rails for the narrow laid within those of the broad gauge, than to have only one, and to use one of the broad gauge rails; as in the latter way, the two trains could not accompany each other, the centre of gravity not being on one line. If the engine were at the head of the trains, it would be of less consequence than if they were propelled from behind. A double system would be required to drive each carriage from the centre, and this is a matter of serious expense. Witness would lay down the narrow within the broad gauge, on the transverse sleepers, and the cost would be about 4000*l.* a mile, or more, in addition; Mr. Brunel estimates a single line additional at 2500*l.*, besides the extra cost of station. This is on the supposition that the broad gauge is first laid down on transverse sleepers, but the expense would not be materially different in either case. The rails would not be packed well with longitudinal sleepers, on both systems. In adding a pair of rails within the broad-gauge, witness would lay down the transverse sleepers independently; for with other longitudinal sleepers, there would not be room for another bulk like the present, and the ballast of the weight would not be in the centre. Could not mix the systems of sleepers, on account of the length of the transverse, which would almost cut the longitudinal in two. It would be impracticable to lay down the broad on the narrow gauge, without sacrificing one line in tunnels, which would, from danger, amount to a prohibition. On the narrow gauge 24 feet are required for tunnels, and on the Great Western 4 feet to 6 feet more. Four feet is the minimum space between the two, just room for a man to stand, and the same spaces at each side of the tunnel, and any diminution would be fatal. Recesses might be made at intervals, to meet a diminution, but a man might not be near a recess when the train came. Recesses could be made after the tunnel is formed, but in many cases the brick-work would thereby be much injured. Impossible to place the broad gauge on the London and Birmingham, without enlarging the tunnels and closing the line for two or three years. Would rather make a new one than enlarge the present Kilsby tunnel. A cutting could not be kept open there, and it would be a gigantic work. With reference to the present and future meeting of the broad and narrow-gauge lines, does not apprehend much interruption to the express and other passenger trains at the points of junction, if they are made at the proper places; thinks Bristol and Oxford two places where the two gauges ought to meet, as at these two points he believes there is the least quantity of cross traffic; this explained by witness.

The principal Midland Counties traffic, from Rugby to the Great Western, supposing the double line were constructed from Oxford, would be coals going towards Oxford, and corn coming back. Looking to Southampton as the port, it would only require, supposing the narrow gauge carried down to Oxford, a line from Oxford to the South Western to complete the narrow gauge system over the kingdom, as far as Southampton is concerned; the Great Western Company have a line from Reading to Basingstoke, and if that were laid on the narrow gauge, and the double system from Reading to Oxford, there would be no break in the country at all; commercially, Southampton, London, Bristol, and Liverpool, would interchange with each other, and with the manufacturing districts, by the same carriages. No extension of the wide gauge towards the London and Birmingham would relieve Lancashire or Yorkshire from a change of gauge, but an extension of the narrow from Oxford to Basingstoke would relieve the whole question of embarrassment. The Great Western Company can be compelled to lay down the double gauge from Rugby to Oxford, and on the greater portion from Wolverhampton to Oxford, and to Worcester, as they agreed to do that. The loss of time in transferring a passenger train at Rugby to go to Oxford on the broad gauge, would depend on the amount of passenger traffic; it is a point of small passenger traffic; it may be a large one of coals and corn; the extension of the wide gauge into that district must multiply the points of junction of the two gauges, and the chances of interruption: passenger trains could not be changed in less than half an hour. Has experienced the inconvenience of changing carriages, and scrambling for luggage on the Belgian railways, at Malines. Was detained the last time about half an hour. If the change of gauge took place at Rugby, a new station would be required.

With regard to agricultural traffic, at any point of change, the beasts would require to be grased before removing them from one carriage to another, and is afraid the loose bodies would be required for pigs; they could not be managed otherwise; they must be lifted *en masse.* The wagons themselves upon the narrow gauge vary from 2 tons 10 cwt. to 3 tons; some recent large ones run as far as 3 tons 10 cwt., and they will carry 5 and 6 tons of goods. I think the latter is as near two to one as possible; that is, that if the dead weight is one, the useful weight is two. The difference is here against the broad gauge; the trucks for intermediate traffic seldom average more than a ton each, so that all the intermediate traffic on the Great Western is carried on with trucks of five tons, with one ton of goods in them. As railways extend into every corner of the country, the advantages of the narrow gauge would be most apparent, and as the wide is more expensive than the narrow, the former would limit the ramifications of railways. The narrow gauge wagons are infinitely superior for mineral traffic, particularly coal; if the mixed gauge system be allowed to extend in this country, the charge on coal will amount in many cases to a prohibition. Thinks the broad gauge has a disadvantage as to horse-boxes; their motion is sometimes fearful; they want length with reference to their width, while on the narrow gauge a carriage of the same length might be very steady. Prefers the narrow gauge passenger carriages, carrying three in width, to those of the wide, carrying four; the latter are cold in winter, and want ventilation in summer. There has not been so much attention paid to the construction of the narrow gauge passengers carriage as to the broad, but the narrow could be made 6 feet high, so that a person might stand up in them. The lowest longitudinal distance between the axles of 4 and 6-wheeled engines on the narrow gauge, is 10 feet, and the highest 12 feet 9 inches; the last are too long; witness adopts a maximum of 12, and a minimum of 10 feet; relatively the centre of gravity is the same height in both gauges. Though there would be great difference as to the cost of constructing the broad and narrow lines, cannot say there is any difference in the cost of working. Whether the traffic be much or little, it is merely a question of expenditure of power, and though the most powerful engine is cheapest to work with a proportionate load, each may have engines of the same power.

The wide gauge engines are not more powerful, but are heavier in proportion to their power; everything in the width gives the engine no power at all, but is an encumbrance. Neither commercially nor mechanically has the wide gauge any advantage over the narrow, but rather the contrary. The driving wheels of the broad gauge engines are not generally of greater diameter than the narrow; 6 and 7 feet engine wheels are used on the Great Western. The greater diameter of the driving wheels has a tendency to reduce the axle friction; but comparing 6 and 7 feet, the amount of this is not worth measuring, but if by increasing the gauge, the axle has to be increased in size for strength, what is gained on the one hand is lost on the other. The friction of the flange of the wheels against the railway has a retarding effect on curves, but not much on straight lines. Any lateral friction arises from the angle of the wheel against the line, and must be greater on the wide than the narrow gauge; round curves the sliding motion must be directly as the width of the gauge.

The evaporating power of a passenger engine, on the Northern and Eastern, is about 180 cubic feet an hour; he has some evaporating 160 feet. The most powerful engines are constructed with either outside or inside cylinders; the largest are inside. Certainly, some engines that have been recently made with outside cylinders have too much of that motion than I like. It is exceedingly difficult to say how the motion is produced; if you consider the action of the cylinder, it is perfectly rigid metal—engine and cylinder altogether. Now, when the steam presses upon the piston, it is at the same time pressing against the lid of the cylinder; the action and reaction must be equal. Therefore, that it is not the steam that causes the irregular action, but the mere weight of the pistons themselves, and therefore if we could contrive to balance the pistons by the weight upon the wheel, we should get rid of that very much; but in the most recent designs of engines of that kind, he has brought the cylinder much nearer to the driving wheel, and nearer to the centre of the engine; at present they hang over the wheels a good deal; now he has brought them within the wheels.

It is now an indispensable part of the broad-gauge system to use the longitudinal bearings; it is a question of expense. As you increase the width of the gauge, of course, on the longitudinal system, it leaves the expense the same; whereas, if you adhere to the transverse system, you increase the size, and, of course, you increase the expense more rapidly; therefore the transverse system with a very wide gauge would be very objectionable on account of its expense, but I think the principle of construction would be better. With reference to the maintenance of the way, imagines that the way is kept in better order upon the transverse system than upon the longitudinal at the same expense; has never seen any portion of longitudinal bearing railway in perfect order. It is more difficult to pack, and there is always more friction in a longitudinal railway than in a sleeper railway. The Hull and Selby is part of it longitudinal and part of it transverse. The engines, where they were heavily laden, upon the longitudinal bearings would just creep along; the moment they got to the transverse bearings they went 5 or 6 miles an hour more directly, from the yielding in one system, which gives a little less noise and a little softer motion which the Great Western has. Does not think that in that particular case it resulted from the longitudinal bearings being of insufficient dimensions and slighter than the Great Western, thinks they were the same size;—Memel balks, 12 or 14 inches square, cut up; and the Great Western are 14 inch balks. In the longitudinal system there is a little less noise, and there is a little softer motion than upon the transverse system, but there is a great deal more motion; there is far more actual motion upon every longitudinal railway than upon the transverse sleeper system.

If the London and Birmingham had originally been made on the broad gauge, estimates that it would have cost about 3000*l.* a mile more, without including the additional cost of the central station at Wolverton, which must have been much larger. As to altering the existing gauge on the London and Birmingham, thinks as it would stop the line for at least two years, that it is practically impossible. It would cost about 15*l.* a yard for tunnelling, taking good ground and bad. To make the Kilsby tunnel as large as the Great Western tunnels, it would have cost a great deal more than that. On the other hand, in increasing the size of the tunnel in good ground, such as chalk, the additional cost would not have been so much. States the results of experiments, showing the consumption of fuel and water, by an engine with different load. Found that the consumption of fuel for drawing the engine without a load, was equal to about the consumption of fuel to overcome a load of 15 carriages at 30 miles an hour; that is, it took as much to move the engine and tender as it did additional to move 15 carriages. There have been many reasonings upon that without considering the precise application of it. A large proportion of the fuel in moving the engine alone is consumed in overcoming the resistance of the atmosphere to the pistons; it will not require more than three or four pounds to overcome the friction of the engine and tender proper, but it requires 15 pounds in addition to that to overcome the engine and tender, taking into account the atmospheric resistance to the piston; so that there is always 15 pounds of pressure of steam in all high-pressure engines absolutely lost; it is not the friction of the engine; certainly it is a defect in the engine from its being a high-pressure engine, but on no other account. It is not a peculiar loss applicable to locomotive engines alone, but to all high-pressure engines; and therefore in estimating the consumption of fuel and dividing the proportion of expenses, it became important to ascertain what was the relative expense of conveying 8 carriages, and of conveying 15, because all the trains of the Croydon Company were small, and all the trains of the Dover Company were comparatively large; and from this experiment it appears that as to the cost of coke, whether to convey 8 carriages or 15, there is a very small difference. Therefore, if you proportion your expenses by the load, you give the small load very greatly the advantage, because you charge them only half the fuel, say as 8 is to 15, whereas you ought to charge them as 8 plus the engine is to 15 plus the engine, which will make a very great difference.

Believes the gauge of the Dutch railways, constructed in 1842, to be 6 feet 5½. The Amsterdam and Haarlem Railway is essentially level, and laid on longitudinal timbers, which are best suited to the unsound ground of Holland. The line laid over Chatmoss is laid on transverse sleepers, but the moss there has much more tenacity than the substratum of peat in the low part of Holland. Mr. Conrad constructed or projected the line in Holland; he examined railways in this country, but does not know whether he was assisted by any English engineers.

Joseph Locke, Esq.—Is the engineer who completed the Grand Junction Railway. This line was opened to the public in 1837. When witness assumed the office of engineer on this line, the rails and sleepers had been contracted for, the bridges designed, and some portion of the work commenced for the narrow gauge. Alteration of gauge at this time would have been attended with considerable expense; narrow gauge selected for this line because surrounded on all sides with lines of similar gauge, and it was desirable to preserve uniformity of gauge in the district. Great Western Railway not commenced at this time. Narrow gauge rails may be laid down on a broad gauge railroad, so as to carry on the narrow gauge traffic continuously; this process is very expensive, and in reference to the stations, very inconvenient. Where two gauges meet, the station by this plan must not only be made larger, but also of a different construction than if made for one gauge only. If called upon to project a series of railroads in a new country, would prefer an intermediate gauge, between 4 feet 8½ inches and 7 feet; wide gauge not necessary for machinery; carriages on narrow gauge lines can be made longer and loftier than at present, giving as much space to each passenger, three on a side, as in broad, as four or five on a side.

Height of carriages on narrow gauge lines lately increased 6 or 8 inches. At high speeds higher wheels are necessary; the centre of gravity would consequently be raised, rendering wider gauge than 4 feet 8½ inches desirable; at the same time, witness is of opinion, that looking to the construction of the road, the speed now attained is as great as is consistent with safety, and would neither increase the gauge, speed, nor size of wheels without more experience in the construction of engines and strength of materials; inequalities of road from change of temperature and weather impossible to be overcome; some engines on South Western Railway with wheels 6 feet 6 inches diameter, where the boilers are not higher than on engines with wheels of 5 feet 6 inches; this done by placing the cylinder outside the boiler, and bringing the boiler nearly on to the axle; the centre of gravity as low with the large wheels as the small ones by this arrangement. No disadvantage caused from this change; application of power outside the wheel does not produce a rocking motion. Great changes have been made on engines on narrow gauge lines, with a view to obtain increased power; engines of enormous power have recently been constructed on North Midland Railway to carry heavy trains of minerals. Limited space between wheels and boiler in engines on narrow gauge lines caused some inconvenience in the attempts to obtain increased power. Turned his attention to improving the engine and altering the arrangement of machinery; and now gets all necessary power on narrow gauge lines. Length of boilers on Grand Junction and South Western lines increased from 8 feet 6 to 9 feet 6.

Cannot tell the velocity attained upon the Great Western; express trains on South Western line travel 40 miles, and could no doubt run 50 miles an hour. Does not think 50 miles an hour can be done with safety on any line that witness has been on; is much opposed to such excessive speed. Curves more difficult to traverse with broad than narrow gauge. Facility for turning curves in inverse ratio to the width of gauge.

Broad gauge gives greater facility for conveyance of heavy trains, by giving larger space to put the power in, but witness considers that as much and even more power than is necessary can be obtained on the narrow gauge; disapproves of throwing a large force upon one engine. Has heard of trains of 60 and 70, and in one instance of 77 wagons in one train; would altogether prohibit such trains; would divide them, and not allow more than 40 wagons, each weighing 5 or 6 tons, at one time; more than that number strains the wagons, the frames are thrown out of square, the chains are broken, and cause delay and inconvenience on the road. Would not have greater power than sufficient to drag 60 wagons; the engines on North Midland, with large boilers, cylinders, and fire-boxes, can drag 100 wagons; they generate more steam than they consume.

Wide gauge more expensive than narrow; it required longer sleepers, greater space for embankments, cuttings, &c.; Mr. Brunel of a contrary opinion; his calculations were founded upon using smaller timbers and lighter rails than he is now using. The South Western rail is 75 lb. to the yard; both the Grand Junction and London and Birmingham were originally 65 lb.; have been recently increased to 75 lb. Increased expense of broad gauge would be in bridges, tunnels, cuttings, and embankments. Outside rail of Great Western nearer the slope or ditch than upon other lines; if engines get off the lines, more liable to fall over; witness prefers a wide embankment, and where possible, always gives additional width. Estimates that a broad gauge transverse sleeper would cost 50 per cent. more than a similar sleeper on the narrow gauge. Ordinary width of embankments 30 feet, giving 7 feet on each side between edge and outer rail. In such roads, if engine got off one rail, it would remain on embankment; if off both rails, it would go over. Cannot say how far the extra width in Great Western engines would prevent them getting over the embankment. Would give a space of 7 feet beyond the rails in wide as well as narrow gauge lines.

Rails laid upon longitudinal bearings give greater elasticity to the work, and tend to throw the engines and carriages off the line; tried with longitudinal bearings two viaducts, Dutton viaduct and Birmingham viaduct, and could never keep them in order; considers the principle bad; prefers transverse sleepers. This opinion the result of actual observation. Railways laid with transverse sleepers more easily repaired than a longitudinal road.

Has not seen the contrivances used at Paddington for transferring traffic from one gauge to another. Believes the transfer can easily be made. The machine itself very simple; the practical difficulty is in use of carriages carrying loose-box bodies to be tranferred; a machine was formerly used on Liverpool and Manchester for lifting loose coal-boxes; machine excellent, and saved much labour, but the boxes were so much broken and injured in lifting, that the contrivance was abandoned; carriages with loose bodies not so strong as others; in event of collision passengers would be in more danger in such carriages. On certain French lines the diligences are put on loose wheels, placed under the frame, and with a little hoist lifted up on the body of the carriage, and put upon the truck of the railway, just in the same way as a gentleman's carriage, and taken off in the same manner, and dropped on to a frame of four wheels at the end of the journey. The contrivance is very simple and very facile; but not very safe. They take the truck as it stands when the diligence is loaded; there is first of all a truck made for the diligence. It is not a truck with a simple bottom to it, but has sides to it, and it is then like an ordinary truck; and I believe that when the diligence is upon the truck, it is certainly not so strong as if it were part of the same carriage, but it is very heavy, and they carry a weight upon the Paris and Rouen line of eight or nine tons where the diligence is loaded; and if it were not for the change, you might have a weight of only about five or six tons, so that in every carriage you are carrying a great deal of dead weight in order to avoid the necessity of changing the carriages. There was a collision on the Orleans Railway by some sudden stoppage; one of those very diligences was thrown off its position.

Engines on narrow-gauge lines are not all made with outside cylinders; on Grand Junction line, about one half are so made, and others, as they are repaired, are altered upon the new system; but even with cranked axles, the arrangements of machinery are so simplified and compressed, that no inconvenience is felt from want of space. No difference in construction of horse-boxes on broad and narrow-gauge lines. Greater speed on Great Western attributed to their having better gradients, fewer stoppages, and larger engines than on narrow-gauge. Has travelled on an engine with 6 feet 6 inch wheel (the largest wheel on narrow gauge) 50 miles an hour with ease; that engine capable of taking six or eight carriages 60 miles an hour; one of the new engines on Grand Junction, with only a 6-feet wheel, and expansive gear, recently travelled 57 miles an hour.

Believes that wherever a break of gauge occurs hereafter, either an entirely new line must be laid down, or a narrow gauge line laid upon broad gauge road. In the latter case, continuing the narrow gauge, and having the double gauge upon the shortest possible length, is the lesser evil of the two, and in all probability will be universally adopted. Break of gauge should take place where there is little traffic. An alteration of all the broad gauge lines to 4 feet 8½ inch gauge would be the cheapest mode of obviating the evil of different gauges. Believes the Great Western Company will find the inconvenience of break of gauge so great, that they will be compelled to lay down the narrow gauge from Oxford to London. Is not prepared to say at once that a change of broad to narrow gauge throughout would lead to the greatest economy, and greatest commercial advantage, because the officers of the Great Western Railway believe that the inconveniences attending a change of gauge are less than supposed by witness; could not, therefore, as a government officer, supposing all the railways now made the property of government, advise a change of broad to narrow gauge without greater experience.

Reason of engineer of Great Western Railway adopting wide gauge, after the Bill had passed through Parliament, supposed to be a desire to attain greater speed, a better road, and greater economy of construction; one great item of expense in locomotive engines supposed to be the rapid reciprocation of the piston: and to diminish this was thought very desirable; but the expense of working locomotives on narrow gauge has diminished from 2s. 6d. to 2s., 1s. 4d. down to 10d. per mile run; it is very doubtful whether the expense is not just as great on Great Western as on the narrow gauge; Mr. Brunel at first intended using wheels of much larger diameter than are used at present; wheels on Great Western formerly 10 feet in diameter; those now used only 7 feet; only 6 inches larger than those at present working on South Western Railway; the adoption of the broad gauge it was supposed would tend to diminish the working expenses; this result, however, has not yet been proved. Considers that a far higher speed can be obtained on narrow gauge lines than is compatible with safety. If desirable to change gauge of South Western to broad gauge, should take certain length, and use a single line; this is the practice when any substantial repair is in progress, when a mile or mile and a half of rail is taken up, using a single line, and keeping a policeman at each end. The tunnels on South Western line not large enough for broad gauge, and while enlarging these, the traffic must be stopped; the bridges and viaducts would also require alteration.

Has bestowed considerable attention to the construction of locomotives, particularly at the time the difficulty was first experienced in obtaining greater speed on narrow gauge lines. The first engines used on Grand Junction line of very inferior construction; the difficulty of obtaining greater speed on this line first induced witness to turn his attention to improvements in the construction of locomotive engines. Outside cylinders introduced on Kingstown and Dublin line without outside frames; by this plan the cylinders overhung the frame too much. On Grand Junction line outside frames were used, but the outside bearings were attached to the front and hind wheels only; the cylinder by being attached to the driving wheels, without the intervention of the outside frame, kept the engine more compact. By this arrangement the width of engine was diminished several inches. Inside cylinder has necessarily a crank axle, and more liable to break; on Grand Junction line, accidents from this cause formerly a source not only of expense but of danger, as the crank broke when the train was in motion, and often threw it off the line. Has not had a single accident from breakage since the introduction of outside cylinders. Engines getting off the line not of frequent occurrence; more so now than formerly, in consequence of the increased speed.

Tenders on Great Western line of greater capacity to contain water than on other lines, and run longer distances without changing. Tenders could be made for narrow gauge lines larger than those on Great Western if considered necessary; tenders upon Great Western line all upon six wheels; on other lines upon four wheels only. The 10-feet driving wheels on Great Western abandoned from the difficulty of getting engines large enough to move the trains at any ordinary speed, and the further difficulty of stopping them when once started. Wheels of these dimensions not suitable on a line with severe gradients. By increasing the size of the wheel there will be a danger of the springing of the wheel itself on its motion, from the axle not being sufficiently rigid. In going through points or crossings with a very large wheel, a very little force applied to the flange will spring the wheel unless it is made proportionately strong, and if you do that you will have a wide boss; the bosses are 8 or 10 inches, the spokes are 4 or 5 inches, tapering up to 3 inches at the rim; if you increase it from 6 or 7 feet to 10 feet you must increase the width of your boss, and you will have a very heavy weight and very wide boss. Weight of largest engine on Southampton line, about 17 or 18 tons. No evil will result to the road by increasing the weight of the passenger engines.

Wagons on either gauge can be made to contain 5 tons; in the north of England, where so much more is carried than in the south, small wagons are still adhered to. Wagons upon both lines made to carry 10 tons of coals. Narrow gauge most convenient for side lines running to the pits. Relative cost of working trains at 16 miles and at 40 miles an hour about one-third more. Some engines on Grand Junction line burn 16 lb. of coke per mile. Probable consumption of express trains about 4 or 5 lb. per mile more; on Great Western the consumption is considerably more than this; they have larger and heavier engines; on South Western line, the quantity of coke consumed per mile is considerably less than on Great Western.

There would be increased difficulty in the ordinary working as regards the maintenance of way, packing the rails, &c., if the narrow and broad gauge were combined. The easiest mode of maintaining the road would be, where you have the broad gauge, by transverse sleepers, and then putting a single rail upon one single sleeper; that is the best mode of keeping the road in repair: but it is not a good mode of laying the road for two carriages, nor is it convenient for working, because the centre of gravity is not in the same line. If you take two rails between the longitudinal bearings of the wide gauge, you have not space enough to put longitudinal bearings, unless you put them close together: and you cannot ram them; if you ram down one side you will run a risk of elevating the other rail; and in ramming down the inner rail you would run a risk of lifting it up out of the level on the opposite side; in fact, the want of the facility of getting to both sides of the baulk would be found a very serious inconvenience. Would propose, under those circumstances, to lay both rails upon transverse sleepers; and if railways were to be made in that manner, should certainly lay a large sleeper, long enough to take both gauges.

A considerable number of the transverse sleepers upon the Great Western Railway have been changed; their duration is very variable; those not well saturated decay sooner than others; their duration also affected by the nature of the soil. Construction of passenger carriages on Grand Junction line much improved; they are now made stronger and more substantial. They are now made solid instead of being carved out. This change is adopted partly from economy and partly to obtain greater strength. Liverpool and Manchester Company began with very light carriages, considering that the lighter the carriages the less the draught; on the slightest collision they got out of the square; they have been gradually increased in strength up to the present time; they now weigh about 3 or 3¼ tons, but have not yet adopted the solid frame; cost more from the quantity of iron-work used in their construction. Reasons for the adoption of the solid frame were these:—In the bolt-holes in all these small scantlings of timber not more than 4 inches square, or 4 by 3, on taking a carriage to pieces, you found a little decay; that one corner of the bolt-hole gets a little larger, and there is a little play; consequently it has to be renewed far sooner than if it had been a solid and substantial piece of timber, for the least decay in a small piece of timber renders it unfit for its work, and it must be renewed. Upon seeing this at the Grand Junction workshop at Crewe, witness advised the directors to abandon entirely the construction of the carriages on that plan, and to adopt the solid frame; and they now have carriages with solid frames. Considers the public safety much increased by the alteration. Many engineers entertain a different opinion, and consider that very high velocities may be obtained with much lighter carriages than those now used; Mr. Brunel and Mr. Cubitt are both of opinion, that by the atmospheric system, they will be able to keep the road in better order, use lighter carriages, and go at greater speed than has hitherto been attained on any of the locomotive lines. Witness altogether disapproves of light carriages, and considers that with them accidents are more frequent, and when occurring, more dangerous than with the stronger carriages. Safety of train depends greatly upon weight of engine which draws it. If the engine were a light engine, at the speed at which it sometimes travels, it would leave the rail; but, as it is heavy, it gives security to the train behind it. Recent accident on Great Western line, where all the light carriages were more or less damaged, while the strong one, in the same line, was scarcely strained. Sleepers can be renewed on transverse system at much less expense than on continuous bearings. Estimated expense of one mile of permanent way, £4,838.—

(To be continued.)

AMERICAN PATENTS.

Granted in March 1845, reported in the American Franklin Journal.

MARBLE POLISHING MACHINE.

A machine for "*polishing flat plates or tables of marble.*" Jacob Ziegler, Philadelphia, Pennsylvania.

The plates of marble, &c., to be polished, are placed, face upwards, on the top of a carriage which carries them slowly under the rubber, which is a flat plate of wood or other material, covered with the polishing substance. This rubber receives a movement from two cranks or cog wheels, attached to the lower ends of parallel vertical shafts, geared together and driven by an intermediate cog wheel on the driving shaft. These shafts are hung in a sliding cross head suspended by levers, &c., to regulate the pressure of the rubber.

BRICK-MAKING PRESS.

For an "*improvement in the brick press.*" John Waite, Leicester, Massachusetts.

The improvement is for arranging and operating on the brick machine, so that while one brick is being compressed in one compartment of the mould by the compressing pistons, the discharging piston shall be performing its office of expelling from the mould the brick which had next previously been formed; the mould being progressively moved forward at regular intervals of time, so as to present that compartment of it in which the brick has been compressed to the action of the discharging piston, where the compressing pistons next enter the preceding apartment, to effect the formation of a brick therein.

TINNING PIPES.

For "*improvements in machinery for making and tinning lead pipes.*" Robert W. Lowber, Rochester, N. York.

This is for tinning lead pipes, (which are formed in a die and around a mandrel) by introducing the melted tin through the mandrel, or core, which is hollow and provided with apertures for the discharge of the tin inside the pipe.

Claim.—"What we claim herein as our invention and desire to secure by letters patent, is the method herein described of tinning the inside of lead pipes in the course of manufacture, by passing the melted tin down into the mandrel and out at the side thereof, as above made known, whether applied to this machine or any other substantially as described."

VENTILATING STOVES.

An "*improvement in stoves for warming parlours, and for other purposes.*" John Morrison, Newark, New Jersey.

The nature of this improvement "consists in taking the air from near the ceiling of rooms, for supplying air to the fire, and thus incidentally ventilating the apartment. For this purpose there is a pipe which extends up from the ash pan to within a short distance of the ceiling, where it is made bell mouthed for the free admission of air. This pipe is surrounded by an outer jacket, which communicates with the chimney, the fire chamber, and with the case surrounding the fire chamber of the stove, by separate pipes governed by dampers for regulating the draught, heat, &c.

HYDRAULIC PAINT.

An "*improved mode of making hydraulic paint.*" Thomas G. Warren, Troy, New York.

The patentee says,—"This paint is composed of 'hydraulic cement,' (sometimes called 'water lime') made fine by grinding, and 'linseed oil' to be mixed in such proportions as to make a paint of ordinary thickness. The use to which this paint can be applied is general. It can be applied to houses of either brick or wood, and also to cloth roofs for houses, or other purposes. I have a cloth roof to my house painted with this new paint, and it is perfectly tight. The cost of such a roof is considerably less than that of ordinary roofs. The same materials, but with a less proportion of the oil, make an excellent water-tight putty."

PRINTING PRESSES.

"*Improvements in presses.*" Joseph Saxton, Washington, District of Columbia.

The patentee says,—"My invention and improvements consist, firstly, in the use of a flexible or elastic platen, instead of a rigid or inflexible plate of metal as a platen. Secondly, in the application of pressure to such flexible or elastic platen by means of a liquid, or aeriferous fluid; and thirdly, in the arrangement of machinery in printing presses, copying presses, and lithographic, and zincographic presses, for the purpose of applying such pressure to such flexible or elastic platen. The object and effect of using a flexible or elastic platen with the pressure by means of a liquid or aeriferous fluid is, that the platen is equally pressed or acted upon over its whole surface, and which may therefore be employed in any position, to press upwards, downwards, or sideways. The elastic platen is to be of the necessary size for the press in which it is to be used, as in the case of the ordinary platen, and is to be a thin plate of brass or other suitable metal, varying in thickness from that of a sheet of foolscap paper to about half an inch, according to the dimensions of the platen, and of the vacant spaces between the columns or pages of types or figures, technically in printing called 'the white.'"

SAFETY VALVES.

For "*improvements in the safety valve for preventing steam boilers from bursting or collapsing.*" Abraham Patterson, Rush, Pennsylvania.

The claim is for the employment of the apparatus termed the working column, in combination with the uplifting valve and float, as described, whereby the pressure of steam on the working column is added to the pressure on the safety or uplifting valve, for the purpose of opening it when the water descends below a given point, and which, at the proper height of the water, permits the free action of the uplifting valve. A claim is also made for the employment of a pendulum, so situated, or so suspended, that by the rocking, tilting, or careening of the boiler or boat upon which such pendulum shall be employed, the said pendulum shall so attach itself to, or so suspend itself upon a tackle, lever, or pivot, as thereby to apply its weight as a moving power to the opening of a safety valve or valves for steam boilers, as described.

RAILROAD TRUCKS.

For an "*improvement in railroad trucks.*" Fowler M. Ray, New York.

The patentee says the nature of his invention consists in substituting a single cross beam of timber, having end bearers of metal for the connecting bars of the axles, furnished with a single spring, and having a pedestal connecting the bearer, spring, and cross beam together at each side of the truck in such a manner as to give to the whole frame work or superstructure of the truck a yielding capacity, instead of the usual method of a stiff frame work, and short unyielding springs, two at each side, as heretofore most commonly constructed. By which yielding quality several desirable objects are effected.—1st, The capability of elevating either of the wheels of the truck to a considerable height without affecting the position of the remaining wheels upon the track, and by which obstructions are passed with greater safety. 2nd, It gives to each axle, independent of the other, a facility to vibrate laterally without changing their parallel position to each other, and by which, short curves are made easy. 3rd, Its yielding and elastic quality, rendering vertical and lateral concussions less severe than in the ordinary (rigid frame) truck.

IRON BOATS.

For "*improvements in the manufacture of boats and other vessels of sheet metal.* Joseph Francis, New York.

The invention consists in forming the sheets of metal with mouldings or beads in suitable places to take up the surplus metal, when the said plates are pressed into form, by means of projections on the die and corresponding depressions on the matrix, or concave mould, which gather up the metal and prevent wrinkles around between the upper and lower parts of the boat, so as to present a smooth surface, and also in forming a recess or bed for the gunwale, which holds it in place and prevents its getting knocked down. A flanch around the stem and stern posts, and along the line of keel, is also added, which takes up the surplus metal there, and forms the keel, and stem and stern posts.

REGISTER OF NEW PATENTS.

If additional information be required respecting any patent, it may be obtained at the office of this Journal.

ROLLING IRON BARS.

Thomas Howard, of the King and Queen Iron Works, Rotherhithe, iron manufacturer, for "*Improvements in rolling iron bars for suspension bridges and other purposes.*"—Granted October 6, 1845; Enrolled April 6, 1846.

Fig. 1. Fig. 3.

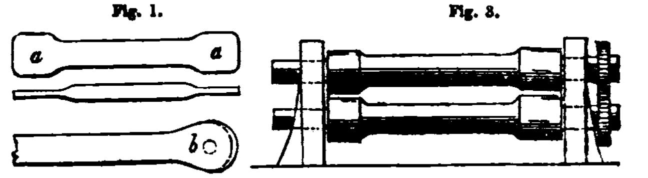

Fig. 2.

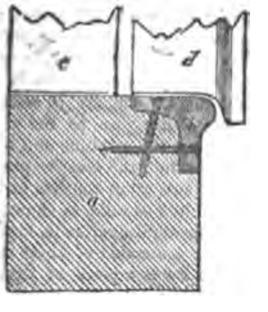
The improvements consist in a method of rolling wrought-iron bars with heads, or increased breadths thereon, in one entire piece, so as to avoid the uncertain and insecure process of welding such heads on to the bars, particularly when subjected to great strain or tension, as in suspension-bridges, and other works requiring similar bars. To effect this, the slab faggot or shingle from which the bar is to be produced, is heated in a furnace and passed through grooved or other rollers in the ordinary way, to form an elongated slab. This slab is then carried to what are termed heading rollers, having enlarged parts or collars upon them, between which the slab is passed edge first, or breadth ways, as often as is necessary, and which produces the form required on the slab *a*, fig. 1, while the intermediate part of the slab remains incompressed by the rollers, which are of less diameter where this latter part passes between them. The slab is then elongated by plain or finishing rollers of ordinary construction to the finished bar or length and thickness required, as shown at *b*, fig. 2. When the heads are intended to be of the same thickness as the other parts of the bar, they should come from the heading rollers sufficiently thick to receive some pressure by the finishing rollers, due allowance being made for the elongation, particularly when the bars are to be employed in suspension-bridges, in order to produce the grain or fibre of the iron in cross directions around the holes made in such heads, when completed by any ordinary means. A view of the heading rollers preferred is shown in fig. 3, and when the bars are large, it is recommended that these rollers have given to them a to and fro or reversing motion, by means of known machinery for such purposes, in order to expedite the rolling out of the heads in conjunction with the other operations, and to render a second heating of the slab unnecessary.

RAILWAY RAILS.

MOSES POOLE, of Lincoln's-inn, in the county of Middlesex, gentleman, for "*Improvements in rails for railways.*" (A communication.)—Granted October 6, 1845; Enrolled April 6, 1846.



The invention consists in so constructing rails for railways, that the wheels of the locomotive engines may run on wood, and the wheels of the railway carriages may run on metal, as shown in the annexed figure; *a* is a rail of wood armed with iron *b*, on the inner edge, *c* the wheel of a locomotive, and *d* the wheel of a carriage. The wheels of the locomotive engine being thus removed from off the metal rail will not be so liable to slip, particularly in damp weather, as has been heretofore the case, when the locomotive engines and railway carriages of the train all run on the same metal rails.

STEERING APPARATUS.

ROBERT CLARK, ship's painter, and ALEXANDER PIRNIE, ship's smith, both of Newburgh, Fifeshire, for "*Improvements in steering vessels.*"—Granted October 2, 1845; Enrolled April 2, 1846.

The improvements relate to an apparatus arranged as shown in the annexed engravings. Fig. 1 is a side view, and fig. 2 a plan. *a* is the steering

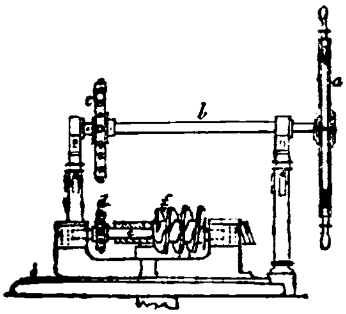


Fig. 1.

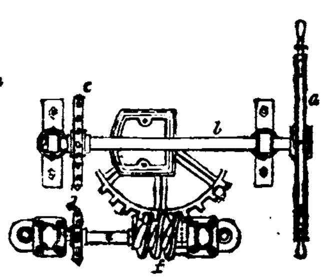

Fig. 2.

wheel fixed on one end of an axis *b*, on the other end is a chain wheel *c*, which by means of a chain transfers the motion to another small chain wheel *d*, fixed on an axis *e*, with an endless screw *f*, that takes into the section *i* fixed on the head of the rudder. The axis *e* turns on bearings, which are formed with cork or other elastic substance placed at the ends, so that any sudden movement of the axis endwise would be counteracted by the elastic packings. For the purpose of keeping the chain at all times tight, the standards carrying the bearings of the axis *b* are made to rise or fall.

GAS APPARATUS.

HENRY FRANCIS, of Wardour-street, London, civil engineer, for "*Improvements in the manufacture of Gas.*"—Granted Oct. 9, 1845; Enrolled April 9, 1846.

The apparatus consists of an ordinary retort, supported on a perforated tile fixed over a furnace; the openings in the tile allow the heat to pass freely to the retort, and at the same time form a complete support. This tile constitutes the first claim for improvements; the second claim consists in the mode of fastening the door to the retort; this door is made with inclined surfaces on the rim, and is ground to the mouth piece, so that when the door is pressed close by means of a key that turns it slightly round under fixed lugs, it will be gas tight. The gas, as it is made in the retort, ascends by a pipe in the front, and enters into a hydraulic main or vessel placed within a larger vessel fixed on the top of the brick-work over the retort; the larger or outer vessel receives the tar and ammoniacal liquor as it flows over from the inner compartment, and at the same time forms the tank for those materials. It is the combination of this apparatus in one vessel that constitutes the third improvement claimed. The gas passes from this inner vessel or hydraulic main by a pipe to a condenser, consisting of a coil of pipe or worm placed in the tank of the gasometer; by these means, only one vessel of water is used instead of two apparatus, as heretofore, for the condenser and gasometer; this constitutes the fourth claim. After the gas has passed through the worm condenser, it then passes into the purifying apparatus, consisting of a vessel divided into two compartments, and so arranged that wet and dry lime purifying can be adopted in the same vessel; this combination forms the fifth claim. From this vessel the gas passes back into the gasometer, and thence to the burners. To prevent the pressure of gas in the gasometer blowing up any part of the apparatus, there is a chain fixed to the inside of the top of the gasometer, and at the other end of the chain there is an inverted cap, which closes the orifice of a pipe standing up in the lower part of the gasometer; the upper part of the pipe just emerges above the water, so that when the cap is down it enters the water and forms a water valve; when the gasometer rises beyond a certain point, the cap is lifted off the pipe and allows the gas to escape down it and pass away to a distance. This valve forms the sixth claim.

CHIMNEY POTS.

GEORGE EWART, of New Road, Middlesex, zinc manufacturer and plumber, for "*certain improvements in the manufacture of chimney pots.*"—Granted November 2, 1845; Enrolled May 2, 1846.

The following is very nearly word for word of the specification of this invention, which is said to "consist in constructing chimney pots in such manner that each pot consists of a double tube, one portion sliding upon the other, and capable of being fixed to any desired height by the aid of thumb screws and nuts, or other convenient means." The pots may be constructed of zinc or other suitable material. The advantages arising from the application of these improved chimney pots are stated to be very great, inasmuch as it gives the power of increasing the draught of the chimney by increasing the height. The inventor claims the constructing of chimney pots to slide one upon another in the manner described.

SHIP BUILDING.

JAMES BOYDELL, Jun., of Oak Farm Works, near Dudley, iron master, for "*improvements in building ships and other vessels.*"—Granted November 17, 1845; Enrolled May 17, 1846.

The first part of this invention relates to a mode of building ships and other vessels with iron and wood, and secondly, to building vessels with iron. Fig. 1 shows a sectional plan of portion of the side of a vessel constructed according to the first part of this invention, in which *a a* represents the iron ribs of the vessel, on the inner edges of which is firmly fixed, by means of rivets, plates of iron *b b*; *c c* is the planking forming the sides of the vessel which is afterwards covered with copper in the ordinary manner

Fig. 1.

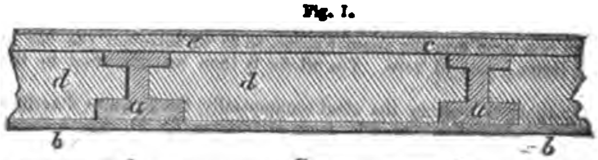

Fig. 2.

the space between the planking *c c*, and plates of iron *b b*, is filled up with timber marked with the letters *d d*, the grain of such pieces of timber or planks being in a direction fore and aft of the vessel. Fig. 2 shows a sectional plan of portion of the side of a vessel constructed according to the second part of this invention, in which *e* represents plates forming the sides of the vessel, *f* one of the ribs of the vessel having a groove throughout its entire length. The edges or ends of the plates are bent at right angles so as to enter the groove, and are secured therein by means of a wedge-formed bar *g*, the whole being firmly held together by means of keys *i*, which pass through holes in the rib, edges of the plate, and bar or wedge, as shown in dotted lines.

ATMOSPHERIC ENGINES.

JOSEPH RICHARD ATHA, of Walton, near Wakefield, of Yorkshire, engineer, for "*improvements in atmospheric engines.*"—Granted November 4, 1845; Enrolled May 4, 1846.

This invention consists in the application of wind power, as the first mover in the following manner. Four or more sails are to be attached to a shaft, which shaft is intended to give motion to two force pumps for the purpose of compressing atmospheric air into a large vessel or vessels, denominated receivers, which may be provided with a safety valve for preventing accident. From this vessel there is to be a pipe leading to a minor receiver fixed upon the carriage of a locomotive, the pipe to be capable of being connected and disconnected at pleasure, for the purpose of filling the minor receivers, and from which receivers the compressed air is to be admitted into the working cylinders of an ordinary locomotive instead of steam. The specification is not accompanied with any drawings to show how the above is to be carried into effect.

COMBINING STEEL AND IRON.

Charles Sanderson, of West-street, Sheffield, steel manufacturer, for "*improvements in combining steel and iron into bars for tyres for wheels, and for other purposes.*"—Granted Nov. 4, 1845; Enrolled May 4, 1845.

In carrying out this invention it is proposed to take iron which has been manufactured into a bloom in the usual way and of any required form, and pass the same through rollers suitably formed for making a cavity in the iron, which is afterwards to be filled up with liquid steel in the following manner. The bloom when in a hot state is to be passed between rollers or hammers, so as to form an indentation or hollow sufficiently large to contain the liquid steel intended to be incorporated with the iron as shown at fig. 1, in which *a* represents the bloom, having an hollow formed in one of its sides, which is to be covered over by a thin plate of iron, *b*, welded to the two edges of the bloom, so as to form a sort of tube, into which is to be poured the melted steel; the bloom is then worked up into the form required by the usual process of rolling or compressing, when the steel will be found to be united with the iron in the place required. In manufacturing rollers, piston-rods, mandrels, &c., the inventor takes a thin wrought-iron case or cylinder of about $\frac{1}{16}$ of an inch thick, the internal diameter being equal to the diameter of steel intended to be manufactured; within this cylinder is placed a rod of iron so as to form a sort of core, having an annular space between the iron and internal diameter of the case, equal to the thickness of steel intended to be cast or incorporated with the iron. The bar of iron being placed within the tube, and the same fixed in a vertical position, with the lower end closed; the melted steel is poured into the annular space, so as to surround the bar of iron which forms a sort of core. The whole is then manufactured in the usual way.

Fig. 1.

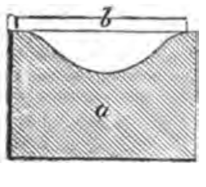

Fig. 2.

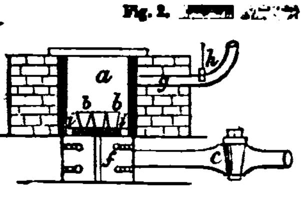

Fig. 3.

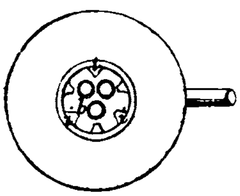

For the purpose of melting the steel economically, the inventor describes and claims as his invention a peculiar form of furnace (fig. 2), which shows a sectional elevation, fig. 3 being a plan; *a* represents the body of the furnace, built of fire brick; *b* are three crucibles for containing the steel to be melted; *c* is a blast pipe, provided with a stop-cock, and is made to enter the lower part of the furnace; *f* are doors which can be opened for the purpose of clearing out the furnace; *g* is the flue for carrying off the products of combustion, and is provided with a valve at *h*. The air from the blast pipe *c* enters a chamber, from which it passes through holes, *i*. into the furnace.

The inventor claims the mode of manufacturing steel as described, and also the application of a thin coating of iron, which protects the steel from injury during the subsequent process of manufacture.

PROPELLING VESSELS.

Stephen R. Parkhurst, of Liverpool, machinist, for "*a method of propelling vessels.*"—Granted Nov. 4, 1845; Enrolled May 4, 1846.

This invention consists simply in the application of seven, more or less, upright propellers on each side of the vessel. Fig. 1 shows one side of the vessel, with an end view of one of the propellers, and the position of the remainder, which are enclosed in an iron case having circular recesses somewhat larger in diameter than the diameter of the propeller, one of which is shown in elevation at fig. 2. In fig. 1 it will be seen that the blade or floats of the propellers are made to project a little beyond the case on each side of the vessel, and in order to protect them from injury by coming in contact with other vessels, a strong wooden beam, shown in dotted lines, is affixed to the casing so as to project a little beyond the floats of the propellers, which are to be driven by straps or other convenient means by the engines on board.

Fig. 1.

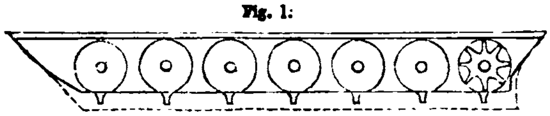

Fig. 2.

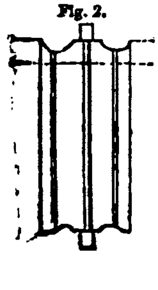
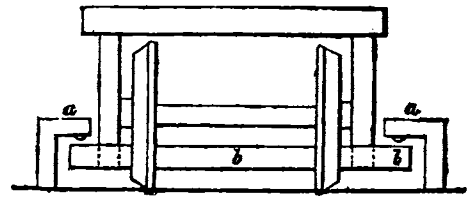


RAILWAY CARRIAGES.

Robert Miller Brandling, of Low Cosforth, Northumberland, Esq., for "*Improvements in railway and railway carriages for the security and convenience of the public.*"—Granted October 31, 1845; Enrolled April 30, 1846.

This invention is said in the first place to consist in a mode of keeping the wheels of the carriages upon the rails by the application of counteracting pressures, and by means that do not cause any shocks. Secondly, in constructing the machinery by means of which the railway trains are firmly attached to or released from the rope which draws them. Thirdly, in causing the trains to pass upon the surface without any obstruction to the usual traffic along the highways; and fourthly, in conveying the machine and rope below the surface, and also in a new mode of connecting the tractive power to the ropes used in railways. The first part of this invention consists in the application of an additional rail on each side of the line of rails, as shown in the accompanying sketch, in which *a a* represent the additional rails, having projecting ribs at right angles to the rails, on the underside of these rails there is fixed the segment or portion of a rail; *b b* is a piece of timber

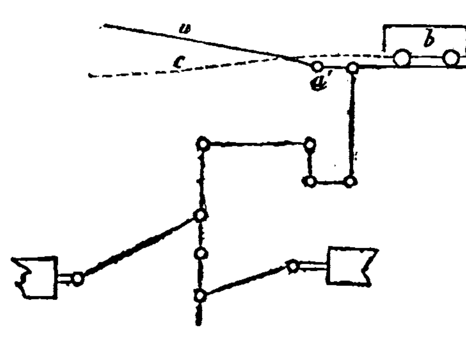


firmly attached to the framing of the carriage, the ends of which are made to pass underneath the projecting parts of the rails *a a*, preventing the carriage from getting off the line, "without producing any shock," which we very much question. The remaining portion of this invention appears to be a pack of nonsence, the drawings and description of which are very imperfect, indeed so much so that it is next to impossible to understand them.

ARRESTING RAILWAY CARRIAGES.

Dylrymple Crawford, of Birmingham, for "*certain improvements in the means of, or machinery for arresting the progress of railway carriages and trains.*"—Granted October 31, 1845; Enrolled April 31, 1846.

The first part of this invention relates to a mode of working the breaks, and consists in the application of a cylinder fixed in a horizontal position on the top of one of the carriages. This cylinder is provided with a piston and piston rod passing through a stuffing box in the usual manner at each end of the cylinder there is a stop-cock. To the piston rod is attached a chain, the opposite end of which passes round a pulley, fixed upon a short vertical shaft this shaft gives motion by means of two spur wheels to a vertical shaft, the lower end of which extends to the underside of the carriage framing, which by a peculiar arrangement of mechanism causes the breaks of the several carriages to be brought into action in the following manner. Suppose the piston to be at the bottom or further end of the cylinder, the stop-cock at that end is closed, and the cock at the opposite end, opened the piston, is there drawn by means of the chain and handle to the opposite end of the cylinder, the consequence is that a vacuum will be formed in the cylinder, and a pressure exerted on the piston in proportion to its area, both cocks are then closed, and the mechanism for withdrawing the piston is put in gear with the vertical shaft which gives motion to the breaks. It will therefore be seen that when it is required to put the breaks into action it is only necessary to open the stop-cock at the near end of the cylinder, when air will be admitted to the cylinder, the pressure of which upon the piston will be transmitted in the manner described to the breaks. For the purpose of opening the stop-cock a chain or rope is attached to the lever, and extends the whole length, of the train, so as to be under the control of the engine driver, or any of the guards upon the train. Another mode of working the breaks is shown in the annexed diagram. The top of the carriage there is a bent lever *a*, moving upon a fixed centre at *a*, *b'* is a heavy weight mounted upon wheels and supported by the lever *a a'*, *c* is a chain extending along the carriages of the



train to any convenient part, and is worked by means of a winch or handle, so that by drawing the weight along the lever *a a'* to the opposite end to that where the weight is shown, the end *a* of the lever *a a'* would be pressed down when the breaks *d d* will be brought into action by the arrangement of levers shown in the diagram which will be understood without further description. Another part of this invention consists in facing that part of the break which comes in contact with the wheel, with a casing or covering of wood, having a number of conical holes which are to be filled with chalk or a mixture of sand gravel, asphalt, or other attritive material. The inventor also proposes to attach to the back of the break a vessel containing a liquid for the purpose of keeping the break moist, and carrying off the heat.

JUNCTION OF THE BROAD AND NARROW GAUGES.

The following is a description of a plan patented by Messrs. Austin and Quick, for obviating the difficulties of diversity of gauges. It consists merely in the application of additional sets of wheels to each axle of the carriages, so that the same carriages may travel with equal facility both on the broad and narrow gauges, and pass from one to the other without stoppage or inconvenience of any kind. Fig. 1 is a section of a wagon, and fig. 2 of a carriage provided with the double sets of wheels. The locomotives of course would not require the proposed alteration, as each line would possess its own establishment of engines which would be changed at the break of gauge. On lines of uniform gauges a similar change of engines usually takes place every forty or fifty miles, without the least inconvenience to the passengers.

Fig. 1.

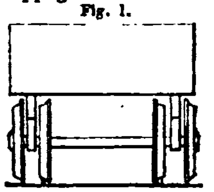


Fig. 2.

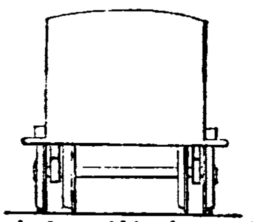
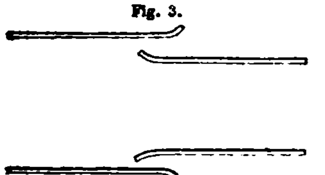


The carriages employed for the purpose would be of narrow gauge dimensions, the axles being lengthened sufficiently to receive the additional wheels. The axle bearings would be most conveniently situated between the wheels on either side, the grease or lubricating box being so placed as to be readily accessible between the spokes of the outer wheels. As the steps of the narrow gauge carriages now project invariably beyond the broad gauge dimensions; the additional wheels would involve no alteration whatever of bridges, tunnels, or even the station platforms of the narrow gauge lines. The only alteration required, throughout the works, for the uninterrupted passage of these carriages, would be an addition to the rails, at the crossings, to sidings, to allow the flanges of the wheels that are not travelling on the rails to pass through. It would be necessary at crossings to make *two* openings instead of one in each rail which is crossed, so that *both* sets of wheels might. At the junction of the gauges nothing more is requisite than that the sets of rails should overlap for a few feet. Fig. 3 represents the means of passing from gauge to the other.

Fig. 3.



The inventors calculate that the alteration of the crossings would at the utmost not exceed 25*l*. each, so that the cost on this head for a long line of railway would not amount to 1000*l*. In the case of a wheel breaking or a train getting off the rails, additional security would result from the extra wheels, as tending to preserve the carriages from upsetting and preventing their running entirely off the railway.

The proposed invention has certainly the merit of simplicity, and it is to be regretted that the Gauge Commissioners had not the opportunity of examining it. It is certainly much superior to the plan of shifting carriages from frames with narrow gauge wheels to frames with broad gauge wheels; an operation which must always produce delay besides lessening the security of the carriages. The telescopic axles are also liable to the objection of insecurity. The only danger from the new plan would arise from the accidental obstruction of the additional set of wheels by obstacles which did not lie across the rails. The additional dead weight would also be an objection of some importance. We can scarcely regard the invention as anything but a temporary expedient, but we are inclined to consider it much superior to those which have been hitherto proposed. The double wheels would only be required for those carriages which were intended for *through* traffic.

The Nelson Monument is once more in progress towards completion, the bricklayers are at work forming the foundations for the flights of steps and stone bases.

DAMPNESS IN BUILDINGS.

ITS CAUSES AND CONSEQUENCES, AND THE MEANS OF PREVENTING IT.

(Translated from the Magazin Pittoresque)[1]

Dampness penetrates into the lowest floor of buildings either from the soil itself or by means of the foundation walls; it frequently arises also from rain beating on the surface of the exterior walls.

The influence of the different causes of dampness varies according to the nature of the soil or climate, the aspect in which the houses are built, the materials employed in their construction, and the different modes of construction. To get rid of humidity in the lowest story, it is ordinarily supposed, that all that is required is to elevate the foundations within the building above the level of the external soil; but if no other precautions were employed, this super-elevation would not diminish the dampness which rises from the earth itself, and that from the walls would be very imperfectly remedied, supposing the buildings constructed without cellars.

Among the numerous bad consequences of dampness we must reckon as the principal its unhealthiness, and its destructive effect on almost every thing subjected to its action; it causes plaster to fall, ceilings and floors to decay, paint to peel off, paper to become rotten: furniture, pictures and books are rapidly injured by it, and even the materials of the walls themselves undergo a gradual alteration which diminishes their solidity.

A constant moisture is not however necessarily destructive to buildings built of stone: stones laid in the ground although constantly immersed in water, will remain uninjured; although this will not be the case where the stone is exposed by turns to dryness, moisture and frost.

It is a common expression that damp always rises: and it might thence be supposed that moisture, in order to affect a hygrometric body, must come from below it, whereas in reality moisture is also diffused downwards, horizontally, and in every other direction. Now the materials ordinarily employed in building, wood, brick, rubble, and stone of every kind, including even marble and granite, are more or less hygrometric; that is to say, if carefully weighed after having been immersed in water, are found to be heavier than they were when completely dry.[2] It is therefore clear that the opposition which the nature of the materials offers to the progress of moisture is much less than is commonly supposed.

Inefficacy of the ordinary remedies.

Till lately attention has been confined to the means of remedying dampness in buildings after they have been constructed; precautions have seldom been taken to prevent it in the first instance. Recourse is generally had to cements, plasters, and paint, applied to the interior surfaces of the walls so as to substitute by means of a body supposed to be impermeable, a dry surface for one more or less humid. Without desiring to analyse the qualities of the plasters usually employed, we do not hesitate to say that these various compositions, not only do not prevent, but do not even diminish, the real cause of the evil. The moisture which has penetrated through the walls is an agent of which the operation is continuous, and cannot be stopped. Its action cannot be diminished except by the action of air. The pretended *hydrofuge* cements merely disguise the evil for a certain period; they are even liable in many cases to the grave objection of diminishing the chances of absorption, and instead of helping to dry the building, tend to retain its moisture.

It is then the first cause of the evil which must be attacked. The only useful means are those which prevent the moisture from penetrating into the walls of the building, for when once it has entered them it is almost impossible to remove it.

Means of preventing dampness in the construction of buildings.

With respect to the dampness arising from the soil, the best means of preventing it is by interposing at a certain height some impermeable substance which will prevent the moisture passing beyond it. The only substances of this kind are lead, bituminous or resinous cements, and certain kinds of mortar.[3]

The interposition of a plate of lead or a layer of some bituminous substance in the thickness of the wall has been already tried with success, and is found to stop the progress of the moisture absorbed by the lower

1 This paper is an abstract of an Essay for which the first prize was awarded by the Society "D'Encouragement pour l'Industrie nationale." The author of the prize essay is M. Vandoyer, government architect.

2 From experiments made on the powers of absorption of different kinds of stone, it appears that a cubic metre of marble will hold 5¼ pints of water. A metre is 3 ft. 3 in.

3 The nature of the mortars best adapted to resist moisture is explained in M. Vicat's work. See the C. E. and A. Journal for February last.

portion of the wall. This plate or layer should be a little above the internal level of the foundations.

This method, however, though efficacious in resisting the dampness arising from the ground, does not prevent the effects which the humidity of the atmosphere produces on the exterior surface of the walls in their lower part. In ordinary buildings we may point out as an excellent preservative against atmospheric moisture, a revêtement of flag stones placed against the external face of the wall, and reaching to about a yard above the ground. If the foundations of the walls be of good limestone or grit-stone, this revêtement will not be necessary. It is well known that in the lower parts of walls to a certain height above the ground, the mortar of hydraulic lime should alone be used, and that when there are means of resting the foundations on an impermeable concrete, the best effects may be anticipated.

The precautions, then, to be taken against humidity in the walls are these—a foundation on hydraulic cement, the employment of hydraulic mortar in the lower parts of the building, the use of calcareous stones or revêtement built against the walls, and the interposition of an impermeable substance through the whole thickness of the walls between the exterior and interior levels of the soil.

ATMOSPHERIC RAILWAY.

Sir—I think your correspondent S. T. is labouring under a mistake when he speaks of monthly attacks on the atmospheric system. The comparison of theory and experiment shows that the development of the latent heat of air, during its sudden compression in the pump, causes a small and unimportant loss when the degree of rarefaction does not exceed the limits assigned by the patentees.

The loss by leakage depends on the degree of perfection in the machinery, and remains to be determined by experiment.

The regularity with which the Dalkey line has acted during the past year, as well as the high velocities attained on the Croydon line, are very satisfactory. The failings of the engines and pumps in the latter case have been frequent, but few will be inclined to doubt the possibility of surmounting this difficulty. After examining all the tables and writings that I can find respecting the practical working of a very defective example, I can see no good reason to doubt the capabilities of the system. One fair trial of the constancy of the system will be of more value than volumes written on the subject. In the mean time it is very desirable that the opponents of the system, should patiently await the result of the experiment that is now being made, for they may rest assured that the case will be decided on its own merits, and quite irrespectively of their assertions. In the mean time it will be remembered that the losses inherent in the system are very trifling.

A few years ago it was believed that the adhesion of the driving wheels of a locomotive to the rail was insufficient to enable it to draw its load and numerous walking machines were patented. A simple trial would have saved much time and money. It will be better to test the constancy of the atmospheric system rather than trust to doubts and surmises.

It has lately been asserted that the power of the locomotive is nearly double of the Croydon atmospheric. However, if the greatest evaporating power of any locomotive engine hitherto constructed be combined with any cylinder and driving wheels, in actual use, I think it will be found that at velocities of 60 to 70 miles per hour, the *efficient* power of locomotives falls considerably below that of the Croydon Atmospheric.

I remain, Sir,

Your obedient servant,

F. Bashforth.

Semper has been chosen architect of the new Picture Gallery at Dresden. At Berlin, the king has ordered the erection of a vast cathedral; the spires are to be 300 feet high. The new Campo Santo, which will be connected with the cathedral and palace by a collonade, will be a large open square, of which the sides will be 180 feet long. There will be a covered arcade or ambulatory all round the square; and the inner walls of this arcade will be covered with frescoes from the designs of Cornelius.

PROCEEDINGS OF SCIENTIFIC SOCIETIES.

ROYAL INSTITUTE OF BRITISH ARCHITECTS.

May 11.—Mr. Tite, V.P., in the Chair.

Mr. Scoles, honorary secretary, read a letter from Mr. Myers, dated Rome, contradicting the reports which were current a short time ago, that the dome of St. Peter's was in danger. Some repairs had been made last summer, one or two of the string courses had been restored, and this had probably given rise to the assertion. A contradiction of the report appeared immediately after the statement was made. With reference to the fact that there had long been numerous cracks in the dome, the chairman reminded the meeting of an anecdote, respecting some figures erected in the cathedral, the architect, on being asked his opinion of them, said there was too much flutter in the drapery. "That;" replied the sculptor, "is caused by the wind through the cracks you have made in the dome."

A paper by M. De Lassaux, on a preparation of plaster of Paris, proposed to be used in England as an improvement on that now sold. In France, plaster is employed extensively for external work, and endures well; whereas that in England will not stand the weather. The buildings in the *Champs Elysées*, erected on lease for forty years, are mainly constructed of plaster. The Circus there, a model in its way, is chiefly of iron and plaster. The English plaster-stone might be called a sulphate of lime; and he considered it was the presence of a small quantity of sulphuric acid in the plaster which prevented its endurance. The plaster, for which he had established a depôt in England, might be used externally, as in France; and, moreover, was very moderate in cost, being 30*s.* per ton. As a guide, the paper stated, twenty-six pounds of the plaster, costing 4½d., would cover one yard of wall; and thirty-two pounds, the cost of which would be 5½d., a yard of ceiling.

Mr. Bellamy observed that the price at which it was stated in the foregoing paper that the plaster could be supplied, was most materially lower than that of English plaster. He wished, however, to know whether the price mentioned included the import duty. The present cost of plaster in England was 3*l.* 10*s.* per ton for the coarse, and 4*l.* 5*s.* for the fine; so that the difference between this and the plaster introduced by M. de Lassaux was very great.

M. De Lassaux replied, in French, that there was no duty on plaster imported into England. He alluded also to the valuable property of this plaster when used as a coating to iron, of preventing oxidation. The plaster was thoroughly dried in eight days.

Mr. Tite remarked on the very extensive use of plaster for external decoration in Paris, which was a principal cause of the difference between the appearance of the streets of that city and those of London. A great difficulty in introducing cement into general use here was its shrinking in the drying, and this difficulty was especially felt when the material was employed for "pointing," or filling crevices. Almost every kind of cement, except plaster of Paris, diminished in bulk in setting, and consequently was apt to fall out when used in pointing. Plaster of Paris, however, expanded in setting: it probably contained a portion of carbonate of iron as well as sulphate of iron. A remarkable illustration of this property of expansion was afforded by the method in which party-walls were usually built in Paris. They were never connected with the external walls, as in this country, but were separated from them by a considerable interval. The reason of this was, that the party-walls being built of rubble, it was necessary to make considerable allowance for their expansion in drying. When used for external mouldings, it was usual in Paris to protect the upper surface of the plaster, which was most exposed to the weather, with thin plates of zinc.

Mr. Poynter thought that the great difference between the climates of London and Paris must have a great effect on the durability of these mouldings when used externally. Wooden blinds which, when exposed to the air, would not last more than a few years in London, would in Paris remain sound almost as long as the houses themselves. Canvass blinds, in England, generally perished in two or three years. He considered that this rapid decay was owing not so much to the actual quantity of rain which fell in a year, as to the general humidity of the atmosphere. This was particularly observable in the vine, a plant which, it was well known, endured a degree of cold far more intense than it was ever subjected to in England, and yet never flourished in this climate on account of its constant moisture.

Mr. Bellamy remarked that he had observed, in Nottinghamshire, two instances of houses being thrown down from space not having been left for the expansion of the party-walls when built with plaster.

Mr. Tite did not think the humidity of the air here was a sufficient cause for the explanation of the rapid decay of plaster. The climates of some parts of Switzerland and Bavaria were fully as humid as our own, and yet these effects were not observable there. At Freiburg, for instance, black tin was very much used externally without decaying or becoming tarnished. The angles of the spires of churches were frequently covered with sheets of tin, which, when the sun shone on it, looked as bright as silver. In the same way, tin was used for the heads of water pipes and other purposes with equally good effect. In Canada, also, the same thing was observable, and it could hardly be disputed that the climate of many parts both of Canada and Switzerland was quite as damp as that of London. He thought there must be another agent at work to produce the destructive effect alluded to; he was, however, unable to indicate the true cause. It was well known that the air here contained a certain quantity of sulphuric acid, arising from the combustion of coal; the quantity of the acid was, however, so small, that it was difficult to detect it by chemical analysis. He had enquired of several excellent chemists, but they were unable to state what effect the sulphuric acid in the atmosphere had upon building materials.

Mr. Godwin alluded to the necessity of seeing that work of every kind was perfectly dry before the cement was laid on. He had recently had occasion to use Jardan's cement, and had, as he thought, used sufficient precaution in waiting till the work was dry. Owing, however, to the slight quantity of moisture which it retained, the plaster all fell off.

Mr. Tite observed, that all cements of this class, beginning with mastic, were, chemically speaking, nothing more than very coarse paints, mixed up with oil or grease. The disadvantages attending this class of compositions was that the sun and wind dissipated the fatty matter or oil with which they were combined, and the cement soon decayed. The Portland-stone cement, which was, in fact, the hydraulic cement of the French, was an excellent material, and was in almost universal use in France. It was absolutely necessary that this material should be mixed with a certain proportion of clay: it was also of the greatest importance that after it had once been "gauged," it should never be disturbed or touched till it was thoroughly hardened. Unless this precaution were strictly observed, the permanence of the work could never be ensured. It was also a good rule that were patent cements were used, the patentees should be required to use it with their own workmen, and not with strangers, who were ignorant of its nature.

Mr. Poynter referred to the use which Mr. Nash had made of the oily cements in his own house in Regent-street, as a proof of the disadvantages to which those compositions were liable. It might be supposed that the cement being applied to the architect's own house, the work would be done in the best manner possible. It was found, however, that the oil soon fried out, and the surface became discoloured with the well-known stains resembling the lines in maps.

Mr. Tite remarked that the Portland-stone cement was, in fact, an artificial imitation of the nodules of lime, from which Roman cement is prepared. The nodules are found in great abundance on the coast near Harwich. They fall from the cliffs, in which they are imbedded, on to the beach, and are there picked up. They are compact masses of carbonate of lime containing a small quantity of iron, to which latter substance they owe their dark brown colour. The *chaux hydraulique* was precisely the same substance, without the colour derived from the iron. He thought, however, that the iron added materially to the strength of the cement when hardened, and that for this reason the Roman cement would never be equalled in strength by any artificial composition. Atkinson's cement was made of nodules in which the iron was not present; the advantage of this and the hydraulic lime was, that they naturally possessed a good colour and did not require painting.

SOCIETY OF ARTS, LONDON.

April 29.—W. F. Cooke, Esq., V.P., in the Chair.

The first communication was "*On Mr. Godson's Patent Furnace for consuming smoke and economising fuel.*" By W. Spence, Esq. The general features of the furnace and the parts of which it is composed may be thus described:—A box with a moveable bottom, or feed-plate for the fuel, and fitting its internal surface, is substituted for the ordinary bars in the middle of the furnace, and is capable of being raised or lowered within the box or chamber, and which is made to occupy a position in the ash-pit below the furnace. The fuel is fed on the plate while in its lowered position; and when raised it is introduced into the centre of the fire, by which means the smoke evolved from the fresh fuel is consumed. In order, however, to render such a mode of supplying fuel available for its purpose, it is necessary that at the time when the feed-plate in the centre of the furnace is to be lowered to receive its charge, the portion of burning fuel resting thereon should be supported: for this purpose two plates of metal are made to enter the furnace, one on each side, and meet in the centre. Again, it is requisite for the due promotion of the draft into the furnace, that inasmuch as the centre support of the fuel consists of a dead plate, that plate should be kept a little below the fire bars, and that a series of oblique bars should be formed, and extend from the ordinary fire bars to the plate. A model and diagrams of the invention were exhibited, and a lengthened discussion took place as to its merits.

The second communication was "*On a Machine to Register the Velocity of Railway Trains when in motion,*" by M. Ricardo, Esq. The machine consists of two parts: one receives motion from the carriage, the other by clock-work. They are arranged in the following manner:—an excentric is placed on the axle of the carriage, and gives motion, by means of a connecting rod, to a lever attached to the machine, which lever acts upon a ratchet wheel, and is so arranged that each revolution of the wheel of the carriage advances the ratchet one tooth. An endless screw is turned on the spindle of the ratchet wheel, and gives motion to a small toothed-wheel below, and on the spindle of which is fixed what may be termed a lateral excentric (as one part projects more than the other on the side of the wheel). Against this the short end of a horizontal lever is pressed, by means of a spring. As the excentric revolves from the projecting to the lower part, it moves the lever, and with it a pencil fixed at its other end, in one direction, till it reaches the lowest point; when, by a spring pressing upon it, it takes the opposite direction, till it reaches the highest point, when it returns again. The wheels are so arranged, that the excentric makes one revolution in each mile that a train travels. The clock-work is used to turn a drum, upon which a ruled paper is wound. When the train is stopping at a station, the pencil is stationary, and marks only a straight line; but when in motion, diagonal lines are drawn by the action of the lever as described. The extreme distance between the two points of the diagonal lines determines the velocity at which the train has been travelling. Thus, the train is made, by this apparatus, to keep a perfect register of the work done, which would at all times indicate the neglect of either the engineer or conductor.

May 6.—Thomas Webster, Esq., M.A., V.P., in the Chair.

The following communications were read:—

1. *On an Improved Poppet Head for Turners*, by W. Everett, Esq. The first attempt at improving the poppet head (observes Mr. Everett) was to take off the point and insert a screw carrying a spindle and wheel fitted up as a drill, to be driven by the overhead motion, and this he found to answer very well when the hole to be drilled could be brought in a line with the drill. Having done this he still anticipated that he could make this part of the lathe more useful, in fact a substitute in a great measure for the slide rest. The following motions have therefore been given to the point. 1st. An upward and downward motion so that it can be applied to all lathes. 2d. A circular motion which enables it to be applied at any required angle; and 3rd, a motion directly across the mandril, and there is no motion but what is strictly mechanical, as each has a scale to guide the workman in its use. Several gentlemen present examined the instrument and its arrangements and considered it likely to prove a valuable addition to the ordinary lathe.

2. *On the Ventilation of Buildings.* By Mr. A. J. Green.—The paper commenced with an account of the various plans which the author adopted for the purpose of ventilating the sick ward and other rooms of the Sudbury Union Workhouse, and it then proceeded to point out the way in which he would propose that all large buildings about to be erected should be built. Where a double chimney is to be erected, he proposes that two air flues should be carried up in the stack as near the centre as they can be got. If the chimneys are not in the centre of the side or end of the room, the flues should be carried so as bring them as nearly into that position as possible. The flues need not be more than 14 inches by 6 or 7 inches, or 9 inches by 9 inches, and should be commenced from the first floor and continued through every successive story to the top of the chimney, in the same way as the flues for the smoke. One flue of the above size would be sufficient to ventilate four or five stories, if each room required it—valves would require to be fixed in the wall or ceiling in connection with the flue. This system of ventilation, he considers, would be very applicable to smoking rooms, tap rooms, eating houses, or any buildings where a large number of persons assemble.

3. *On the Concentrated Gravy of Meat.* By Mr. Warriner.—This article is manufactured at Sydney, New South Wales, from the carcases of oxen and sheep, which are bred there for the sake of their tallow, wool, hides and bones. The value of oxen in Australia is from 15*s.* to 20*s.*, and of sheep 1*s.* 6*d.* to 2*s.* 6*d.* each. During the last year the leg bones of upwards of 109,000 oxen were sent over to this country, the greater part of the flesh of the animals having been thrown away. The object of the present manufacture is to render down the lean of the carcase into a solid portable soup, by stewing it down in its own gravy, without water, in double pans; by reducing it in this way the water in the lower pan prevents the fire passing through, and giving to the soup the burnt flavour which it has always hitherto had. When manufactured it is sold in cakes of various sizes, at the rate of 2*s.* per lb. One pound of the soup is said to be equal to 24 lb. of the best gravy beef.

CHEMICAL SOCIETY.

April 20.—A paper was read by Messrs. Joule and Playfair, "On the maximum density of water." In this the authors contended that the point of maximum density is the proper standard at which water should be taken as unity for the purpose of comparing specific gravities. There are two methods for determining the point of maximum density of water; one of these being the comparison of water in its expansion with that of some other substance the expansion of which had been already determined; the other virtually consists in weighing water in water, and was pursued by Hope in his original researches on this point. The authors adopted the latter method as the one most likely to yield correct results, but altered the method of experimenting, and the nature of the apparatus employed. Their apparatus consisted of two vessels connected at the bottom by a pipe with a cock, above by an open canal. One of these vessels was made to contain water at a temperature decidedly below that of the maximum density, the other being above that temperature. On opening the stopcock, a current took place from the colder vessel to the hotter, until a certain time, when the current became reversed. The rapidity and direction of the current was determined by hollow glass beads. The experiment was tried under varying conditions; and, as a mean of several series of experiments, the authors fixed 39·101° Fahr. as the point of maximum density, stating that they believed this to be within $\frac{1}{100}$th of a degree of the truth; at all events, that it could not be $\frac{1}{20}$th of a degree in error.

AUST SUSPENSION BRIDGE.

SIR—I observe in your number of last month a letter signed "Francis Giles," relating to the Aust Suspension Bridge, to which is appended a diagram and some calculations respecting it. On these latter it is not my intention at present to offer any remarks, beyond expressing my satisfaction that Mr. Giles thus publicly makes known an opinion, which I before knew he entertained, of the perfect practicability of erecting a bridge upon the suspension principle, suitable for railway purposes across the river Severn, between Beachley and the Aust Cliff. It is the general inference from Mr. Giles's letter to which I wish to direct attention: as I feel, though it may not be designedly intended, it is calculated to incline those who may peruse it to the impression, that the idea of erecting a bridge at this locality originated with him.

It will be found upon reference to the evidence given before the same Committee upon the South Wales Bill in the Session of 1845, to which Mr. Giles refers, that I had previously expressed a decided opinion upon this important subject; and that prior to this, James Walker, Esq., had made the following mention of my views in his Report to the Lords Commissioners of the Admiralty as to the crossing the River Severn as proposed by the South Wales Railway Company, viz., "Mr. Fulljames, county surveyor of Gloucester, considers that a Suspension Bridge, 120 feet above high water mark, at the Old Ferry, or Aust Passage, is practicable. He thinks the piers might be placed on rocks which are bare at low water; but being particularly dangerous at some states of the tides, would have their situations defined by the piers." These views were based upon the results of observations and soundings taken by me at the Old Passage in the year 1838. Whilst engaged upon this, I found that in the year 1825, Mr. Telford, the late celebrated engineer, was consulted upon the improvement of the communication across the River Severn at the Old or Aust Passage, and the New Passage three miles to the southward; and though his attention at that time was specially directed to ascertaining and reporting upon the best situations and mode of constructing landing piers for the convenience of the steam boats, the peculiar inducements and natural facilities for the erection of a suspension bridge at the Old Passage did not escape his acute and comprehensive observation; and though foreign to the subject on which he was called upon to report, so strong was his conviction of its desirableness, that he gave a most decided opinion in favour of a suspension bridge at the Aust; particularly adverting (as the reasons for so doing) to the great height of the banks at the Old Passage, to the fact of the bed of the river consisting wholly of solid rock, and to the circumstance that suitable materials for the work could be procured within a reasonable distance.

During the summer of last year I have been professionally employed by the Bristol and Liverpool Junction Railway Company to report upon this site, and the kind of bridge best adapted for it, both as regards their proposed railway and the navigation of the river, and under their directions have prepared designs for this bridge, on one of which, the opinion expressed by James Walker, Esq. (to whom it was referred by the Admiralty to report as regarded the interests of the navigation), has induced the Lords Commissioners of that Board to consent to the principle of the bridge proposed. The reports and plans have been published, together with the design approved by the Admiralty; of these I enclose you copies, by which you will perceive that Mr. Giles is not the only party whose attention has been directed to this truly national and most important subject.

I beg to remain,
Yours obediently,

Gloucester, May 25th, 1846. THOMAS FULLJAMES.

FOREIGN PUBLIC WORKS.

Recent Prizes proposed by the French Institute (accessible to all nations). —Prize of *Mechanics*, founded by M. Montyon, gold medal of 500 francs, for the discovery or perfecting of instruments useful in the mechanical arts, sciences, or agriculture: term of competition, April 1, 1847.—Prize of *Hygiene*, for the discovery of a remedy for making any art or trade less insalubrious: term, the same. The Prize of *Mechanics* of last year, as well as the great one of 6000 francs on the application of *Steam*, has been adjourned, and that on the insalubrious arts decreed to M. Chausserat.

Expulsion of Foul Air from Mines.—An engineer (M. Halaud) has forwarded to the Academy of Sciences at Paris, a very interesting memoir on the expulsion of foul air from mines, pits, cellars, and similar places. It consists in the pumping of *steam* into places thus contaminated, which, if the foul air consists of hydrogen gas, acts merely as a forcible expeller; but if it be carbonic acid gas, the steam will also absorb that substance. As most places where deep excavations are now made, are near steam engines, the pumping of steam into mines, &c., becomes the easier. It is to be done through elastic tubes covered with india-rubber. The inventor states, that in a deep pit, where the work had been suspended by necessity for several days, the emission of steam purified it to that extent, that the workmen were able to go down as usual.

Public Works in France.—A report of M. Oger has lately been distributed at the Chamber of the French Deputies, to be laid before the commission appointed to examine the bill for the completion of several public edifices. The first of these structures is the Palace of the Archives of the realm. The commission, in lamenting the mistakes and disappointments to which the erection of this edifice has hitherto given rise, proposes a grant of 606,000 francs, on condition that the stuccoes, gilding, and paintings of the original project should be replaced by *cases* more adapted to a depôt of archives. It further alludes to the dangers of the steam engine of the Royal printing offices being so near this invaluable collection of national records.—The Conservatory of Arts and Trades (*C. des arts et métiers*) figures for a sum of 1,441,000 francs, which is to employed in the restoration of such portions of the edifice, which have been completed, in augmenting the number of its halls of exhibition, and opening a principal entrance in the Rue Saint Martin by the purchase and demolition of two houses.—250,000 francs is to be expended on works of the Royal Veterinary School, at Alfort; 650,000 francs at that of Lyons; 89,000 francs at the School of Arts and Trades of Châlons*; 180,000 at the building of the Royal Observatory of Paris.—180,000 francs are proposed for the Palace of the Chamber of Deputies. The ancient chapel, says the report, is in the worst possible state, and although used but very rarely, its restoration is desirable as a matter of public decorum.—The offices of the secretary of state for agriculture and commerce require a sum of 43,000 francs; and, finally, 45,000 francs are to be expended in the demolition of the belfry of the north tower of the church of St. Denis, which menaces ruin.

Archæological Society of Rome.—At the anniversary lately held, Dr. Braun stated the present prospects of the great publication undertaken by the Association—the *Monumenti inediti*. Cavaliere Canina spoke of the discovery of the eleventh mile-stone of the Via Laurentina, which has thrown much light on the position of the laurentine villa of Pliny and the city of Laurentium. The elucidation of some ancient inscriptions of Cora was also alluded to.

Munich.—Independent of the great progress which *inventive* art is constantly making here, the multiplying of objects of art is equally advancing. The great engraving of Professor Amsler, after the picture of Overbeck—"Triumph of Religion in Arts,"—which was begun four years ago, is near its completion. Kaulbach's great picture of the destruction of Jerusalem, has also been begun by M. Charles Waagen.

The Architectural Drawings in the late Art Exhibition of the Louvre—are not much praised, as they consist mostly of restorations, of good appearance—at least on paper—of ancient, mediæval, and renaissance structures. The only specimen of interest bearing on a practical subject is the plan for uniting the Louvre and Tuilleries by M. Badenier, of which, the artist had already exhibited some studies in 1844 and 1845. It is, however, not probable that amidst the many plans of a really *practical* nature, the French government will embark an immense sum in a plan, after all, but ornamental.

French Architectural Exploration of the Island of Cyprus.—M. Mas Latrie, commissioned by the Secretary of Public Instruction for the above undertaking, has addressed the following remarks to His Excellency:—"Everywhere in this island I have found traces of the former sway of France. There is scarcely a town or village which does not contain either a church, or abbey, or castle of the French occupants in the Middle Ages. I have made careful tracings of the slabs best preserved of the sepulchral monuments of her once great families, the Ibelins, Brunswick, &c. The Gothic edifices constructed by the French in Cyprus can be divided into two classes—military, and religious. I have especially studied in each of those the modifications which *ogival* architecture has undergone in Cyprus, compared with the Gothic in France at the same period. I have ascertained the position of the principal castles and monasteries, and laid down by the compass many points and localities important to mediæval geography. I have also somewhat swerved into the domains of Classic antiquity, and have discovered several inedited Greek inscriptions, and, by the means of excavations made at Dali, brought to light several fragments of statuary, &c. I have ascertained the real position of ancient Larnaca and Citium, the birthplace of Zeno the Stoic. In excavating a place near the high city of Larnaca, we have found a basalt slab of 7 feet high, 2¼ feet broad, and 1 foot thick. It is covered with cuniform inscriptions, and the figure of a king or priest, bearing the garment of those figures discovered by Mr. Botta in Mesopotamia. I think this to be a tomb, and one of the rarest monuments of the dominion of the Assyrians in Cyprus." M. Mas Latrie proposes, in fine, that some of the specimens should be deposited in the Museum of National Antiquity at Cluny.

Model Railway in France.—It seems that Arles, the place where Roman structures 1800 years old exist in such perfect preservation, is prompting French engineers to similar exertions. The following is a short extract of the projects for the present buildings.—The viaduct of the railway of the Durance River, will have a length of 493 mètres between the abutments, besides 20 mètres of abutment at each side, which will give it an absolute extension of 533 mètres. Its height is to be 9 30 mètres, computed from low-water mark to the level of the rails; its breadth 8 mètres between the parapets. It is to be supported by twenty piers of 3,50 mètres thickness, combined together by twenty-one elliptic arches of 20 mètres opening. The elegance of the piers, the gracious opening of the arches, and the imposing mass of the Viaduct, will make it one of the finest structures of

* Our readers will perceive that all these public institutions are maintained by public money.

the whole line. After this immense art-structure, the thing next worthy of admiration is the cutting of the rock of la Roque—an immense mass of stone, which was to be cut through from top to bottom to the extent of 125 mètres by 25, which yielded a mass of 42,000 cube mètres of débris of rock. Especially also is to be noticed the nicety of the nineteen cottages of the guards of the line, between Arles and the Durance. To each a little garden has been annexed, to employ profitably the leisure of the men and families. Follows then, the monumental viaduct of the Rhone, which will connect, by the way of Tarrascon, the Avignon line with that of Bordeaux to Cette. This gigantic structure is already begun. It is only 370 mètres from the suspension bridge of Beaucaire; thus two of the finest and hugest modern structures will be erected at a short distance from each other. The activity on the railways in the south of France is now so great, that in the arrondissement of Aix alone, 1390 workmen are employed.

New Hospital at Constantinople.—The East, which, during the crusades first established those—unknown to the ancients—institutions of public benevolence, is it seems, reverting again to that praiseworthy practice. A new hospital is to be erected, by the voluntary subscription of the Protestant inhabitants of the Turkish metropolis.

New Excavations in Assyria.—From the head quarters of M. Laynard, at Nimrud, at the embouchure of the Zab in the Tigris, the following is reported. The mound at which M. L. is digging is an artificial one, like that of Chorsabad, and the ruins are covered by soil; but the stratum at Nimrud is less than that of Chorsabad, so much so, that many of the basso-relievos are broken off at the upper part. The vestments of the figures are different from those discovered by Botta; but there is no doubt that the ruins are also of Assyrian origin. There are more basso-relievos of a mythological character at Nimrud, but the structure of both the palaces is the same. Here also are door-ways of colossal winged bulls, lions with human heads and arms, in which they carry flowers, &c. The number of inscriptions is very considerable.

Campo Santo of Berlin.—The celebrated painter, Baron Cornelius, is expected shortly in the Prussian capital, on his return from Rome, where he went to compose the cartoons of the Frescoes, which have to adorn the walls of the great cemetery, which is to be erected in the neighbourhood of Berlin, similar to those of Munich and Pisa.

Safety Harbours in France.—The Lower House of the French Legislation has, of late, received the Report of M. Felix Réal on the above subject. The Commission, convinced that every facility afforded to commerce will react on all other branches of public utility, has sanctioned this Report, with rescinding only the execution of the maritime canal between the harbours of Bouc and the étang de Berne. The Commission has moreover recommended that Government should employ some professional persons to study the means, by which the mouth of rivers can be made accessible to ships during low water tide.

Directorship of the Dresden Picture Gallery.—M. Julius Schnorr Carolsfeld, of Munich, has obtained the above situation, with which also that of a professor at the Academy of Painting is combined. The King of Bavaria has given, but reluctantly, his consent; the more so, as a number of Munich artists had addressed his majesty for the sake of retaining this great artist amongst them. As M. Schnorr has yet to paint several frescoes of the Niebelungen Song in the new royal palace, he will not leave the Bavarian capital until the end of summer, and will return every season until these great mural pictures are completed, which will occupy him many years to come.

The Iron Trade in Austria and the Zollverein.—All the iron to be used for the railroads of Austria must be of *home* consumption, foreign metal being excluded by a heavy duty. This has advanced their forges and furnaces to a great extent. But it is to be seen, whether this exclusive and *protectionist* principle will work well in the long run.

The Bronze Statue of Charles John, King of Sweden—has just been cast at the foundry of Munich. According to all appearance, it will be a superior work of art, and ready for being conveyed in a few months to its destination at Norrköping, in Sweden.

The Monumental Fountain of the Place of St. Sulpice, at Paris—will be completed this season. For months past, the square has been encumbered by immense blocks of stone, which have been cut for forming the immense basin of this monument.

M. Jules de Saly, architect of the Chamber of Commons of Paris, has been elected honarory and free member of the Imperial Academy of Fine Arts at St. Petersburg.

Monument to the Duke of Belluno.—An enormous block of white marble, from the quarries of Laveline (Vosges), of the weight of 10,000 kilogrammes, has been of late conveyed to Epinal. It is to form the basement of the statue of the duke, which is to be erected to his memory at Lamarche, the little village where this distinguished warrior first saw the light.

Trying of Railway Bridges.—It appears that these structures are not made use of for public traffic in France, until their solidity has been tried, by official persons. Thus the elegant bridge over the Seine, at Courcelles, near Paris, on the Rouen line, has undergone that ordeal, and been found completely safe.

Organization of Public Works in Algeria.—The French Government has created an especial *direction of Public works* for Africa, and a member of the Council of State is placed at its head. Even the name of the supreme office of public works is to be changed, which will henceforth be called Direction of the Interior and of Colonization. Chief Engineers have been nominated for each province. The hydraulic works of the harbour of Algiers and the service of mines in that province, are under the charge of especial government engineers.

Railroad through the Continent of South America.—Means have been discussed at Rio de Janeiro, to connect, in the first instance, Liverpool and Para by the means of steamboats, from which latter place minor crafts have to ascend the Amazon river so far as Bolivia. A railroad has to traverse the latter country and to extend as far as Arica, on the shores of the South Sea. The government of Bolivia has already given its assent to that plan, and a similar step is expected to be taken by that of the Brazils.

New Structures at Berlin.—Much scope to the industrial exertions of the inhabitants of that capital will be afforded shortly by the construction of the new navigation-canal, and the buildings over that large area now called *Köpenicker* Fields. The latest news from Berlin, state that an especial commission for carrying these plans into execution has been appointed by the king. The plans proposed exhibit a thorough ornamental, spacious, and sterling *ensemble;* and amongst the public buildings, new parochial churches, both Protestant and Catholic, occupy the first place. It is generally hoped that they will approach the grandeur of the new religious structures at Munich.

NOTES OF THE MONTH.

The first stone of a new wing of the University College, in Gower-street, has been laid. The ceremony was performed by Lord Brougham, the president of the council.

A new story has recently been added to the Treasury and adjacent Government offices, under the superintendence of Mr. Barry. The show sides fronting Downing-street and Parliament-street are nearly completed; the columns are hoisted to their former position on the first floor.

An equestrian statue of the Duke of Wellington is about to be put on the top of the triumphal arch in Piccadilly. A huge arch supporting nothing is bad enough; but the proposed addition makes it absolutely *too* ridiculous. Even members of Parliament have been able to dedect the absurdity, and have complained of it in the House of Commons. The view of the statue will be the exact reverse of a bird's eye view: an admiring public will have excellent opportunities of contemplating the horse's belly and girth, and the soles of the hero's shoes.

The evidence before the Royal Gauge Commissioners and their report have been referred to the Board of Trade.

The Archœological Congress of France will commence on the 1st of June. The proceedings of the British Association for the advancement of science will commence at Southampton on the 10th of September.

Masses of iron and nickel, having all the appearance of aerolites or falling meteoric stones, have been discovered in Siberia, at a depth of 10 metres below the surface of the earth. From the fact, however, that no meteoric stones are found in the secondary and tertiary formations, it would seem to follow that the phenomena of falling stones never took place till the earth assumed its present form.

The restoration of the western part of Ely Cathedral progresses. Fears are, however, expressed as to the stability of the octagon tower. The lanthern is of Perpendicular architecture, and a subsequent addition to the octagon, which is of much earlier date, and does not seem to have been built of sufficient strength for sustaining the load now resting on it.

The Cathedral of Spires is to be adorned with frescoes at the cost of the King of Bavaria.

A great black stove has been placed in the choir of Bristol cathedral, with a black chimney mounting straight up to the vaulted roof, which is pierced to make a passage for the smoke.

LIST OF NEW PATENTS.

(From Messrs. Robertson's List.)

GRANTED IN ENGLAND FROM APRIL 28, 1846, TO MAY 26, 1846.

Six Months allowed for Enrolment, unless otherwise expressed.

William Edward Newton, of Chancery-lane, civil engineer, for "certain Improvements in clocks or time keepers." (Being a communication.)—Sealed April 28.

Samuel Pickford, of Stockport, glass dealer, for "certain Improved apparatus applicable to casks or vessels for preserving ale and other fermented liquors, and also for raising or forcing the same for draught."—April 28.

Isaac Henry Robert Mott, of 76, Strand, for "certain Improvements in musical instruments, whereby they are rendered much more durable, much more capable of resisting the injurious and destructive effects of the atmosphere, (especially of extreme climates,) and whereby the quality of their tone is greatly improved and remains good for a much longer period."—April 28.

William Higgs, of Westminster, chemist, for "the means of collecting the contents of sewers and drains in cities, towns, and villages, and for treating chemically the same, and applying such contents when so treated to agricultural and other useful purposes."—April 28.

Anthony Nathan de Rothschild, of London, merchant, for "Improvements in heating apparatus and buildings." (Being a communication.)—April 28.

William Mather, of Salford, near Manchester, and Colin Mather, of the same place, millwrights and engineers, for "Improvements in metallic pistons."—April 28.

Charles de Bergue, of Arthur-street west, London, engineer, for "Improvements in atmospheric railways."—April 28.

James Timmins Chance, Handsworth, Stafford, glass manufacturer, and Henry Badger, of West Bromwich, glass stainer, for "Improvements in the manufacture of glass."—April 28.

Joseph Douglas, of Newcastle-upon-Tyne, rope-maker, for "Improvements in the manufacture of yarn, twine, and cordage."—April 30.

Joseph Touché, mechanist, of Rue St. Antoine, Paris, for "Improvements in lamps."—April 30.

Edward Augustin King, of Warwick-street, Charing Cross, Middlesex, gentleman, for "Improvements in the production of magnetic electricity." (Being a communication.)—April 30.

Thomas Lambert, of New Cut, Blackfriars, brass founder, and Charles William Rowley Richards, of Charlotte-street, Blackfriars, engineer, for "Improvements in cocks for drawing off liquids and gases."—April 30.

John Mercer, of Oakenshaw, Clayton le Moors, Lancashire, chemist, for "Improvements in scouring and cleaning wool and woolen fabrics, also in bleaching and clearing silk, cotton, and linen, and other fabrics."—May 2.

George Palliser, of Finsbury-place, for "Improvements in the construction of outside seats of carriages."—May 5.

William Longshaw, of Manchester, for "certain Improvements in machinery or apparatus for spinning and doubling cotton and other fibrous substances."—May 5.

Peter Carmichael, manager for Baxter Brothers and Co., Dundee, for "Improvements in hackling or dressing flax, hemp, and other fibrous substances, and improvements in machinery for rubbing, stretching, and equalising the breadth of cloth made from flax, hemp, jute, and other fibrous substances."—May 5.

George Riddett, of Ryde, Isle of Wight, upholsterer, for "Improvements in reading-tables."—May 5.

John Carter, of Fleur-de-lis-street, London, ivory merchant, for "Improvements in paddle-wheels."—May 5.

Alfred Vincent Newton, of Chancery-lane, mechanical draughtsman, for "certain Improvements in machinery for manufacturing screws." (Being a communication.)—May 5.

William Church, of Birmingham, for "certain Improvements in machinery, to be used in making candlestick pans, and various other articles which are usually produced wholly or in part by means of the process called stamping; and also in machinery for making sockets or tubes for candlesticks and tubes, or tubular articles applicable to various other purposes."—May 5.

William Pidding, of Wigmore-street, gentleman, for "an Improved process for preserving the flavour of coffee and cocoa, or of any preparations thereof, from the effects of the atmosphere."—May 5.

Thomas Melling, of the firm of Melling and Co., Rainhill, Lancashire, engineers, for "certain Improvements in steam engines, marine, stationary, and locomotive; and in machinery and apparatus connected therewith, parts of which are also applicable to regulating the flow of fluids generally."—May 7.

Edward Shepard, of Trafalgar-square, gentleman, for "certain Improvements in gates, doors, shutters, and other articles of the like construction, and in fastenings to be attached thereto."—May 7.

Mark Rollinson, of Brierly-hill, near Dudley, engineer, for "certain Improvements in steam-engines."—May 7.

Alexander Angus Croll, of Suffolk-street, Clerkenwell, chemist, for "Improvements in gas meters."—May 12.

Robert William Sievier, of Upper Holloway, gent., for "Improvements in printing."—May 13.

William Little, of 198, Strand, publisher of the "Illustrated London News," for "Improvements in machinery for printing."—May 12.

John Lloyd Bullock, of Conduit-street, Hanover-square, chemist, for "Improvements in the manufacture of quinine." A communication.—May 12.

Christopher Vane, of Frederick-street, London, gent., for "Improvements in apparatus employed when transmitting and drawing beer and ale."—May 13.

Charles Hancock, of Grosvenor-place, gent., for "certain improvements in the manufacture of gutta percha, and its application alone, and in combination with other substances."—May 15.

Henry Valentine Bartlett, of Sheffield, dentist, for "Improvements in artificial palates, teeth, and gums, and certain machinery employed in the manufacture thereof."—May 15.

Julius Jeffreys, of Norfolk-crescent, Hyde-park, gent., for "Improvements in steam-engine boilers and furnaces, and improvements in propelling vessels."—May 16.

William Rodger, of Shamfield-street, Chelsea, Lieutenant R. N., for "Improvements in anchors."—May 18.

George Duncan, engineer, Edinburgh, for "an improved method of making comfits confectionary, losenges, and all description of pan-goods, the machinery and apparatus for the manufacture of the same, or for any other article to which the said apparatus or machinery may be made applicable."—May 19.

Stephen Perry, of Woodland-place, St. John's-wood, gent., for "certain Improvements in the manufacture of rings, straps, bands and bandages, cords and string, and in their application to clockwork, to locks and other fastenings, to presses, to books, to paper-holders, to candle lamps, to window-sashes, to doors, to window-blinds, to seats and surfaces for lying and reclining upon."—May 19.

Alfred Markwick, of Langham-place, for "Improvements in the manufacture of epithems, used for medical and surgical purposes." A communication.—May 20.

Zachariah Major Parkes, of Peckham, surveyor, for "Improvements in the manufacture of coffins for the dead."—May 22.

Charles Thomas Lutwyche, of Birmingham, gold and silver chain maker, for "Improvements in the manufacture of porcelain buttons."—May 22.

Hugh Greaves, of Hulme, Manchester, engineer, for "Improvements in the construction of railways and the carriages to be used thereon."—May 22.

Charles Wright, of Southampton-row, Russell-square, boot-maker, for "certain Improvements in the manufacture of boots and shoes."—May 22.

John Walker Wilkins, of Stanhope-street, Hampstead-road, for "certain Improvements in water-closets."—May 26.

Charles Bertram, of Gateshead, Durham, Esq., for "certain Improvements in the manufacture of artificial fuel, and in the application of the residual products to useful purposes."—May 26.

Timothy Kenrick, of West Bromwich, ironfounder, for "Improvement in glazing and enamelling the surfaces of cast iron."—May 26.

James Montgomery, of Salisbury-street, for "certain Improvements in the construction of steam-boilers and steam engines, and in steam-vessels, and in the machinery for propelling the same."—May 26.

Edward Alfred Cowper, of Smethwick, near Birmingham, engineer, for "Improvements in the manufacture of railway chairs."—May 26.

William Mayo, of Silver-street, London, manufacturer of mineral waters, for "Improvements in the manufacture of aerated liquids, and in bottling aerated and other liquids."—May 26.

"BLASCO GARAY" STEAM SHIP.—The engines of this new vessel are remarkable for being by far the largest yet constructed on the oscillating principle. They are 350 horses' power; the engineers are Messrs. Miller and Ravenhill. An experimental excursion was made on the 14th of May, and proved perfectly satisfactory. The regularity and smoothness with which the enormous cylinders oscillated on their trunnions was really surprising. The principal peculiarity of construction to be noted is that the valves and ports are placed over the inner trunnions, and oscillate in the same direction as the cylinders: the advantage of this method is that the necessity of having large balance weights is avoided. The equability of the motion of every part of the engine is a most gratifying proof of the extraordinary perfection to which English workmanship has attained. Messrs. Wigram and Son are the Builders. She is intended for the Spanish Government.

The following are the principal dimensions:—

Length between the perpendiculars	187	
——— over all	209	
	ft.	in.
Breadth between the paddle-boxes	31	11
Depth of hold.	20	
Mean depth with machinery on board . . .	10	6
Diameter of cylinders	0	68
Length of stroke	6	

Messrs. Miller and Co. have undertaken to construct for the Oriental Steam Company three pairs of oscillating engines, on the same plan, but of still larger dimensions. The cylinders are to be of 76 inches diameter, and the length of stroke 7 feet.

CORRESPONDENTS.

"A Working Mechanic" (Newcastle on Tyne).—We are not certain that we correctly understand the construction of the proposed mercurial air-pump. Without the mercury be allowed to run out at the bottom of the conical tube, the mere turning of a screw will not make it descend. In any case, the mercury in the conical tube will descend no lower than the point where the difference of the heights in the conical and the upright tubes balances the difference between the pressure of air in the receiver and the external air.

"Messrs. Blair and Phillips" have sent us a very pleasing design for a railway bridge. It is not our custom to publish designs for structures not actually erected or about to be erected, but the inspection of the drawing which we have had the pleasure of receiving reflects credit on the taste of the designers, and induces us to think that we should agree better with them on architectural than on mechanical subjects.

"J. Huntingdon" (Wanstead, Essex).—When an engine is travelling with uniform velocity, the pressure on the piston depends not on the pressure on the boiler, but on the *load drawn*. If the size of the train be such as to produce a resistance of A lb. per inch to the piston, the pressure on the piston must also be A lb. per inch. If it be more, the speed will be accellerated; if less, diminished. If, therefore, as is always the case, the boiler pressure exceed A lb., the steam must be dilated in passing to the cylinder. The whole theory is correctly laid down in De Pambour. The ratio 10 : 16 must have been arrived at by a *statical* process: the problem is a dynamical one. The only correct way of determining directly the relation of the force of the driving-wheel to that of the piston, is by equating the impressed and effective forces by D'Alembert's principle. A much more simple method is however to compare the respective distances traversed by the piston and a point in the circumference of the driving-wheel in equal times. For instance, suppose the length of the stroke 18 inches and the circumference of the driving-wheel 17 feet: while the piston makes a double stroke (3 feet), the engine, if there be no slipping, travels a distance equal to the circumference, 17 feet. Consequently, the ratio of the average force of the driving wheel to that of the piston is (neglecting the friction and inertia of the crank) 17 : 3. *If* l be the length of the stroke, and D the diameter of the wheel, the relation of the force of the piston to that of the wheel is $\pi D : 2l$ or $D : l \cdot 6367$. Mr. Huntington makes it $D : l \cdot 8$, which is too large by more than one-fourth of the real value.

"Mr. R. H. Sharp."—Received with thanks and will appear next month.

(With Two Engravings, Plates IX. and X.)

The gradual improvement of direct action engines, and the general adoption of them in the place of beam engines in steam navigation are subjects of the greatest importance to the mechanical engineer. On the first introduction of direct action engines it was imagined that they could never be made to work so steadily as those of the original form, and that consequently the application of the principle must be extremely limited in extent. It was confidently predicted that in large engines, the great mass of metal pot in motion must cause such a vibration, if the beam were dispensed with, as would speedily cause the pistons, slides, &c., to work untruly.

It has been found, however, by actual experience, that the evil in question may be entirely removed by accuracy of workmanship, and by skill in the arrangement of the working parts. And on the other hand the diminution of the weight of the engines and of the space occupied by it, are advantages of so great importance in navigation, that they far outweigh the supposed disadvantage of removing the beam.
