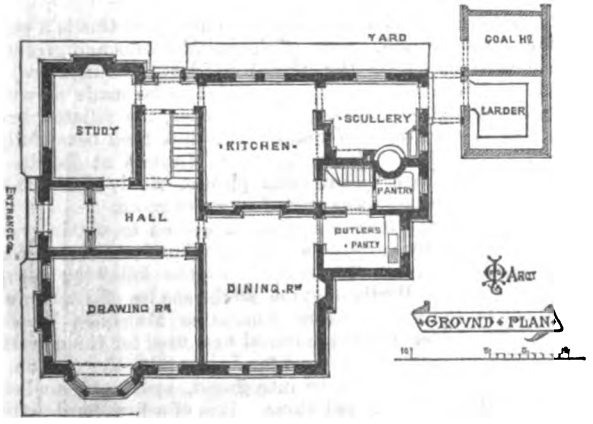
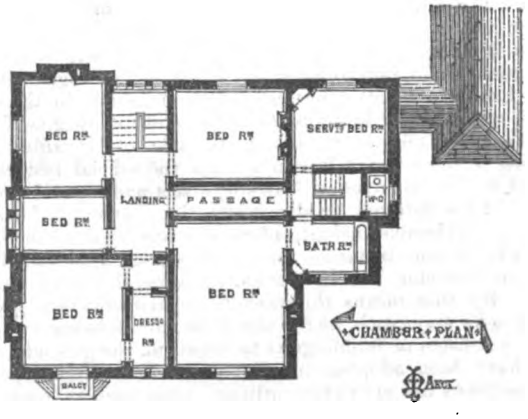
THE VICARAGE FILLONGLEY NEAR COVENTRY.

Digitized by Google

THE



CIVIL ENGINEER AND ARCHITECT'S JOURNAL.



FILLONGLEY VICARAGE, WARWICKSHIRE.

(*With an Engraving.*)

FILLONGLEY is a small village situated between Nuneaton and Coventry, about six miles distant from the latter city. It can boast of a fine old church, which possesses features of Early English, Middle Pointed, and Perpendicular. The structure consists of a wide nave, chancel, and north chancel aisle, with tower of three stages at west end. The old tower, whose two lower stages are Early English, was erected without any staircase; but recently a substantial and characteristic staircase turret of stone has been erected at its north-east external angle, which leads to the ringing chamber, formerly access having been obtained by a ricketty wooden one. The village possesses remains of several half-timbered buildings of Domestic Gothic character. Several alterations and partial restorations have been carried out, but the greatest improvement is the erection of the new vicarage. On the appointment of the new vicar, the old vicarage was found much dilapidated and unsuitable, which necessitated the erection of the one we now illustrate. The accompanying plans and view will be sufficiently explanatory of the structure, with the addition of a few particulars respecting the materials of which it is built.

The walls of the building are constructed of red brick, with bands and checkered work, &c. of black bricks. The cills, plinths, copings, and other stonework of the exterior are of Hollington stone. The roofs are covered with Tamworth brown tiles. All the windows are sash windows; and the fittings generally of the interior, although Gothic, are quite equal to the much sought after Italian in appearance and finish. The floor of the hall is of Minton's tiles. The domestic requirements have received every consideration. The arrangement of the rooms is most convenient and complete: a basement story is under the kitchen department.

The whole of the works have been executed by Messrs. Harrold of Hinckley, for a sum under 1000*l*. Stables, coach-house, and other outbuildings are in course of erection. The architect is Mr. James Murray, of 8, Queen's-road, Regent's-park, London, late of the firm of Pugin and Murray.

THE NEW FOREIGN OFFICE, WESTMINSTER.

This great architectural question, which has agitated the public mind equally with that of the profession during the last eighteen months, may now be presumed to be decided by the award of the parliamentary committee, to whose investigation the matter had been referred, in favour of the design of Mr. Gilbert Scott, A.R.A., and which was numbered in the Westminster Hall collection as 116A. The name of the successful competitor may be taken as a guarantee for two things, viz., that the chosen design is in the Gothic style, and that, in carrying it out, the detail will be so studied in all its bearings as to be a worthy exponent of the general conception. It is not our place here to enter into the comparative eligibility of Gothic or Classic for a site in the vicinity of which superior specimens of both styles may be found, nor into the motives which have actuated the last mentioned referees in their adjudication. On this point much has been said and written, as doubtless will be the case for some time, since the partisans of the several premiated competitors, or of some favourite style, will find abundant materials for their purpose in the conflicting opinions of the judges and those of the public at large, not to mention other circumstances which have been commented upon. As the recent decision has however yet to be sanctioned by Parliament, these knotty points will probably be again brought under discussion, and, in a question of such national interest, it is befitting that everything should be placed in its true light, with a view of showing that, under the circumstances, the selection made is the one which, in conformity with preliminary instructions, appears to be best adapted for the purpose, due regard being had to the subjects of arrangement, appearance, and cost.

It is perhaps needless to remark that the new Foreign Office now alluded to constitutes but a portion of a scheme for remodelling the whole of the Government offices, and one, the magnitude of which, if carried out, will completely annihilate the present aspect of all the streets and buildings between Whitehall, the Abbey, and the Park. The entire site would be divided into two nearly equal portions by Parliament-street, and this determines the first line of subdivision in Mr. Scott's block plan, each area thus marked out being, in rough numbers, about 600 feet square. The western half, being the most important, merits the first consideration, and of this the northern portion takes the precedence as being the first to be built upon. For this two designs were submitted—the one presenting an open court, and the other a continuous front towards Parliament-street, the latter being in the author's opinion the preferable treatment. The flank elevations towards Downing-street and Charles-street have each a grand entrance in the centre between the two offices; in the one case, however, this leads into a spacious quadrangle, common to the War and Foreign Offices; in the other, into a smaller one, belonging exclusively to the Foreign Office. Into the questions of the War Office, and the present buildings, it is needless to enter now, as its erection is not contemplated immediately, but in all the arrangements the object has been to combine unity with simplicity in the entire design, with variety in its parts. The position assigned for the new Foreign Office is on the south side of Downing-street (opposite to the present Treasury), and the official residence is allotted to the wing facing Downing-street and a portion of the Park. In the internal arrangements, since some of the rooms require considerable height, advantage has been taken of this to obtain, in some instances, mezzanine stories, approached from the same corridor, but by the aid of a small gallery running above. By this means the various departments are brought within more easy reach, and it also does not necessitate such an undue extension of buildings as to crowd up the ground. High roofs have been adopted in some parts of the buildings, and other portions rise above the ordinary level, such as towers, &c., so that while an agreeable diversity of form is gained, ample accommodation for attendants, besides much spare room, will be available internally. On the ground floor the rooms specified for the Foreign Office are readily provided, but on the first-floor the required space exceeds that below, so that, in one instance, a department has had to be divided by placing two or three of its rooms in a mezzanine over the others. To facilitate communication with these, an extra spiral library staircase is added. The principal staircase to the building is to be in the centre, and it is proposed to be covered by a sort of dome of glass, ornamental in pattern, and occasionally stained in colour.

The design of the exterior is, as we have stated, based upon a simple outline. The principal front is of three stories below the cornice, but with a high-pitched roof rising behind, the monotony of which is relieved by a succession of elegant dormer windows, gabled and crocketted. The centre portion is carried up as a tower above the abutting roofs at the sides, and is covered by a lofty roof, hipping back, continental fashion, all four ways, and surmounted like the others by an enriched metal cresting. The centre portion slightly projects before the general face, and its angles are masked by large octagonal piers, which are continued to the top of the tower, and terminated by the range of the cornice. The only doorway to this front is in its centre, and consists of a bold archway, deeply recessed and moulded, having also a good deal of carving, on each side of which is a corresponding panel-arch of smaller dimensions, and all three are surmounted by crocketted gables. On each side of the central projection the design is uniform, consisting of a series of windows in each stage; the lower being of three lights, and the two upper of two lights each. Every window is placed in a comprising arch, and has the space thus enclosed pierced. On the ground story there is a series of medallions in circular panels between the window heads, and on the first or principal floor the piers between have shafts standing on the string course below, and bearing full length sculptured figures, protected by handsome carved canopies. The third floor has its windows agreeing vertically with the centres of those below; but, being narrower, there is room for a blank panel-arch between each. The outer angles to the flanks are strengthened by solid octagonal piers or turrets, as already described for the centre; these are not finished at the cornice level, but are carried up detaching themselves from the roof, and forming octagonal pinnacles arcaded, and terminated pyramidally.

Considerable attention has been bestowed in the design of the windows generally, and, compared with those of buildings in other styles, they will be found to contain a very unusual proportion of open space. Many of them have 6 feet width of glass, with only one mullion, others have nearly as much without any division. They are arranged to open as ordinary sashes; and, in some instances, there being additional lights in the head, these would open as ventilators by other means. Those windows which may open on to balconies may have French casements, or sashes, as may be preferred. All are intended to be glazed with plate glass in single sheets. The only exceptions to this are the upper parts of the windows on the first-floor of the official residence, which, above the transom, are to be filled with stained glass. The style of the façades is, generally speaking, more columnar and more thoroughly arcuated than has been usual in the modern treatment of the style, the architect considering that this will add greatly to the boldness and effect of the design.

The internal construction is proposed to be fireproof, on a system resembling that prevalent at Paris; but this is a point for further consideration. Some of the metal beams and girders used in the construction (in the official residence for instance) would be exposed to view; these are intended to be made of wrought-iron, and plated with decorations of brass, the foliated brackets under them being also of brass. This has been beautifully contrived in another style in the new Museum at Berlin. The ceilings are to be of ornamental plaster, richly decorated with painting, and the patterns varied in every room.

In the external masonry it is suggested to obtain a certain degree of relief by variety of colour. This is not intended to be very marked, but to be arranged in the following way:—The great mass to be Portland stone, slight shades of difference to be obtained by the use of either Anston or Mansfield Woodhouse stone. The latter was the material first used for the new Houses of Parliament, and it has stood far better than the Anston. The third colour proposed to be introduced, sparingly, to heighten effects, is the Mansfield red stone. It is of a firm hard texture, of a beautiful colour, and very durable. It may be seen in the pavement of the terrace in front of the National Gallery, above Trafalgar-square, where the white stone alternated with it is worn down, while the red remains all but perfect.

Among the more valuable and effective materials intended to be employed are polished red granite, or serpentine, occasionally, for shafts, &c. There will also be considerable beauty derived from the application of inlaid work,—a beautiful species of decoration, but hitherto much neglected in this country. The patterns would be of the three stones above enumerated, but heightened at particular points by polished granite and other

Digitized by Google

materials. Internally, in the grand staircases and official residence, a great deal of Devonshire and Derbyshire marble could be used with advantage, as also alabaster from Derbyshire and elsewhere, under certain circumstances.

In the foregoing description we have entered pretty fully into the chief characteristics of Mr. Scott's design, as submitted in the great competition, and now ultimately selected; it may possibly not be carried out in its integrity, precisely as shown; for the best arranged plan would doubtless be open to improvement on mature investigation; but, whatever modifications may be insisted on, we may rest assured, that, from the able hands into which the building has been entrusted, every appliance which skill and genius can command will be brought under contribution to render the "New Foreign Office" a structure in every way worthy of our country and of our age.

ST. JOHN THE BAPTIST CHURCH, GLASTONBURY.

THE works which have been for nearly two years in progress at this church, are now beginning to promise a speedy termination. Owing to unexpected causes, the time occupied in a comparatively ordinary restoration, as far as the amount of alterations is concerned, has been unusually protracted, but it has enabled the parties to proceed with a care which it could be wished were oftener exercised, both for the sake of old buildings, which are too frequently sacrificed through over hurrying as much as through wilful neglect, and for the sake of the architect, who thus has opportunities of conscientiously investigating the difficulties which he is sure to encounter if he act up to his duty, and then well maturing his scheme of operations.

Externally, but little reparation has been attempted, indeed the building does not require it, for, the masonry being executed in what is unquestionably one of the best local stones (from the quarries at Doulting), it retains a sharpness of arris and substantiality of condition which comparatively few structures of even the Perpendicular age can now boast. The colour, too, imparted by time is a most agreeable one, and the noble church, with its majestic tower (of the true Somersetshire type) is, from all points of view, an interesting and impressive object.

Internally, the whole of the fittings have been cleared out, and are being replaced by new ones of more suitable design, the floors and passages are being relaid, the pulpit and font thoroughly restored, and various architectural features disclosed. Besides this, the roofs have been throughout carefully repaired, and various improvements made in the arrangements of the chancel. Some old altar-tombs between the latter and its north aisle, will be cleaned, but will have to be refixed, owing to the ground (or vaults!) below having partially given way. The slender pier forming the south support of the chancel arch, and which partially receives the thrust of three others, had declined so much from its verticality that it was found necessary to shore up the arches and rebuild it.

THE ROYAL POLYTECHNIC INSTITUTION.

THE managers of this instructive establishment, while preserving for daily inspection a vast amount of permanent attractions, are constantly on the alert in providing extra entertainments, consisting for the most part of lectures and experiments illustrating one or more of the popular subjects of the day, treated in a scientific manner, and yet in a style so comparatively devoid of technicalities, as to be intelligible to all classes of hearers. A highly interesting topic at the present time is discussed and explained on alternate evenings, which is "On artificial light as applied to Photography," practically illustrated by Moule's patent photogenic apparatus, and explained by the professor of chemistry, Mr. E. V. Gardner. The great strides which the art of photography is now making, and its extensive application in a variety of ways, renders the discovery of a substitute for solar light one of extraordinary interest, as increasing to untold degree the facilities for pursuing scientific studies. At present we are not aware that it has been made available for anything beyond taking portraits, but in this it is so successful an auxiliary, that from the specimens we have examined (including one taken in our presence for the purpose of illustrating the process) we may fairly pronounce them equal to those taken by daylight even under the most favourable circumstances. The light possesses an amazing brilliancy, and is specially used by Mr. Moule for the purpose of producing photographic portraits at night or in dull weather. It is generated by burning a compound of antimony, sulphur, and nitre, called "Photogenic composition," the apparatus being designated the "Photogen." It is stated to be perfectly safe in its use, wholly free from sulphurous fumes and like annoyances, and also inexpensive, the cost of the largest size portrait being but about twopence. For theatrical performances, where pyrotechnic compositions are employed, it will doubtless supply a great desideratum. The fact that the process is introduced under the patronage of royalty will of itself be accepted as evidence in its favour, while the patentee, Mr. John Moule, of the Hackney-road, has already secured patents for England, France, and Belgium. The explanatory remarks of the lecturer were all that could be desired, and were evidently appreciated by his audience. Among the earlier lectures is one delivered daily by Mr. King, called "New Inventions Demonstrated." Entertainments such as these merit the widest possible support, and we have much pleasure in recommending them.

In the large gallery may be observed a stand exhibiting a "Foliographic press," a new machine for printing from nature, invented by Mr. G. J. Cox, of Great College-street, Camden-town, which will be found a useful auxiliary to the botanist, and to the architectural carver who culls ideas from the exhaustless resources of nature, inasmuch as, by a very simple method, the exact forms and fibres of leaves, &c., may be transferred to the sketch-book almost instantaneously. The leaf is to be put within the folds of a sheet of prepared carbonised paper, and then subjected to pressure from a roller, by which means it becomes impregnated with ink. It has then only to be shifted on to the intended sheet of paper, which is now to be introduced under a leather flap, and pressed by passing the roller once over the surface, when an accurate result will be obtained.

It would scarcely be worth while to regard with critical eye such transient things as "dissolving views," were it not that they are sure to attract an eager crowd of gazers; it is, therefore, surely desirable, where certain specified objects are professedly delineated, that the representations should be as nearly as possible true to the originals. The subject now depicted is "The Thames" from its source to the Nore; and it naturally presents in its meanderings several architectural scenes. These, it must be confessed, are needlessly incorrect, even allowing the utmost artistic license. To mention only two examples:—The first picture is supposed to show the spot whence the incipient river springs from the earth in the county of Gloucester, but at a distance of very many miles from its capital; and yet Gloucester Cathedral is visible, not exactly in the foreground, but, as it were, in the adjoining field or so, and standing quite *per se!* The other case is the city of Oxford, in which the artist appears to have had a vague idea that its sky line presents a playful variety of tops of steeples and colleges, but nothing more. The only form which can be at all recognised is that of the Radcliffe Library, but the scale to which it is seen is much short of the real one. It would not have been difficult to procure an authentic view, and a thoroughly artistic-looking one too, so that the neglect is the more inexcusable. Such productions tend only to mislead, and are therefore better left alone. Apart from these drawbacks, which we refer to only in a friendly spirit, the several dissolving views may be pronounced successful.

ON THE MANUFACTURE OF THE UCHATIUS CAST-STEEL.*

THE manufacture of cast-steel, of which this paper treats, although not directly in the department of mechanical engineering, is so much connected with it, that a few words on that subject may be interesting to the members of the institution. The quality of the materials used for all parts of machinery and for the tools employed in their construction is of the greatest importance These materials should possess the greatest strength and tenacity, and at the same time a durable and uniform wearing surface. Now cast-steel perhaps beyond all other available metals possesses these qualities, and it is only its great cost that has hitherto prevented its more general application. It has a bearing strength of nearly three times that of best forged iron, and having a per-

* Paper read at the Institution of Mechanical Engineers.

Digitized by Google

fectly uniform texture it wears equally; it must therefore be acknowledged that cast-steel is the best material that can be used where lightness and strength are required, and for all parts of machinery that are subject to much wear and tear. Its great cost being the difficulty in the way of its extended application, the great object in view for some years past has been to find out some process of making cast-steel of a good quality, and at a price that would allow of its free employment. Amongst a great number of metallurgists who have within a very recent period directed their attention to this subject, may be mentioned Bessemer, Chenot, Uchatius, and others. It is intended in this paper to enter only into the details of the Uchatius process of making cast-steel, as compared with the ordinary processes at present in extensive use, which are two,—the English or converting process, and the German or puddling process.

To compare these processes with the Uchatius process about to be described, it must first be considered what steel really is, and in what manner it may be produced. This point may be illustrated by the following series, comprising the various degrees of wrought-iron, steel, and cast-iron, arranged according to the amount of carbon in each, beginning with the softest wrought-iron, that is with the iron containing no carbon or the least amount of carbon:—

Soft wrought-iron, containing		0·0	per cent.	of carbon.
Hard wrought-iron	,,	0·4	,,	,,
Soft steel	,,	0·5	,,	,,
Hard steel	,,	2·4	,,	,,
Cast-iron	,,	2·5	,,	,,
Hard cast-iron	,,	5·0	,,	,,

In this series, beginning with the softest wrought-iron containing little or no carbon, the proportion of carbon increases until there is ½ per cent., which then forms soft steel; a further increase of carbon up to 2½ per cent. forms cast-iron; and the proportion of carbon increasing to 5 per cent. gives the hardest cast-iron. Hence it appears that the operation of steel making may be effected in two methods,—either by adding a certain amount of carbon to pure wrought-iron; or conversely by taking away a certain amount of carbon from cast-iron, removing at the same time the impurities of the cast-iron.

The English or converting process is carried on according to the first of these methods, by adding a certain amount of carbon to wrought-iron. The cast-iron is first made into wrought-iron, which is then converted into steel, forming blister steel; this is broken into small pieces and melted in crucibles, which renders it homogeneous, and is then poured while fluid into ingot moulds, after which it is known as cast-steel. The chemical changes which the cast-iron has undergone in this process are—firstly, when it was manufactured into wrought-iron all or nearly all the carbon was abstracted from it; and secondly, by the converting process a certain amount of carbon was restored to it; and finally, the steel thus produced was made homogeneous by melting and casting. It is evident that this is a very circuitous way of manufacturing cast-steel, and it has the following disadvantages: the great loss of weight in manufacturing the cast-iron into wrought, the difficulty in converting the wrought-iron so as to carbonise it equally in all parts; the great length of time that this process requires for the production of cast-steel, and the great cost of manufacture.

The German or puddling process is effected by the converse method, by taking away a certain amount of carbon from cast-iron. The pig-iron is puddled in the same way as in making wrought-iron, except that the process is stopped when a certain amount of carbon has been taken away, a point which it is difficult to judge of. This partially puddled iron, so-called puddled steel, is then made homogeneous by melting it in crucibles in the ordinary way. The chemical change which the cast-iron has undergone by this process is the abstraction of a portion of the carbon in the puddling furnace; and the puddled steel has then been rendered homogeneous by melting and casting. The disadvantages of this method are: the waste of iron by the puddling process; the uncertainty of getting equally discarbonised iron, owing to the difficulty of measuring the quantity of oxygen acting on the puddled metal; and also the cost of manufacture.

The Uchatius process is based upon the same principle as that last described, consisting in taking away as much carbon only as is required to produce steel, and removing at the same time the impurities of the cast-iron. The first and most important of these objects is effected by bringing a certain measured quantity of oxygen, in the shape of oxides of iron, in contact with the cast-iron, so that while the iron is hot the oxygen combines with the carbon and passes off in the form of carbonic acid gas. The purification of the cast-iron from silica, sulphur, magnesia, &c., is effected by bringing the iron when it is in a melted state into contact with the alkaline earths, so that the impurities combine with them and remain floating on the top of the melted metal.

In order to effect these two operations at the same time the pig-iron is first melted in a furnace or ordinary foundry cupola, and then run into a cold-water tank, where it is reduced into small granules. The mode in which the granulation is performed is stated to be as follows:—the cold-water tank has a horizontal wheel placed in it at one end, provided with wooden floats dipping below the surface of the water, and driven at a considerable speed; the melted metal running into the tank from the furnace falls on the wheel, which scatters it in a finely divided state towards the deep end of the tank, and it falls to the bottom in the form of small granules. This granulated cast-iron is mixed with pulverised oxide of iron and some alkaline earths, and the whole put into the ordinary steel-melting crucibles and placed in the furnaces and brought into a fluid state. The degree of hardness of the steel is thus capable of being regulated by the size of the granules and by the quantity of oxides used.

The chemical change which takes place in the crucible is as follows:—Each granule being surrounded by the pulverised oxides, &c., the decarbonisation takes place first on the outside of each granule, and so progresses towards the centre as the heat increases, the oxygen in the ores combining with the carbon in the granules and passing off as carbonic acid gas; if therefore during the process the granules could be examined, it would be found that the outside of each is entirely deprived of its carbon, the next portion partially decarbonised, and the centre not decarbonised at all; so that each granule would be composed of pure wrought-iron, steel, and cast-iron. By increasing the heat, the cast-iron centre portion of the granule first become fluid, and the granule bursts and falls by its own weight to the bottom of the crucible. At the same time the earths mixed with the ores melt and rise to the top, forming a layer of scoria or dross floating on the surface of the melted iron. Each granule of melted metal has therefore in falling to pass through the rising scoria; and it is in the passing through that the combination of the impurities of the metal with the alkaline earths takes place, so that the decarbonised iron on reaching the bottom of the crucible is cleansed from all impurities. The heat continuing to increase melts the outside portions of the granules, and the whole is reduced to one homogeneous fluid mass in the crucible, which is then ready for being poured into the ingot mould. The iron contained in the oxides mixes at the same time with the fluid mass, and yields about 6 per cent. more of cast-steel than the weight of granules put into the crucible.

The oxides employed in this process are iron ores of the finest quality, such as spathose and hematite, which are previously calcined and pulverised. The proportion of the oxide to the granulated iron is according to the hardness of steel required, say from 20 to 30 per cent.; the greater the quantity of the oxide employed, the greater the decarbonisation, and consequently the softer will be the steel produced.

The process is attended with the following advantages:—A rapid manufacture of cast-steel, the pig-iron being turned into cast-steel in the space of a few hours; certainty in producing a uniform quality of steel, that is steel containing a determinate proportion of carbon, which is accurately determined beforehand by the weight of oxide mixed with the granulated iron; and less cost than the ordinary methods of making cast-steel, since the processes are fewer and the materials used are simply pig-iron and iron ores.

Some experiments in making cast-steel by the Uchatius process have been made by the writer at the Newburn Steel Works, near Newcastle-on-Tyne, from which it appears there is little doubt that a very fine quality of cast-steel can be produced at a cost little more than one half of that entailed by the common processes.

A specimen of steel bar was shown made by the process described in the paper, which had been tested and broke with a load of 30 cwt. at the centre, the bar being 1 inch square and 3 feet in length between the bearings; the deflection was 3⅜ inches at the time of breaking. A specimen was also exhibited showing the welding of two pieces of the steel, and specimens of the granulated iron and the pulverised ore used in the manufacture, and of the bars and plates produced, with some volute springs

Digitized by Google

made from the steel; also a piece of the steel twisted cold to show its toughness.

Mr. T. Spencer said that he had not tested the tensile strength of the steel at present, but found it stood well in the volute springs that had been made of it, which had proved quite satisfactory in working. Only some small plates had been rolled from the steel at present as a trial, but these had proved quite satisfactory; and he did not anticipate any difficulty in making any size required. It would be observed in the specimen exhibited, that the plate was quite sound on the edges, although it had not been rolled edgeways, but simply rolled down lengthways. No wire had yet been made from it; the bars and plates made had been hammered and rolled down from the ingots of cast-steel. The total cost of the finished bars was about one-half of that by the ordinary process; but where the makers hammered and rolled their own steel, and the cost of the ingot only had to be compared, the proportion would be considerably less.

Mr. W. Fairbairn thought this process was a very important step in steel manufacture, and would prove of great advantage in the construction of machinery, if a sound uniform steel could be obtained at a moderate price. The bar of the new cast-steel that was exhibited certainly showed great strength, having sustained nearly three times as great a weight as iron; and he thought in process of time they might reasonably expect to obtain plates cast and rolled of that manufacture at least double the strength of the present wrought-iron boiler-plates for the same thickness, and not much more expensive for the same strength; and it had now become a very important desideratum to get plates for boilers only half the thickness at present used, as the thinner plates were so much less liable to injury from overheating and unsoundness in manufacture.

Mr. T. S. Prideaux thought the dropping of the melted iron into water in the process of granulating it would have a beneficial effect in assisting to free the metal from sulphur, by the metal coming in contact with water in a red-hot state; the plan had been tried in Austria, he believed, with success. It was not at all easy to separate sulphur from iron by simple exposure to oxygen in atmospheric air; and he thought the plunging of the highly-heated granules in water would be the means of removing the sulphur to a considerable extent from the iron.

Mr. W. Smith thought the process that had been tried in Austria was that of Capt. Uchatius now described; the plan of granulation seemed a very ingenious and important step towards obtaining steel by the direct process of decarbonising, and offered the best chance of carrying that process to a successful and economical result. Great advances were being made at the present time in steel manufacture, and they were doubtless greatly indebted for these advances to the investigation of the subject that had been excited by the publication of Mr. Bessemer's plans, although he had not succeeded in all that he had attempted himself; and they were also much indebted to Mr. Binks for having called more minute attention to the chemical principles involved in the manufacture of steel. The new process described in the paper appeared to have effected a great success in obtaining cast-steel by the direct process; and if the uniformity of quality could be maintained, the economy of manufacture would allow of the use of cast-steel being extended to many important new applications, such as boiler plates, and steel wire for the manufacture of telegraph cables.

Mr. A. Lenz explained respecting the process, in the absence of Captain Uchatius, that the only object in dropping the melted iron into water was to effect its granulation, and not for the purpose of depriving it of sulphur. The process of this manufacture of steel was to decarbonise the cast iron by the action of oxides under a high temperature, the great object being to expose the largest possible surface of the iron to this action, and by granulation this object was obtained to a remarkable extent. As to the actual composition of the steel, Capt. Uchatius had come to the conclusion, from the results of his observations, that the best steel required some small portion of what are considered impurities, such as sulphur, silica, &c.; and that chemically pure steel was not the result to be aimed at, and he had found that even with ¼ per cent. of sulphur the steel was of good quality. The great desideratum was to make steel at a very cheap price; and he had hopes it might even be practicable to apply it ultimately to the manufacture of railway bars.

Mr. J. Anderson observed that the first steps had certainly been accomplished towards obtaining a better material at a reduced cost, and this was a very important object to be aimed at. Mr. Binks had been the first to draw attention to the fact of steel containing nitrogen, which from his researches appeared to be an ingredient of great importance in the composition of the different qualities of steel, and he was not aware whether any further information had been obtained upon this point

Mr. E. A. Cowper remarked that, in the list of compounds of carbon and iron given in the paper, the hard cast-iron was put down as having the largest proportion of carbon; but he supposed it was not meant that the hardest cast-iron was that containing the most carbon, as the extreme of soft grey iron was kishy from an excess of carbon. He asked whether the Uchatius process removed the phosphorus from the iron; and what were the results of Chenot's process, by which a spongy mass of iron was produced, which was then compressed and dipped into oil, converted and worked into bars.

Mr. A. Lenz said that only the good qualities of iron were attempted to be used for steel making by the Uchatius process. and the Indian and Swedish iron was principally used, containing very little trace of phosphorus, as it was doubtful whether any phosphorus could be removed in the process.

In Chenot's process the principle was to employ pure magnetic iron ore in powder, which was found in a few situations in the Pyrenees in a natural state of powder, and was separated by a machine from the earths mixed with it. This powder was put into a furnace like a cupola, within a tube in the centre protecting the ore from the fuel, and exposed to a great heat; the powder then became in a spongy state, by reduction to nearly pure iron, but was not able to melt. It was then compressed cold with great force under a hydraulic press to solidify the mass, and was finally carbonised by covering with mixtures of oils and other carbonaceous substances, and melted in a close crucible. He doubted the process being adapted for the actual manufacture of steel on any large scale, and thought it more suitable for the laboratory than the shop; various articles had been made of the steel for trial, which he believed were of a good quality, although he thought there was not any regular manufacture carried on.

Mr. W. Fairbairn had seen the process in operation two years since in Paris, and the steel that was manufactured by that means was of good quality; but the process was carried out only on a small scale, and seemed scarcely suitable for any wholesale manufacture.

Mr. T. Spencer observed that a magnetic machine was employed to separate the iron from the earthy matter, when in the state of powder as found naturally. The pig-iron was broken into 6 or 8 inch pieces, and was at first put into the cupola for melting in the ordinary way; but they had now constructed a furnace for the purpose, as the ordinary cupola rather increased the proportion of sulphur in the metal by absorbing some from the fuel: the new furnace was a kind of reverberatory furnace, melting the iron in a chamber separate from the fire. The fluid metal was then run into the granulating tank; and the granules of iron were collected at the bottom of the tank by drawing off the water

ON THE GEOMETRIC TREATMENT OF SCULPTURE.

By John Bell, Sculptor.

The title of this paper would be accepted as grouping together some considerations of much importance in the association of his art with that of architecture, and on which he would venture to offer a few remarks. They might afford at least a sculptor's view of the subject, which had in that room the best chance of being checked and guided by that of the architect. What, then, might the title "Geometric Treatment of Sculpture" be held to imply? Using the word geometry in its accepted sense, he would submit—that selection of forms and masses founded on lines of geometric contour, as straight, square, circular, elliptical, pyramidal, or wave-like, &c., which especially suit sculpture for the purposes of harmonious decoration. Now although, no doubt, a work of sculpture—as a unit and isolated—is the better for being of a symmetric outline, and well balanced and adjusted in itself as an ornamental form, yet still more was this the case when it was regarded in reference to those situations in which sculpture was usually placed, which also, he conceived, might

* Paper read at the Royal Institute of British Architects.

Digitized by Google

nearly all, more or less, be considered architectural. In a garden, for instance,—those gardens which were suitable for such decorations as vases, statues, or fountains, where there was more or less a symmetric plan, might all in degree be considered as extensions of the house itself to which they were attached—as its outer works, as it were, as affording apartments with walls indeed, but with no roof but the sky. Under this aspect none of such decorations of art as were introduced in these situations were altogether beyond and without the bounds of architecture, but their effect would be influenced in a large degree by the same laws under which they appeared within the immediate courts, halls, and apartments of the edifice itself. When, therefore, a work of sculpture on its pedestal was placed in a garden, the two together, as a mass, would have the best effect if they justly subserved some theory of decorative arrangement, which required in that spot an architectural feature of that quality. He said this in order to acknowledge that even when not directly associated with architecture, it might be very well for sculpture to hold itself bound by the same ties of geometric harmony as if in nearer relation. Of course, when more closely connected with the sister arts—as in statues to fill niches, relievi to occupy panels, figures to become the finials of columns, or extended and diversified compositions to adorn and enhance the tympanum of a façade, or the summit of a triumphal arch—the geometric treatment of the sculpture became more intimately an architectural question. So vital, indeed, did this appear in those cases, as regarded the eventual good effect of both the building that was to be adorned and the sculpture that should adorn it, that there seemed but a remote chance of a happy result unless a geometric laying out of contours and masses, and light and shade, had formed the ground-work of the design. In such cases the most delicate and artistic detail would fail to make up for deficiencies in geometric plot; which latter consideration, however, being regarded, the more beauty of finish the better, as the Athenian had so well illustrated in the exquisite workmanship of those figures which remain to us from the tympana of the Parthenon, which were viewed at an elevation of more than 50 feet. It appeared, therefore, that sculpture should never lose sight of those family ties which bound it to architecture, and by which so much mutual benefit was to be attained. The freedom of sculptural lines, which sculpture drew from the contours and movements of vital forms, might well give flow to the stricter types and masses of architecture; while, on the other hand, the latter, spreading out and aspiring more under the steadfast laws that govern the mineral kingdom, might lend in turn to sculpture the most valuable hints of geometric construction. And that held even in cases where the sculpture was not in direct association with architecture, but was a principle also affecting the art by itself, insomuch that a work of sculpture was ever the most perfect in itself when its general contour possessed that quality and character of geometric symmetry which fitted it for an architectural decoration. In illustration of these remarks, he had selected a few works of ancient and modern sculpture. He had necessarily been limited in his selection; and he had also thought it best to obtain small copies of those works instead of the large originals; and the more so, insomuch as his present theme only related to the general treatment of mass and line, which the reductions before them would serve to illustrate pretty nearly as well as the larger originals, some of which it would have been out of the question to bring there. In those examples, familiar because they were good—like the good tunes in the streets—the eye acknowledged, he fancied, at once the advantages of geometric treatment and balance which they possessed, and in which they advanced the valuable precedents of the best masters. It might, however, be as well to make *in limine* an acknowledgement that to that precedent there were exceptions. In such cases, however, we could not tell how far such examples as did not possess this even adjustment were intended to act as one of a pair; in which case, although when considered as units they did not balance, yet, as parts of a twin decoration they might do so most agreeably,—as was the case with the ears of a sarcophagus, or the handles of a vase, which as units were irregular, yet as a pair regular; and though singly uneven, yet, when justly disposed, were mutually responsive, as was seen in the two side figures of the Medici tomb before them. Had either of those two figures been found separately, or alone, in an ancient ruin, its form would have been deemed irregular; but as they exist now according to the artist's original plan, they were an apt example of geometric and responsive arrangement. He might as well acknowledge, however, that the more he saw of works of art the more vain it appeared to him to attempt to enact perfect canons of taste or treatment. A perfect canon in such matters appeared as impossible in existence as that of a perfect specific in medicine. Thus in this case, although geometric treatment was undoubtedly a part of fine sculpture, and although certain cases of apparent divergence from this rule might be argued away, yet, without pedantry or special pleading, it could not but be allowed that there were some noble works which appeared to play truant to these rules. That remark, however, applied chiefly to figures in the round, in which, in any decided action, it would be recognised at once that a form of geometric symmetry could hardly be obtained in all views. In these cases it would be admitted that that arrangement was the most happy which gifted the front and principal view with the best balanced decorative form. The noble statue of the Belvidere Apollo and the Borghese Diana were in some views of an irregular contour, and yet in others they presented one sufficiently geometric to render them suitable for central forms without a pendant, especially in the centre of an ample space, and comparatively aloof from such lines of architecture as would emphasise their departure from the balanced character of an architectural finial. Although, however, some views of these and some figures might be irregular, yet he conceived that even in these cases the desire was perceptible—to obtain, as much as the subject and action admitted of, a well-balanced and geometric form. Also, with respect to the above-mentioned two statues, we did not know how they were originally placed. The colossal elephantine works of Phidias—the Jupiter at Elis, and the Minerva of the Parthenon—were recorded as having been evenly balanced works; while we were also informed that they were symmetrically placed within the temples that contained them. Without further introduction, he would now advert to two forms of geometric character, to which various of the best works in the round of ancient and modern sculpture appeared to incline. It was on that account, and on account of their simplicity, that he spoke of them especially, and not, of course, with any idea of excluding other geometric resemblances or types. He alluded to the forms of the pyramid and of the vase. These were types which not only moulded the masses and contours of compositions in the round agreeably as sculpture, *per se*, but by the same influence suited them for the purposes of architectural enhancement. In regarding examples of these treatments, however, they must not, of course, expect perfect pyramids or perfect vase forms. The conditions of vital forms were not such as to be confined within limits so rigid; and they could only expect such coincidence as might evidence the plan of their geometric conception. In some works, also, they would perceive the pyramid tall, like an isosceles triangle; in others, flat and spread out, as in the Dying Gladiator, or the exquisite figure of Eve, by Baily, which was before the meeting in small,—a joy for ever as long as sculpture lasted. In one statue or group they might recognise the contours of a tall vase; in another, that of a broad, wide one, as in a seated figure. The proud and expressive group of the "Laocoon" aimed evidently at a pyramidal form, though that was somewhat blown aside by the gust of passion and of pain. The great group of "Circe and the Bull," of which there was a full-sized cast at the Crystal Palace at Sydenham, was on a similar principle, as it was, at some sacrifice, made more or less pyramidal on all four sides. The group of Niobe and her Youngest Daughter, among other works, evidenced an intention towards this form; and in most of them there was a near coincidence with that of a flame of fire, which had ever a tendency towards the pyramid. Milton spoke of Satan, when touched by Ithuriel's spear, as springing up "like a pyramid of fire;" and even the word pyramid was derived from that source. That form was also finely present in the general composition of the tombs of the Medici, as illustrated by the engravings before the meeting, in which, although the facts were so boldly cast about, and so grandly classified, yet that was effectual without disturbing the general geometric arrangement, which was here so finely preserved. He would now pass on to the second form he had indicated as frequent in fine statues and groups—that of the vase—and cite some examples which partook of the general form of a vase-like finial, of which a few familiar examples were before them. The outline and general contour of the far-famed Venus de Medicis afforded, especially in the first view, the general balance of a vase-like finial. The Hercles of Glycon,

Digitized by Google

commonly called the Farnese Hercules, although a figure as far removed as possible from this in character, had a similar quality of arrangement, only it was wider at the foot. Both these statues possessed to a great degree, in their principal view, an evenly balanced vase-like contour. And that quality, no doubt, had a very large part, along with their other merits, in obtaining for them that great popularity which they had ever enjoyed. They were more repeated in ancient art than any other statues: one great cause of this, no doubt, being that, in consequence of their geometric arrangement, they were found so very convenient as architectural decorations; and sculptors might well keep that point in mind when they desired a wide-spread public for their efforts, and tried to work for posterity. The elevated figure of the Phocion, also before the meeting, presented a similar character of contour, illustrating the application of a vase-like outline to a portrait-statue. There was, however, another well-known treasure of ancient art, that still more presented perfection as a vase-like finial—viz., the well-known classic group of Cupid and Psyche embracing, of which a little copy was brought before the meeting. Turn it which way they would, in each view it preserved the just balance, elegant proportions, and general mass of a tall taper vase. In this exquisite and graceful group they possessed a charming example of geometric balance and contour applied to the human form, and of the perfect coincidence of the architectural, decorative, and sculptural element. Although symmetry of form of this character endowed a work of sculpture with a great charm, insomuch that its high value might be received as an axiom, yet occasionally divergence from this might be not only obtainable, but even of great service in emphasising the action and expression of a statue, and that without injuring the effect of its architectural associations. But divergences of contrast were only, he thought, to be looked on as exceptions, and were in all cases to be guided by artistic taste alone, which was more subtle than rules.

Having cited the tomb of Lorenzo de Medici in its whole composition as an instance of the pyramid, he would now apply to the central seated figure, which formed the apex of the composition, for an example of the vase form, drawn together towards the base, swelling out on either side in the centre, and contracting again at the top (as was exemplified in an engraving and a small bronze copy of the Lorenzo on the table). Michael Angelo, being a proficient in all the four arts, was the more open to their combination. In regarding this remarkable tomb, if the spectator would in his mind's eye substitute for the figure of Lorenzo a vase form of similar proportions, and architectural features, or some features of like character, for the recumbent figures on either side, he would perceive how happy was the mere decorative combination as such, even apart from the nobleness of the figures; and, indeed, there were extant previous sketches by Michael Angelo of trials of the arrangement of these figures, in which was evidenced that their architectural arrangement in a geometric manner was his first thought. The Premier Berceau, by Le Bay, of which there was a small copy on the table—that beautiful, wild, melancholy group of Eve and her children, of which conception even the great Florentine himself might have been proud—afforded another charming instance, especially in the front view, of a symmetrical vase form. In the two last instances the vase outline was not tall and tapered, like that presented by the Cupid and Psyche, but was wider and more luxuriant, which was in both cases gained by a seated attitude. It could not be denied that the general contours of both those works were in a high degree just and pleasing, and it appeared to him a great pity that in this country there seemed to be a disinclination to public seated statues in picturesque attitudes. He considered that to be a misfortune to the art of the sculptors at the present time. Seated attitudes were much adopted by the Greeks and Romans, and in later times by the Italians and French; and they had a most satisfactory effect on pedestals in the front of buildings, as would be the case in front of the Royal Exchange and the British Museum. If the authorities especially concerned in the erection of our public statues would first take an architectonic view of the subject, and consider what class of geometric decorative form would be most harmonious in a special site before they determined for a standing or a seated figure, he thought that seated figures would be more frequently executed than they were now, as decorations of this city. The well-known group of the Rape of the Sabines, by John of Bologna, afforded another instance of a vase-like form, round which spiral festoons of flowers might be imagined to be introduced, much as they were in those alabaster vases and flowers which we used as drawing-room decorations. He would now pass on to busts. The ancients frequently made use of the terminal bust, and perhaps that was the most dignified way in which a work of this class could be based; but did not so well subserve the purposes of decoration in our dwellings, and thus, in modern practice, it had been replaced by the bust with the round pedestal. Nollikens introduced, and Chantrey continued this mode of fitting for these works, by which means, especially when placed on the frustra of columns, they became finials, of a vase-like form. Chantrey was very careful in so adjusting his busts that they should preserve a general symmetric form, even at the back, fitting them well for decorations and finials, as might be well, for instance, remarked in the bust by him of William IV., in the centre of the dais at the farther end of the hall in Greenwich Hospital. Mr. Bell next proceeded to offer a few remarks as to the treatment of sculpture in a tympanum. In this feature of art, the general pyramidal form enforced by the space to be filled appeared to be by no means the only consideration. It was unfortunate that they had no absolute record of the precise arrangement of any whole composition of Phidias filling these spaces in the Parthenon; although from such data as remained there was a sort of circular form in the centre, treated in a full manner, and lessening off in waving lines, and inwards the extreme ends might be imagined, as the general geometric treatment entertained. It had been conjectured that the figures of Niobe and her children occupied a tympanum of a temple of Apollo and Diana; but that was not certain. Nor would it be safe to deduce, from a series which had been arbitrarily arranged, the mode of the Greeks in this feature of decoration. We had the arrangement of the Æginatan tympanum; but that was of a crude and archaic character. In illustration of his views of a fine geometric treatment for the sculpture of a tympanum, he was happy to allude to an English design—the beautiful design by Professor Cockerell, which was on the wall. It appeared to him that this charming design afforded a geometric treatment of a rich circular composition in the centre of the space occupied, tangent to the base line, and to the two lines of the roof. That it thus, as it were, supported the apex of the roof, and thence ran off agreeably in diversified lines towards either end. Fancifully, this treatment might be likened to the appearance of a vast mask in the centre of the tympanum, the hair of which flowed off on either side to either end, like that of the "Medusa;" or, travestied by more common ornament, was like that of a coat of arms in the centre, and foliage branching or curling off to the extreme points of the space to be occupied. Another exceedingly picturesque example of the effective filling of a tympanum, and one very familiar, for they could hardly go up Ludgate-hill without seeing it, was in the tympanum of the west front of St Paul's, in the relievo of the "Conversion of St. Paul," sculptured by Francis Bird. It was charming in effect, and one was glad to be able to say, for once, something favourable for London smoke; for the mode in which that had darkened certain parts of this relievo and left others white, had subserved the scheme of the composition, and most vigorously enhanced its chiaroscuro. As regarded the arrangement of sculpture in a tympanum, there was one mode which, he thought, one might safely say should never be adopted—namely, that which would repeat the upright lines of the columns beneath. As regarded the decimation of square spaces, the lecturer mentioned the well-known metopes of the Parthenon cornice, a well-balanced covering of the surface so as to obtain that amount and quality of light and shade that was just for the situations they occupied; but farther than that, any precise adoption of any common geometric line in them was not apparent to him. In the frieze of the same building, especially in the equestrian parts of it—which would be allowed to be the finest example of the kind in existence—a horizontal ribbon-like character of geometric decoration had been adopted; the mass of the relievo, consisting of the bodies of the horses and the lower portions of the riders, formed the centre of this band of decoration, which was shaded off, above and below, with smaller forms—above, by the heads and upper portions of the riders, and below by their feet and the horses' legs. Although all these details were charmingly varied, their continuity as ornament was not broken; nor, although probably the background was made slightly blue, did he believe that anything was done in the way of colouring that was calculated to break up this continuity. The guiding line of this frieze might be said, therefore, to be horizontal, affording an arrangement of men and horses in harmony with the principal architectural lines on the cella immediately connected

Digitized by Google

with it. The lecturer then proceeded to the sculptural treatment of circular forms in relievo, and the geometric arrangement afforded by good examples. He next referred to a very graceful little bronze figure of Sappho, to the statue of the first Napoleon in the Place Vendome, Paris, &c. He next proceeded to consider the character of form suitable to crown a triumphal arch; and, in conclusion, referred to some of the highest works of painting as well as sculpture, as to the evidence they afforded of the dignified and satisfactory results of geometric arrangement in a sister art. He said, that apparently there was no subject that more illustrated the connexion and union of the four arts—architecture, painting, sculpture, and decoration—than the subject of this lecture, insomuch that it might not be inappropriate to conclude with the well-known observation of Michael Angelo, who, when questioned on a collateral subject, replied—"I know but of one art."

THE APPLICATION OF NATURAL FOLIAGE TO ARCHITECTURE.*

By James K. Colling.

The author expressed his regret that at the present time there should be such strong party feeling raging in respect to the different styles in architecture; persons now ranged themselves either upon the side of the Goths or the Greeks—Classic against Gothic; but without going into the merits of either side, he merely premised that in the observations he was about to make he wished to view foliated ornament and architectural enrichment in the broadest and most comprehensive light—to avoid as much as possible the clashing of any styles, or the advocating of one more than another. It was true that ornament received a certain colouring or conventional treatment, according to the style in which it might be used; but the principles and leading lines should be the same in all. The anatomy of the leaves should be alike in every style, although the leaves themselves might be tinged by its peculiarities. All that they could see most to admire in the foliage of the Classic or Gothic eras could be clearly traced to natural forms and natural arrangement; and by studying nature, the fountain head of all true design, had been hitherto followed, they were enabled to improve or vary their ideas, and to take advantage of the other beauties which were sure to spring up before the mind of the diligent student. His remarks were intended to apply to Classic foliage quite as much as to Gothic, and he considered there was far greater room for improvement in modern Classic foliage than in modern Gothic. They went on year after year copying and recopying the old conventional forms of Classic foliage, without attempting or seeming to wish for any change or improvement. They were too much in the habit of looking upon Greek foliage as perfection, and had been contented in merely copying, or at most in recombining and rearranging. If nature were more studied and more adapted to Classical architecture, a vast field of varied and elegant foliated decoration would be soon opened up. They should also at all times take such foliage as was characteristic and belonging to our climate, as the oak, the ivy, the thorn, the maple, and all the beautiful and lowly weeds and plants of our hedges and gardens. In our indigenous flora there was a vast variety and wonderful beauty—beauty of form, beauty of light and shade, and beauty of colour. The forms of leaves alone was in itself a complete and delightful study, yet this was but one portion of the vast page which was opened to us,—there was the study of flowers, some of the most lovely works of our Creator, their form and arrangement, their structure and colour,—the light and shade upon leaves, the moulding as it were of their upper and lower sides, the ramification of their veins, which was very different in different leaves,—the manner of leaves in growing, their colour and ever varying hues, and their harmony with the flowers which grow among them;—all these formed subjects, the study and contemplation of which would be of infinite value to the architect or decorator; his mind would be expanded, his taste refined, and the beauty of nature would be infused into his works. Nothing, however, was further from his intention than to advocate a literal translation of natural leaves and flowers for the purposes of architecture. Natural foliage, however well rendered or cunningly carved, if merely copied from nature, without being translated by the mind of the artist, would fail entirely in its purpose, and would be less effective than the literal copyism of the foliage from any of our architectural precedents. This could not be too strongly insisted upon, because if they told their artists that they should not copy from old examples, but simply say, as it often had been said, that they should "go to nature," they would soon be so deluged with literal representations of natural foliage, that this system of copyism would become worse than the present.

In the rendering of natural into architectural foliage there must be study and thought—life and beauty. It must be the creation of the artist's mind, working upon nature's principles and nature's laws. Flowers and leaves, although so wonderfully various, are to a remarkable degree geometrical and regular in their form and structure. Yet there exists such an extraordinary freedom, that the hard forms of geometry are concealed with an art which alone marks the hand of the Divine Creator and Designer. It is this apparent irregularity and seeming negligence, combined with harmonious colouring and strictly geometrical formation which gives the natural vegetation that charm which so delights us. It is this missing in modern carving of the geometrical and regular as a ground work or skeleton, neglecting nature's first principles, and only aiming at its irregularity, that causes the failure of our otherwise beautiful carving. If we do not commence upon a proper foundation it is of no use arriving at perfection in the art of carving, We are aiming at the shadow and neglecting the substance—producing leaves and flowers before we have arranged the branches. Every flower and every leaf is arranged with such precision and regularity, blended with such marvellous irregularity, that no two flowers or leaves can be found precisely alike, yet all are formed in the most simple and regular manner. Flowers, which radiate from a centre, are arranged upon the triangle, the square, the pentagon, the octagon, and other geometrical forms, and the precision with which this is carried out is very remarkable. Mr. Colling instanced the common white lily, which is formed upon the triangle, and explained its arrangement by a diagram. There were many other flowers which were arranged upon the same principal as the lily, as for instance, the crocus, the snowdrop, the daffodil, the tulip, the wood anemone, the jonquille, and the iris, and it was somewhat remarkable that nearly all these were early spring flowers. He explained a large number of diagrams representing various leaves and trees, and continued to say that these diagrams showed that nature, although ever remaining the same, was always fruitful in change combined with the utmost simplicity—while in modern ornament unfortunately the reverse was the case—there was constantly a want of change with the greatest intricacy. They showed also that nature was regular and geometrical. What could be more in accordance with architecture? They could alter and conventionalise in any manner they pleased. They need not copy, for they could produce changes by substituting leaves of various forms for the simple petals—there they could substitute the triple leaf for the plain petal, or put leaves together after the manner of flowers, as they have seen exemplified in nature, when looking on the top of branches such as the lilac and the maple. Great prejudice existed among many architects against adopting the natural form of a leaf, and they extolled what they chose to call "purely conventional foliage," as being above the natural—although all must be natural that retained any character worth preserving. In the treatment of foliage several things had to be considered—in the first place, the general arrangement of the leading lines, which must be purified from all inelegant forms, and be such as would best harmonise with the architecture that surrounds the composition. Next the material, its texture and colour; and the breadth of form and depth of cutting must be suitable to it. What was suitable and appropriate for a rough-grained stone would not answer for a fine one, and so on. Then the position was to be remembered, and whether the architectural member which the foliage enriched required to be of a flat character or otherwise. What was suitable near the eye must be simplified according to its intended distance or height. Then the light and shade must be studied, which must above all be carefully and duly balanced, while the form of the leaves and foliage required the greatest consideration; and, as among natural leaves and flowers, they found some of the most pleasing and elegant forms which could be conceived, it was perfectly legitimate to take advantage of them. The forms of leaves varied from the most simple to the most complicated—yet, even in the most complicated there was such a simplicity and beauty of arrangement that they could often be altered or adapted in the most happy manner to suit the purposes of the carver, without losing sight of their natural formation.

ST. CUTHBERT'S CHURCH, HAWICK, N.B.

The new church just completed at Hawick, at the sole cost of the Duke of Buccleuch, was consecrated by the Bishop of Glasgow on the 16th of November. It is dedicated in honour of St. Cuthbert, the apostle of the district, and is the revival of a church of the same name which existed about the tenth century in the immediate neighbourhood, and in a similar situation. Divine service has not, however, been performed in a consecrated building for the last 170 years; but in 1850, the Duke of Buccleuch erected handsome and large school-rooms, with master's house adjoining, which were so arranged that they could be used for that purpose until a proper edifice should be built. This desideratum has now been accomplished, from a design of Mr. Scott, of London, who has adopted the Early Geometrical style for the characteristics of the building. It consists of nave and aisles under one continuous roof (like the well-known example of Skelton, Yorkshire), a chancel terminated by a circular apse, an organ chamber on the north side, and a vestry. There is no tower, but a bell-cot, which rises over the chancel-arch, and has a crow-stepped gable, as is not unfrequent in the mediæval work of Scotland, has a picturesque effect. The internal admeasurements are as follows:—Nave, 60 feet long, by 19 ft. 6 in. wide; chancel, 33 feet long, by 19 ft. 6 in. wide. The nave piers are circular on plan, with plain square capitals, and the arches are formed of one square order only, with a very bold label. The roof is constructed of trussed rafters without principals. On entering the church, a prominent object is the handsome font, quatrefoil on plan, and having four small marble shafts with carved caps at the angles, and a cover enriched with metal scroll work, &c. The aisle windows encroach upon the roof timbers, in order to gain increased light in the absence of a clerestory. On either side of the chancel-arch are placed the pulpit and an oak lectern. The chancel is elevated two steps above the nave, and is lighted by traceried windows at the side, and by three single-light windows with shafts in their jambs for the apse. Its fittings are of oak. Round the chancel walls is a rich arcade, with small trefoil heads and marble shafts, the caps of the latter being exquisitely carved; the windows are filled with stained glass. The floor is laid with Minton's encaustic tiles, in patterns with the Arbroath stone; and a portion of the chancel roof is enriched with polychrome. An important feature, externally, is the porch; the arched entrance to which consists of three moulded orders, resting upon detached shafts, with a well-carved tympanum, the whole having a bold look of substantiality, united with symmetry of form. The carving has been executed by Mr. J. B. Philip, of London, the metal-work by Messrs. Skidmore and Son, of Coventry, and the polychrome by Mr. Moxon, of Edinburgh.

ON THE NECESSITY OF FURTHER EXPERIMENTS ON FRICTION.

By E. Morris, C.E.*

A long roll of the ablest mechanical philosophers have devoted themselves to illustrating the friction of substances,—from Amontons (1699), through Coulomb (1781), Vince (1785), and Rennie (1829), down to Morin (1831-4).

Although Amontons, De la Hire, and Euler had assumed the co-efficient of rubbing friction between hard bodies (without unguents,) to be usually about $\frac{1}{3}$ of the insistent weight, Rennie and other acknowledged authorities had shown experimentally, that without unguents the rubbing friction between hard metals might "very generally be estimated about $\frac{1}{4}$ of the pressure"—† but this (in Rennie's trials) was with small insistent weights of less than 33 lb. to the superficial inch of contact, and we may here say, that all the mechanical philosophers limited the deductions from their experiments "within the limits of abrasion" —and though Morin showed that all frictions without unguent produced some slight abrasion, this militates not against our generalisation, as under the moderate insistent weights employed in the experiments, that abrasion was necessarily but little—too slight, indeed, to seriously affect results.

Morin's experiments confirmed generally those of Rennie, but the applied weights were not all adequate in magnitude to represent what we now term "railroad frictions."

A reliance upon the results of these philosophers (accurate though they may be within their limited range), led at once to erroneous conclusions, when applied to the heavy frictions of railroads.

A brief illustration of this will suffice:—in 1838, Nicholas Wood published in London a much enlarged and carefully revised and improved edition of his valuable and well-known treatise on railroads; his own experiments therein cited (though made with too small weights) showed $\frac{1}{6}$ to $\frac{1}{16}$ adhesion or bite of the wheels of locomotives upon rails; and this adhesion, it is well known, furnishes the fulcrum for their motion, and absolutely limits their progressive power.

Nevertheless, Mr. Wood in the standard work referred to, finally concluded to assume only $\frac{1}{15}$ of the insistent weight as the effective adhesion of a locomotive clear of that necessary to move itself.

To show the anomalous condition of the science of friction at that day (1838), though more than four years subsequent to the publication of the bulk of the celebrated experiments of Morin, and nine years subsequent to those of Rennie, we may state, as a curious fact, that in the very same year (1838) B. H. Latrobe, C.E., in his famous report upon the location of the Baltimore and Ohio railroad, assumed (as the result of experience here) 1-7·5 as the coefficient representing the effective adhesion of a locomotive engine.

We see, then, that upon opposite sides of the Atlantic ocean, at the same moment of time, two of the highest authorities on railroad subjects (both thoroughly acquainted with the accepted laws of friction) were founding the most vital and important conclusions upon the adhesion of locomotives; and yet the English authority was assuming that adhesion to be only $\frac{1}{15}$ of the weight upon the driving wheels, while our American authority (as the result of actually existing experience here) stated it at 1-7·5, or precisely double. And we may add that Mr. Latrobe was much the nearest right.

At a long subsequent period (1853), Mr. Latrobe found by careful trials at the opening of the mountain division of the Baltimore and Ohio railroad, that the performance of the heaviest class of locomotives with full loads, upon the 105 and 116 feet ascending grades of that well-known railroad, showed an adhesion in actual work of nearly $\frac{1}{3}$. And in support of this we may state, that the working of fully loaded locomotive engines on other roads has now shown conclusively, that at low speeds in the haulage of heavy freight we may fully rely upon an average adhesion of $\frac{1}{4}$ of the weight upon the driving wheels of a locomotive; while under favourable circumstances an adhesion of $\frac{1}{3}$, or even more than $\frac{1}{3}$, will be developed, in defiance of the maximum of friction having been fixed by modern writers at $\frac{1}{6}$.

The late W. R. Casey, C.E., was the first to draw the attention of professional men to the fact that we were largely under-estimating the maximum adhesion of locomotives; and he showed conclusively that even in 1836, Baldwin's and Norris's American locomotives had already realised an adhesion of between $\frac{1}{2}$ and $\frac{1}{3}$ of the weight imposed upon their drivers.

These, and other facts, clearly indicated that the laws of friction, as then accepted by the mechanical world, were inadequate to guide us in the new frictions developed by the application of steam power to railroads; and the uncertainty existing in the minds of even professional men, as to the true coefficient of friction developed by the adhesion of a driving wheel upon a rail, accounts in part for the astonishment with which many engineers witnessed the accession by locomotives of inclined planes previously worked by stationary power, and this uncertainty doubtless had its weight in inducing a leading English engineer (Prof. Vignoles), even so late as 1844, to name 1 in 50, or a gradient of $105\frac{6}{10}$ feet per mile, as the limit of grade which could be practically worked by locomotive power; though at the present day we know that upon the Baltimore and Ohio, and Virginia Central railroads, gradients of 1 in 20, and even 1 in 10, have (temporarily) been successfully surmounted by locomotives with passengers.

For the very important discrepancies which are found between the railroad frictions actually developed by practice, and what they should have been had they followed the laws laid down by Rennie and Morin, the writer has endeavoured to account (without invalidating the labours of either), by remarking that all the experiments upon the friction existing between metals in motion, from which the mechanical philosophers have deduced

* From the 'Journal of the Franklin Institute.'

† Vol. 119, Philos. Trans. 1829, p. 160.

Digitized by Google

their governing laws of friction, were made within the limits of abrasion, and were usually stopped so soon as the metals began to abrade each other—while, on the other hand, all railroad frictions are destructive frictions, or those in which the metals in contact constantly abrade each other.

It will be seen, then, that the ordinary experiments upon friction are inapplicable to some of the most important railroad frictions; and hence there would seem to be a real necessity for further experiments under the actual circumstances which occur on railroads, or at least with such great weights and small surfaces of contact as may more closely assimilate to them.

A somewhat similar view of this subject was taken by the writer in an article in the "Journal of the Franklin Institute" in 1851, in which he argued the probability, that (contrary to the received laws of friction), under great insistent weights and small surfaces of pressure, as between the driving wheels of locomotives and the rails on which they move, there was strong reason to believe that friction increased in some ratio to the surface pressed.

It will be remembered that Rennie and Morin both concur in laying it down as a law, that friction is always "proportional to the pressure," irrespective of the extent of surface pressed or of velocity, and that this is almost universally accepted by the mechanical philosophers of our day (though recent French experiments indicate that velocity should not be neglected); if then it can be established that within the important range of railroad frictions, whether owing to abrasion or any other cause, "friction actually increases in some ratio to the surface," and not wholly irrespective of it (as now taught), important consequences can hardly fail to flow from such conclusion, and the necessity of further experiments to establish the laws of abrading frictions between metals in motion will become apparent.

In his article of 1851 the writer said: "When engines slip their wheels on railways, both wheels and rails abrade, the law of friction changes, and we enter at once upon a new field, in which we have no exact results recorded, and of which we only know that the coefficient of friction is greatly increased."

The writer had frequently computed the adhesion of locomotives from actual loads drawn by them on railways of known grade, and like others had found that the adhesion exhibited far exceeded the extreme limit of $\frac{1}{6}$, laid down as the maximum by Rennie and Morin; and he had also noticed that fully loaded locomotives, in passing from broad to narrow rails, invariably slipped their wheels upon striking the narrow rail; and hence, in the article of 1851, he inferred that the adoption of rails of the top width of the available wheel-tread (say 4 inches) would largely augment the ascensive power of locomotives on high gradients. Since then a striking fact has been made known, which seems to confirm, in a conclusive manner, the accuracy of the views then taken on this important point in railroad affairs.

The fact referred to has been developed in the working of the Mine Hill and Schuylkill Haven Railway, a heavy coal-road; the chief engineer of this work, R. A. Wilder, states, that upon his road a 92-feet grade laid with narrow-topped rails is immediately succeeded by a 130-feet gradient, on which rails of full width are placed, and in the working of this road with heavy coal-trains "it is found that an engine can draw more (ascending) upon the 130 than on the 92 feet grade, although the actual resistances on the former grade are full 33 per cent. greater than on the latter." We quote here the words of Zerah Colburn, C.E., and we think he might fairly have estimated the resistances upon the 130-feet grade as being full 40 per cent. over those of the 92-feet gradient, since gravity alone upon the former would amount to 55 lb., and on the latter to only 39 lb. per ton of 2240.

In observing various of the frictions connected with railroads, the writer has been irresistibly led to the conclusion that friction between metals, under heavy weights, must increase in some ratio to the surface pressed, or to the weight imposed, or to the velocity, or in combined ratio of the three;* and he is glad to find that many intelligible mechanics (struck by the anomalous results of our present theory of rubbing friction, when great weights or severe pressures are in action), are beginning to entertain similar views.

It is a singular fact that one of the series of Rennie's experiments (table viii. p. 159, 119th vol. Philos. Transac. 1829), although evidently regarded as anomalous by him, nevertheless sustain fully, as far as they go, some of the views above expressed; made under much heavier weights, in proportion to the surface pressed, than in Rennie's other experiments, and pushed in some instances up to or beyond the limits of abrasion; they represent more nearly the conditions of railroad frictions, and they give far higher coefficients for the friction of iron on iron without unguents, than any other of Rennie's experiment; these coefficients augmenting with the weights imposed, varying from 1-2·4 to $\frac{1}{4}$, and averaging $\frac{1}{3}$. Nevertheless, Mr. Rennie in his general conclusions, while deducing the laws of friction from his experiments, passed almost unnoticed over this remarkable table (No. viii.), and assumed the rubbing friction between hard metals without unguents, as being only $\frac{1}{8}$, whilst in no single instance of iron on iron recorded in that table was the coefficient of friction less than $\frac{1}{4}$th.

In the trials recorded in this table (No. viii.), the insistent weights varied from 186 to 560 lb. per square inch, and the coefficients of friction with the same surface in action (6 square inches), constantly augmented with the weights from $\frac{1}{4}$ with the former, to 1-2·4 with the latter pressure. So that it may ultimately prove that a correct formula for friction in such cases may have to involve both weight and surface, and perhaps also time and velocity, instead of being in ratio of the weight alone, irrespective of time, surface, or velocity, as laid down by Rennie and Morin.

But even the highest pressures used by any of the experimentalists are but small when compared with those imposed in the working of railways upon the driving-wheels of locomotives, on each of which 4 tons in this country, and 6 tons in England, are common weights.

Now if, in consequence of unavoidable deflections in the track, we admit that the practical bearing of a locomotive wheel upon a rail may be so much as $\frac{1}{2} \times 2$ inches., we have only one square inch of surface of iron to resist an imposed weight of from 8960 to 13,440 lb.

No such weights per superficial inch have ever been used by the mechanical philosophers in their general experiments upon friction, and therefore none of these can fairly be said to represent the conditions of railroad frictions; for in these frictions the comparatively enormous weights applied render abrasion certain and unceasing, while in deducing the general laws of friction, the experiments which involved material abrasion have been uniformly set aside.

Mr. Casey, in the article before quoted, has shown that it is quite probable the adhesion of locomotives in certain cases has even exceeded $\frac{1}{3}$, and every engineer knows that it very often far exceeds $\frac{1}{6}$, though the latter is the maximum coefficient allowed by those experimentalists who are now recognised as being the highest authorities upon the laws of friction; further experiments are therefore unquestionably necessary to settle this important point in the science of mechanics, and it is to be hoped that they may soon be undertaken upon a suitable scale.

Although Rennie and Morin (on whose experiments the usually accepted laws of friction are mainly based) decided unequivocally that the coefficient of friction depended solely upon the pressure, "without regard to surface, time, or velocity;" nevertheless, an earlier philosopher (Dr. Vince), whose experiments were well known to both, had shown (vol. lxxv., Philos. Transac., p. 175), that "the friction of a body does not continue the same when it has different surfaces applied to the plane on which it moves, but that the smallest surface will have the least friction," and this is to be understood as within the limits of abrasion.

Notwithstanding Dr. Vince's conclusions have usually been disregarded by modern philosophers, upon the ground that his experiments were on a scale too limited to establish mechanical laws; nevertheless, it would appear quite probable, that under certain circumstances the deductions of Dr. Vince may be found the most correct, as scarcely any branch of mechanical science is based upon experiments so anomalous in their character as those from which the usually received laws of friction have been inferred by a generalisation evidently forced.

Nor is this observation too strong when we recollect that Rennie, after showing by table No. viii. of his paper, that iron on iron without unguents, and with only ordinary pressure, had a friction of over $\frac{1}{3}$, yet finally adopted a fractional coefficient for this very case of only $\frac{1}{6}$th.

Morin in another case, that of hard wood with unguents (to which we shall again refer), adopted 1-6·2 as the coefficient of the

* Prof. Renwick (1832) recognised the necessity of this, and proposed a formula, embodying pressure, surface, and velocity. See Renwick's Mechanics, p. 120.

Digitized by Google

friction of rest, and 1-13·7 as that of motion; whilst the experiments made upon a large scale by a committee of the Franklin Institute, showed that these coefficients were in reality less than half as great as those announced by Morin.

The writer will now refer more particularly to some striking anomalies in the friction of heavy weights on wood, with unguents, which are remarkable as indicating the inaccuracy of some of Morin's coefficients, when applied on a great scale to heavy masses in motion upon lubricated wood.

In a report by a committe of the Franklin Institute on the coefficients of friction developed at the launching of the U.S. war vessels, the Raritan and the Princeton, they show conclusively that the friction of rest of these vessels upon wooden ways, well lubricated with tallow, was about $\frac{1}{16}$, while the friction of motion was about $\frac{1}{30}$. Now, Morin (as above stated) gives a coefficient nearly as high as $\frac{1}{8}$ for the former and $\frac{1}{14}$ for the latter; the differences being over 100 per cent. Had Morin been correct, these vessels would not have launched at all, instead of moving off as they did of themselves the moment the stay blocks were sawn asunder.

The Raritan was estimated to weigh 1200 tons, and her pressure on the ways was 3560 lb. per square foot, while the Princeton weighed 577 tons, and had a pressure on her launching ways of 2280 lb. to the superficial foot.

These conclusions of the Franklin Institute, notwithstanding their extraordinary variance from the coefficients of Morin, are in close accordance with similar experiments in England and France, as quoted by Rennie (vol. cxix. Philos. Transac., p. 155), where the Salisbury, a frigate of 58 guns, with a pressure of 6336 lb. per square foot upon her launching ways, and soft soap for the lubric, had a coefficient of friction of $\frac{1}{26}$,—while for similar cases, with hogs'-lard for the unguent, and a pressure of 7056 lb. per square foot, Coulomb made the coefficient of friction $\frac{1}{17}$, and with tallow Coulomb made this coefficient $\frac{1}{28}$.*

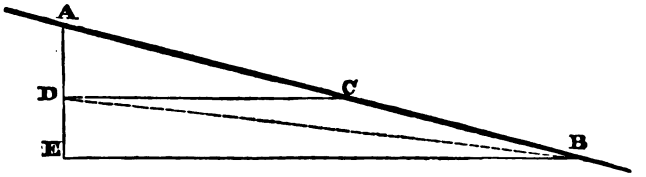
We may therefore conclude, that whether with hard metals without unguents, or with hard woods lubricated with the usual lubrics—as in the adhesion of locomotives in the former, or in the launching of men-of-war in the latter case—Morin's coefficients of friction are entirely inadequate to represent the facts, being in the case of adhesion but half as great as practice indicates; while in that of launching ships they err the other way, being twice too large.

It is quite probable that the recent extraordinary difficulties attending the famous launch of the Leviathan, arose from an under-estimate of the friction of abrading surfaces of iron, of which the coefficient under the circumstances doubtless exceeded $\frac{1}{8}$, while if our recent books were relied on, it would have been assumed at $\frac{1}{6}$,—a difference great enough in such a vast weight to have created all the difficulty and extra cost which attended that celebrated launch, and called forth all the resources of the distinguished engineer in charge.

We can hardly therefore avoid the conclusion, that the laws of friction as now received, if applied to the heavy pressures often used, are entirely inadequate, and that further experiments are necessary to the correct solution of many practical problems.

Should any such be undertaken, the writer would suggest that a long inclined plane be used, and great sliding weights, so as to assimilate the case to that of launching ships—then by an automatic contrivance, such as was devised by that able mechanic, Joseph Saxton, and used by the committee of the Franklin Institute at the launches of the Raritan and Princeton, the exact motion of the body under trial, in seconds, or parts of seconds, could be correctly marked upon a tape, and the following simple formula will determine the coefficient of the friction of motion of rest (by taking the space described in the first, second, or half second), or of both combined.

The following note to the report of the committee on the launches exhibits a simple formula for determining the friction of the inclined planes, as well as a graphic mode of representing the inclination of the plane of the friction of motion, or angle of friction:



"Another method of considering the subject of friction upon inclined planes has been suggested by a member of the committee, which results in a formula different from that we have employed.

Thus calling AC=S, the space actually slid over in a given time, t, by any body descending an inclined plane.

AB=S′ the space which the body would have described by theory in the given time, $t=\frac{1}{2}gt^2 \sin. i$, friction being null.

ABE=i, the angle of inclination which the plane forms with the horizon.

DBE=f, the angle of friction due to the body in motion.

"Then AE being the total vertical space through which the body would have fallen in the given time t, if friction had not existed; and AD being the actual vertical space fallen through in the given time t, it follows that DE represents the retardation due to the friction of the body upon the plane AB. DBE will be the angle of friction of the body, and $\frac{DE}{BE}$ will be the tangent of the angle f, or coefficient of the friction of motion pertaining to that body.

"Knowing then simply the actual time occupied by the sliding body in descending any measured distance along the plane, the formula for finding the coefficient of its friction will be

$$\text{Tan. } f = \text{Tan. } i \left(\frac{S'-S}{S'}\right)$$

which represents all the resistances encountered by the moving body.

"By this formula the angle of friction of the Raritan frigate, computed from a time of 11 seconds, occupied in sliding 59 feet upon a slip of 3° 40′ slope, is 1° 55′, the coefficient of friction or natural tangent of that angle being ·0336, or nearly 1-30th.

"The angle of friction of the Princeton steamer, computed by the same formula, from a time of 5½ seconds, occupied in sliding 19·62 feet upon a slip of 4° 25′ slope, is 1° 53′, the coefficient of friction or natural tangent of that angle being ·0328, or rather more than 1-30th.

"The mean of these two results gives an angle of friction for launching such vessels as these of 1° 54′, or a coefficient of friction of very nearly 1-30th."

So that the angle of the friction of motion in launching men-of-war may be fairly assumed at 2°, and the proper declivity of the launching ways at 4°.

The old experiments on friction made in the last century by Coulomb, Vince, and Ximenes,* have been lightly laid aside by more recent philosophers, but they seem in fact to be much more applicable to practical affairs than the more elaborate experiments of Rennie and Morin.

* See Renwick's Mechanics.

THE EXHIBITION OF THE ARCHITECTURAL PHOTOGRAPHIC ASSOCIATION.

THE second annual exhibition of the works offered for selection to subscribers is now open at the Old Water-Colour Gallery, 5A, Pall Mall East. The collection is not as yet quite complete, some Spanish views, which are expected, not having arrived; but it numbers now 379 subjects, from twelve contributors, most of whose names are familiar to the art-world. Some of the works have been taken expressly for the Association, and we may mention at once, as perhaps as interesting a series as any in the room, those produced under these circumstances by Mr. Bedford. Making some allowance for the freshness of tone and clearness of detail which recent photographs usually possess, there is a charm about these which only a skilful artist and manipulator could impart. They are chiefly views of Tintern Abbey—one of the loveliest ruins in England, and in one of the loveliest spots. Besides these there are two or three of Raglan Castle, and two of Chepstow. Of a former series (exhibited in 1857) there are some reproductions; they are, almost without exception, good, but show that the art has since made considerable advances.

* For an excellent summary of these see Renwick's Mechanics.

Digitized by Google

The most liberal contributor is Macpherson, of Rome, who sends 120 works, a large proportion of which are architectural in their character, and the whole are, we believe, Italian scenes. Many of these might be singled out: one of the cleverest is (14) "the Castle and Bridge of St. Angelo, Rome," in which art and nature are happily combined. There are several views of St. Peter's, but none of particular interest; also two of the "Columns remaining of the Temple of Jupiter Stator" (72 and 79), and one of the noble Coliseum (74). A fine view of the "principal doorway of the Church of Sta. Maria at Toscanella" (30) must not be overlooked, nor some excellent reproductions of various bas-reliefs from the triumphal arch of Titus, and the Antonine column in the garden of the Vatican.

As may be imagined, Venice is not unrepresented, but there are not many novelties; indeed it would be difficult to find any portion of the "city of the sea" which, if worth doing at all, has not been done over and over again—the Doge's palace in particular, and the Church of St. Mark. However, the majestic "Bronze Horses" of the latter (133), and the "Sitting" (131) and "Recumbent" (135) "Lions of the Arsenal" are really fine specimens of sculpture, and, as such, are worthy of a place here, though, perhaps, they would not be so attractive in an ordinary picture-frame.

Recurring again to English scenery, we have, from (157) to (184) some photographs by Cade, of Ipswich, principally of Cambridge colleges, in which the scale is too small to admit of expressing more than their general features. The two neighbouring priories of St. Botolph, Colchester, and St. Osyth (the latter once the residence of Bishop Bonner), are worthily transferred in (173, 174, 177); while the beautiful church of Southwold, one of the most perfect specimens of flint-ornamentation existing, is shown in (180); and the ruins of Walberswick Church, which are in the immediate vicinity, in (179).

Great variety is given to the character of the exhibition by the extensive field in which photographic artists are now labouring, and the consequent diversity in the subjects that come under their observation. We have already referred to some of the phases of architectural art in this country, in Italy, and in Venice; our catalogue now conducts us to Egypt, and presents us with an instructive series of illustrations by Robertson and Beato, of Cairo. Of the majority of these we can only say that their small size renders it quite impossible to convey a satisfactory impression of ponderous and stately piles. This is the more perceptible, inasmuch as some large photographs which have recently been imported from Egypt are among the grandest and most successful achievements in this line; and some others on these walls, by Frith, are deserving of high praise.

The Spanish views, by Lousada, will be examined with interest, also the French series (though few), by Baldus, of Paris. Among the latter we would call attention to the beauty of (268), "the Steeple of St. Pierre, Caen."

On the whole this exhibition is well deserving of a visit, not merely from those who, as subscribers, are personally interested in the matter, but from the public at large, since improvements in photography have now been carried to that extent that, in an artistic as well as instructive point of view, in collections such as this there must necessarily be much to delight. It stands too, at this season, almost *per se* of its class, now that the Architectural Exhibition is no longer a winter one; and the reasonable terms (half-a-crown each) on which "season tickets" are procurable should be a further stimulus to encourage the institution. The *single* charge for admission is a shilling, but to subscribers it is free. Besides being open daily from nine to dusk, the rooms are lighted on the evenings of Tuesday and Thursday from seven to ten, to enable those to see the collection who may be precluded from attending in the day-time.

THE NEW ADELPHI THEATRE.

The new Adelphi Theatre, with the exception of the enlargements which have been made, stands on the same site as the old. By excavating the pit to the level of the Strand pavement, instead of having it, as formerly, more than 10 feet above it, and by carrying the roof a little higher, an addition of some 25 feet is gained in the clear height of the interior, and this important enlargement is at once manifest in the lofty and imposing effect of the tiers of boxes. The wall on the western side, though rebuilt, is in the same position as that which it replaced, but the eastern wall has been moved some 30 feet further away, so that, in fact, the area of the interior has been very nearly doubled. Thus, the width between the boxes is now 44 feet, 6 feet wider than the Lyceum, and nearly 12 feet wider than the Olympic theatre. The total length of the whole of the new building is about 110 feet by 70, almost the largest minor theatre in London, and this space is so carefully and judiciously broken that the idea of space is entirely removed, and the audience see only a series of most graceful curves marking the line of boxes, and the fronts of which are so decorated as to make them the richest and most effective portions of its internal architecture.

The old entrance from the Strand still remains, and through this the audience pass at once to the level of the pit, which is nearly twice the size of the old one. The part nearest the orchestra is railed off for three rows of orchestra stalls, each seat in which is an ample and well-padded armchair, and gives the same dimensions for perfect comfort to the occupant as is afforded by the pit-stalls at Covent-garden. Behind these are four rows of pit-stalls. Above the pit is the first tier of boxes, which projects 6 feet beyond the iron columns which carry the other tiers. In this balcony are two rows of seats, each 1 ft. 10 in. wide by 16 in. deep, with the backs sloping 4½ inches instead of 2 inches. The front of this balcony is a light and exquisitely wrought iron railing decorated with white and gold, and with interstices sufficiently wide to allow the varied colours of the ladies' dresses to be plainly seen. Behind the balcony, on a level as to projection with the tiers above, is a row of public or private boxes. Beautiful spiral cast-iron columns, with elaborate capitals in white and gold, support the upper tier. The front of this is enriched with white and gold decorations, with panels in bas-relief representing the figures of the Muses. The sitting accommodation here is equal that in the stalls below. Above this, and supported by the same kind of columns, is the gallery tier for gallery stalls. The front of this tier is also exceedingly handsome, and adorned in panels with medallion portraits of dramatic authors. Behind this is the gallery proper, with the usual side galleries, every part being constructed with the same regard to comfort and a good view of the stage. In order to secure the latter important object a point of the stage 35 feet from the front was taken as the centre; and from this the seats were ranged, so that the radius of each is unbroken by any obstacle. The ceiling is in what may be called the Genoese style, but the admirable effect of Mr. Sang's decorations impart a lofty dome-like aspect to it, which enhances the appearance of the whole interior. Looking from the pit, it is difficult to believe that the ceiling is not a high dome. On the west side of the proscenium is the Queen's box, on the east that of the Prince of Wales. Each of these is as large as a well-sized modern drawing-room, and the richness of their appearance is increased by the fronts having balustrades of the most brilliant cut glass. The effect of this handsome but novel style of decoration will be beautiful; the execution has been entrusted to Messrs. Defries and Sons, whose artistic labours in glass manufacture have done so much to enhance the beauty of our London theatres. The whole of the proscenium, and the ceiling immediately over it, is covered with bold yet delicate traceries in white and gold, which preserve the beauty of detail without detracting from the harmony of the whole. The proscenium itself is 38 feet high by 35 feet wide—several feet larger each way than the proscenium of either the Lyceum, Olympic, or Princess's. The whole theatre has sitting seats for 1500 persons, but this estimate allows such ample accommodation for each that one may fairly say the new building will accommodate 2000 with far greater comfort to themselves than ever the old one did one-half of that number. The mode of lighting is simple but brilliant in the extreme, the whole building being illuminated from the ceiling with one of Stroud's patent sunlights. The light itself is concealed, though its effect is increased by an exquisitely formed chandelier—a glittering mass of cut glass coronets, prismatic feathers, lustres, spangles, and which has also been designed and furnished by Defries and Sons, and reflects the highest credit on their taste and skill.

The whole theatre from pit to ceiling is fire-proof, and in case of a chance or mischievous alarm of fire so many exits are provided into Bull-inn-court, and from the back of the stage to Maiden-lane, that the whole audience could quit the building almost instantly. The architect is Mr. T. H. Wyatt.

THE WESTMINSTER CRIMEAN MONUMENT.

In a former number we mentioned that preparations were being made for the foundation of a memorial column in honour of Lord Raglan and the "Old Westminsters" who fell in the Crimea. The whole cost is to be defrayed by their schoolfellows, and the site chosen is a felicitous one, viz., the intersection of the centre line of the archway into Dean's Yard (leading to Westminster School) with that of the longitudinal axis of the Abbey, and therefore directly facing its great west door, in the open space of the Broad Sanctuary. The memorial consists of a column of Peterhead granite, banded in the middle with a cable-moulding, from which depend a series of shields, appropriately charged. This column stands on an octagonal pedestal, which, with the whole of the remainder of the work, is of Portland stone. On the cardinal faces will be the several inscriptions, while the alternate faces have square piers with enriched capitals abutting against them, and supporting each a recumbent lion. A flight of octagonal steps, on the lower of which is a handsome iron railing, completes the lower part of the design. The capital to the column is somewhat of the Corinthian type, bearing a square abacus, with the corners notched back so as to form a kind of plinth for four canopied and gabled niches, in which are represented, each in a sitting attitude, King Henry III., Edward I., Queen Elizabeth, and Queen Victoria. Behind these niches rises a square pedestal, on which stands a bold group of St. George and the Dragon, which forms the crowning feature.

The dimensions are as follows:—Total height, 62 feet; height of shaft, 27 ft. 6 in.; diameters of shaft, 3 ft. 6 in. and 2 ft. 11 in.; height of base, 14 ft. 3 in.; and width of base 10 feet. The architect is Mr. Gilbert Scott, of Spring-gardens, London, and the sculptor, Mr. J. Birnie Philip, of Vauxhall-bridge-road. The large upper group is to be modelled by Mr. J. R. Clayton.

The foundation stone was laid on the 10th ult., by the Rev. C. B. Scott, the head master of Westminster School, in the presence of a goodly muster of past and present school-boys. A brass plate was introduced into the stone, bearing an appropriate Latin inscription, which we here transcribe:

THE BAROMETER AS AN ENGINEERING INSTRUMENT.*

By John M. Richardson.

It is firmly believed that a proper use of the barometer in all reconnoissances will lessen the number of experimental lines usually surveyed, facilitate the location of the road or canal, hasten its construction, and thus confer a benefit upon the public.

Before setting any survey on foot, it is the usual custom for the chief to pass over the proposed line and examine it with the eye alone, selecting "guiding" or "ruling" points through which the road must pass, and gaining all possible information with regard to the country from the inhabitants along the route. The knowledge thus obtained is of great importance, and its benefit is felt when the more careful and accurate observers, the level and chain, follow after, noting with the utmost minuteness every change of grade. But the eye is a very unsafe engineering instrument, and should not be too implicitly relied upon when used without the aids which science and art have given it. It is true that by long practice, some can judge pretty correctly as to the distance of two objects apart, or as to their relative difference of level so long as they both remain in sight: but when space, and forests, and mountains intervene between two stations, A and B—especially if their be a succession of ascents and descents between the two—an engineer, aided by the eye alone, cannot say with any certainty when he has arrived at B, "I am below A," or "I am above A," except in one case, viz., when he has been following the course of a stream.

The use of the barometer will prevent the occurrence of any such errors, and it is probable that they are numerous. By it the level of one gap in the range of hills or chain of mountains can be compared with that of another, and thus the comparative ease or difficulty of connecting the contiguous plains or valleys by passing through one or the other, ascertained in the shortest possible time and with the least expense. If merely examined *par un coup d'œil* in the reconnoissance, experimental lines must be run through both gaps, and the two routes can only be compared, their relative merits and demerits ascertained, after a long, laborious, and expensive instrumental survey.

By using the barometer, the chief after his reconnoissance can say, with almost absolute certainty in any case, which terminus is above the other, which is the highest point along the route, which the lowest, and where the greatest difficulties are to be encountered. The barometer does not indeed give horizontal distances, but in determining the practicability of any proposed route they are of subordinate importance compared with differences of elevation. A pedestrian, a carriage, a locomotive, can accomplish horizontal distances with ease, but they cannot so easily ascend and descend hills and mountains. "These are the chief obstacles to the construction of roads and canals, and are the natural enemies of the engineer." By using the barometer he does not lessen their hostility to his improvements, but he discovers in the most expeditious manner where they are weakest, and where he can best attack and most easily evercome them. This is all that is claimed for the barometer as an engineering instrument; and it is enough. Its results are not so correct as those of the level. They are only approximations. It goes before, and, as it were, sketches out the work—gives the outline; the level follows after and completes the picture. But by means of the sketch which the barometer furnishes the level, the latter is enabled to accomplish its work in much less time, and at a vastly diminished expense. Up to the present time the barometer has been chiefly used by travellers in determining the approximate altitudes of mountains, by chemists in ascertaining the specific gravity of gases, and by mariners as a weather glass. Its utility as an engineering instrument has been recognised practically but by few, either in this country or in England; on the continent of Europe it has been (such is the writer's information) more extensively employed.

The recent "Pacific Railroad Surveys," instituted and carried out by the general government, have been instrumental in calling the attention of engineers more particularly to the barometer, and have demonstrated beyond the shadow of a doubt, its great value as an engineering instrument, particularly where the reconnoissance extends over long lines, and where there are, anywhere along the line, considerable changes of level.

The reports of the surveys alluded to, and more particularly that of Lieut. Williamson, afford much valuable information on this subject. Lieut. W., as already quoted, states that the profiles "determined by the spirit level and barometer agreed remarkably well." This is important as bearing upon the relative accuracy of the level and barometer.

The following determinations of the height of Black Mountain in North Carolina, have been going the rounds of the newspapers, and are presumed to be correct.

Barometer	6708 feet	Prof. Mitchell,	1855.
,,	6709 ,,	,, Guzot,	1856.
Level	6711 ,,	Major Turner,	1857.

(Mean of barometers 6708·5); difference +2·5; per cent. +·000372.

$$H = 1{\cdot}000372\,h, \quad . \quad . \quad . \quad . \quad . \quad . \quad (10)$$

Combining with (9),

$$H = 1{\cdot}003178\,h, \quad . \quad . \quad . \quad . \quad . \quad . \quad (11)$$

If the above reputed measurements of the altitude of Black Mountain are the ones determined by the gentlemen whose names are attached to them, formula (10) is valuable.

The results are remarkable, and, as bearing upon the relative accuracy of level and barometer, important. The altitude of the mountain was determined by means of the barometer at two different times by two different observers, and probably with two different instruments. The results differ by 1 foot. The third determination was made by means of the Y-level, by a third observer, and at a different time. It exceeds the loss of the previous determinations by 3 feet, the greater by 2 feet, and their mean by 2½ feet. The names of the observers are a sufficient guarantee that every precaution was taken to insure the greatest possible accuracy.

A few such independent determinations of the altitude of the same point are of more value perhaps than a number of isolated observations made to determine the altitudes of different points by the same individual with the same instrument. And if scientific men, who have opportunity, will only multiply the observations with regard to the height of Black Mountain, the question with regard to the relative accuracy of level and barometer will be set at rest, at least for such high altitudes.

The report of Lieut. Williamson does not state what means were taken to secure the greatest accuracy, though it is presumed that every precaution was adopted. The survey appears to have been conducted thus:—The party divided; one portion remained in camp and made hourly observations with the barometer; the other ran a line of levels along the route to be surveyed, and made hourly observations with the barometer also; the heights of those stations at which the levelling party made barometer observations, as determined by the level and barometer, were then referred to the station in camp. The observations made with the barometer in camp and along the route were noted at the same instant, and thus the party carried out the instructions of Biot on that subject.

SOME REMARKS ON THE CONTENTS OF THE ALBUM OF VILLARD DE HONNECOURT.*

By H. B. Garling.

If anything might be expected to prove interesting and instructive to architects of the Nineteenth Century, occupied constantly in the attempt to instil new vigour into their art, by investigating the principles by which it was regulated at a period when it was practised under healthier and happier influences, it must be some document which should throw light on the professional character, the method and objects of study, the feelings and the habits of thought of those artists who fixed those principles and decided their expression, but of whom individually we know nothing beyond that which is afforded by the reflection of their mind exhibited in their works. Such a document is the Album of Villard de Honnecourt, the contents of which I propose to sketch briefly this evening, and which, although they may not satisfy all the curiosity we feel, nor convey much instruction to those before whom information must be laid in its most obviously practical and tangible form, yet will be found replete with interest, and suggestive of abundant matter for speculation.

The history of the manuscript is told in a few words:—It was originally discovered in the library of St. Germain des Près, and subsequently transferred, on the confiscation of ecclesiastical property, to the National Library. It consists of thirty-three sheets of parchment, about three-fifths of the original manuscript, which consisted of fifty-two.

The manuscript was first noticed by Willemin in his 'Monuments Français inédits.' Later, in 1849, Mons. Jules Quicherat, Professor of Archæology, published a notice of the author, with a few of the sketches. It was however reserved for the industry and enthusiasm of M. Lassus to present it to us in its entirety in fac-simile, illustrated with all the skill of an accomplished artist, and all the learning of an experienced archæologist. Of the author, Villard de Honnecourt, we gather incidentally a few particulars from a careful analysis of the legends, and a comparison of the dates of historical events with those mentioned in the book. He appears to have been born at Honnecourt, on the Scheldt, near Cambray, and he writes in the Picard patois. There is great reason for believing that he was the architect of the choir of Cambray Cathedral, now unfortunately destroyed. He tells us that he travelled much; he visited Laon, Chartres, Lausanne, and Rheims, the latter place undoubtedly during the progress of the works at the cathedral; we get, therefore, an approximate date, somewhere between 1230 and 1250. He was then sent for into Hungary, where he stopped many days. Now we find that in 1242, Strigonia, then the capital of Hungary, was destroyed in an irruption of the Tartars, and that on their being driven back the next year, Bela, the King of Hungary, commenced rebuilding the city and the cathedral dedicated to the Virgin; and we may presume that Villard de Honnecourt, then a man of great reputation, was sent for to design and execute these works. It is alleged by the editor, M. Lassus, that there are various churches in that neighbourhood which exhibit evidences of French influence. All these dates and circumstances compared, give us some data for fixing the identity of the artist.

The contents of the book may be arranged under the following heads, viz.—1. Mechanical Contrivances. 2. Geometry and Practical Trigonometry. 3. Cutting of Stones and Masonry. 4. Carpentry. 5. Design in Architecture. 6. Design in Ornament. 7. Drawing of the Figure. 8. Furniture and Utensils. 9. A variety of Drawings, sketches from natural objects or from paintings either mural or on glass, for application to various decorative features in architecture. We therefore see that it embraces every department of an architect's studies. Many of the sketches have legends attached, describing them with more or less minuteness. On the page originally the first, is a legend forming a sort of introduction, and proving I think beyond all doubt, that the Album was not a mere memorandum-book for the author's own use, but that it was intended for the instruction of others, and that it contains a general sketch of the art practised in that day, as illustrated by the author's own experience. The legend reads as follows:—"Villars de Honnecourt salutes you, and prays all those who work in the various kinds of work contained in this book to pray for his soul, and to remember him; for in this book one may find great assistance in learning the principles of masonry and carpentry; you will also find in it the method of drawing the figure as geometry commands and enjoins."

Under the first head, Mechanical Contrivances, we have a saw-mill moved by water power, a machine for cutting piles under water, a screw-jack resembling that now in use, the method of forcing back into the perpendicular timber-buildings that have bulged, military engines, mechanical toys, and a curious scheme for perpetual motion, with several other matters.

Under the second head, Geometry and Trigonometry, a variety of problems more or less useful, some for setting out, or proving the truths of the setting out of work; for a variety of purposes connected with the practical application of geometrical lines and figures in architecture; for ascertaining the measurements, dimensions, and distances of inaccessible objects; for striking a variety of curves, and other things of minor importance.

Under the third head, Cutting of Stone, numerous problems and methods for setting out the lines of the more difficult and complicated parts of construction, the voussoirs of arches and vaulting in various positions, voussoirs of arches circular on plan, moulds for cutting the stones for spires, the best methods of bonding piers so as to conceal the joints, or to break joint, lines for constructing pendant arches, for corbelling from angular towers, and a variety of other matters of more or less interest.

Under the head of Carpentry, designs for three roofs and for a timber bridge. A portion of this division of the work has been lost.

In Architecture, we find internal and external elevations of one entire bay of the nave of Rheims Cathedral, and of the chapels of the choir, sections of the flying buttresses, and details of the mouldings and plans of the piers, with the bond marked; plans of the churches of Cambray and Vaucelles, now destroyed, and of the Tower of Laon, with an elevation and sketches of the rose windows at Chartres and at Lausanne; the latter from memory, and very incorrect. The sketches of Rheims appear to have been taken from the working drawings, for they show precisely the sort of variation likely to occur between the original design and the work when executed.

In Ornament, we have sketches of foliage, animals, grotesque and natural, and a variety of similar objects scattered through

* Paper read before the Royal Institute of British Architects.

the book. In Furniture, designs for stall work, for a maison d'orologe, as he calls it; for a lectern and a monumental cross, and one or two other matters.

Under the last head there are a variety of subjects, either for mural painting, for stained glass, or for sculpture; some are particularly beautiful, as that of Christ on plate 20, and again that on plate 31; there are also some very good sketches, of which the subject is not very intelligible, but which are well worth attention; a Descent from the Cross, the Twelve Apostles, figures and compositions emblematical of various sacred subjects, suitable as decoration in various ways in ecclesiastical buildings: the figures are generally very well draped. There are also sketches from nature, academic studies, with one or two evidently from classic subjects, as one of a sepulchral monument, and some apparently of bas-reliefs representing the Games of the Circus.

It may be alleged by some that but little information of practical use can be gleaned from the matter contained in this book; but I submit that this wholly depends on the faculty of gathering ideas in the individual himself—to the wise a hint suffices—to the artist, to the man of idea, the barest outline, the simplest fact, is frequently suggestive of the brightest creation,—to such it is addressed, and such will undoubtedly reap profit. For the man of dull perception, of mechanical routine, for the man who mistakes an incapacity for rising above practical matters for a special aptitude, for him who learns by rote only, and practices by precedent,—for such this book is certainly not intended; but to such men, we must remember, are we indebted for much of that which renders our art contemptible in the present day.

Having thus sketched briefly the contents of the album, allow me to say a few words on the character of the author, and of the artists generally of that interesting period, of whom we may assume that he was a fair type.

There is no pretension to mystery—no secrets of craft. We find him a man of restless activity of mind, of singular versatility of talent, and of powers of observation at once subtle and comprehensive; eager to gain information from every source, ready in applying it to every purpose. He appears to have resembled (taking the standard of his age) the ideal character sketched by Vitruvius—the man of universal accomplishment, the *facile princeps* in every art—trying his hand at everything, and proving himself master of all. Thoroughly versed in all the practical science of his day, we should suppose that this alone was his forte, from the attention he enjoins to its precepts, did we not find that it simply assists him to the more perfect mastery of higher accomplishments. In mechanics, he gives us now a mechanical toy and now a military engine, machines for cutting timber, hoisting, screwing up, and executing the rougher preliminary operations of building. In architecture, he studies only from the most beautiful subjects and the best models, and educates his powers of hand and eye to the highest vocation of the artist. He gives us sketches of natural objects to be applied to their most appropriate places in design, drawings of mouldings, and details, all of exceeding beauty. To geometry he pays the reverence so characteristic of his age, and would fain make us believe that his skill in free-hand drawing is simply a more refined application of its principles. As an artist, he adds the finest feeling in design, in some instances, to the most enviable skill in draughtsmanship; the conception just, appropriate, and spirituelle, expressed by the outline firm, vigorous, and free.

But applying these remarks to ourselves, and assuming him to be the type of the artists of that age, let us note particularly the wide and unrestricted field over which they spread their studies, how thoroughly eclectic they were in their habits of observation, how they swept off everything that came in their way, sacred and profane, that offered new ideas and new images; with what honesty they set themselves the task of meeting the requirements of their age, how candidly they admitted its conditions, how thoroughly they expressed its spirit; and this liberal, and catholic, and unprejudiced view brought its natural reward, in inexhaustible fertility of invention, in unerring propriety of application, and in matchless vigour and originality of expression. For we must remember, where genius, essentially the creative power in man, exists in the greatest degree, we shall find, if we analyse its operations, that it does not create new forms or new images, but simply creates new combinations of images and forms already existing; and that by natural consequence, its powers are disciplined, nourished, and perfected by abundant observation, and its stores increased only by the accumulation of matter, of raw material, so to say, which it renders back again refined, wrought up, transformed, and combined in endless variety, by those processes which genius alone can effect. Can we then by study that accumulates matter, by education that disciplines thought, hope to rival the glories of the great epochs of art? I mean of those periods when it had such truth and grandeur, when it aimed so high, and so nearly attained its mark, that it became the standard, the starting point for everything that followed. Most assuredly not; for the true causes of this excellence lay infinitely deeper than any we can touch by the most skilful training. If we examine the history of the time we shall find that all these great awakenings, so to call them, followed hard upon some mighty political convulsion, some movement of a character so deep that it stirred up from the very bottom that class of feelings and emotions which, when the tumult had subsided, find their natural expression in poetry, and in the most truly poetical phases of art. Convulsions so absorbing in their influence that they forced everything into one channel, so comprehensive that they left no space for rival influences, so powerful that they communicated impulses of which the duration may be reckoned by centuries, and which, like undulations from a common centre, became feebler as they widened in circuit, till crossed by counter influences they exhibited only a surface of troubled water, as in our own day, heaving indeed tumultuously, but moving in no definite direction, attesting only the mighty force of the first impulse, and the elastic and impressible element through which it was propagated. Such convulsions were the Persian invasion in classic, and the Crusades in later times; for though the direction of these two great events was different, the feelings and emotions they roused were identically the same, and their effects precisely parallel. The results in each instance were precisely the same. In the Greek, of more ethereal temperament, they were more rapid, more brilliant, and more dazzling. In the Goth, of sterner mould, they were more solid and more enduring. The one gained at a bound the height, which the other reached by slower steps but sure; the influence of the one expired, for though lofty it was essentially human; the other survives, through the Divine element with which it was interwoven. I say, then, a combination of influences only, such as occur but twice or thrice in the history of the world, at particular stages of advancement in knowledge and civilization, can alone produce what we desire so earnestly to see in this our own day. Shall we, then, do nothing? Certainly not. If we cannot do all we could wish, we can easily achieve some improvement, and I would make a few suggestions in furtherance of this desirable object.

First,—That enlarged study will remove narrow prejudices. Secondly,—That it is by thorough digestion, and not by the accumulation of matter, that we learn to invent. Thirdly,—That to copy great works is not to imitate great masters. Fourthly,—That it is only in the Nineteenth Century that fine art is considered one thing, and the vernacular, so perhaps truly named, another; in the Thirteenth, the vernacular expressed the popular want, the necessity of the case, the conditions of design; while fine art showed how the artist could refine what was coarse and vulgar, ennoble what was mean, and spiritualise what was gross and material,—his proper and highest vocation. Lastly,—That the benefit of enlarging our views beyond the limits of one phase of art, of adopting that eclectic method in study which enables us to appropriate some meritorious principle of another style, without confounding its distinctive character, which is chiefly expressed in detail, is singularly evidenced in the case of that particular school of artists who most strongly insist on the opposite principles; for we must admit that, after twenty years of unremitting investigation, after thousands of experiments in the revival of Mediæval art, the only symptom of real advance in meeting actual requirements by some new combination or idea, is the abandonment of the mullion, the adoption of the horizontal lintel, and the introduction of the monumental column; all so essentially classic in character that they were but a few years back instanced as a reproach to that style, as evidence of false principle and inappropriate expression. They do exist we know well in Mediæval art, but this simply adds weight to the point I insist on, viz., that it is necessary to enlarge our field of study, and to accumulate facts, before we decide on our principles, and that this point, so essential in practical science, is equally applicable to all the arts of design.

In the discussion which followed, Mr. BURGES said he had carefully compared M. Lassus' work with the manuscript. He thought the original drawings had been made with something like an ordinary black-lead pencil, probably a lead point, and that the lines were afterwards traced over with a crow-quill. The ink used was generally of a brown colour, in some parts nearly black, but in others the lines were of a light yellow. De Honnecourt did not state that he built Cambray Cathedral. It was only known that he visited Hungary; but he was probably a man engaged upon one work at a time, who therefore had not the opportunity of leaving the impress of his style all over the country. It would be interesting to know with certainty whether he had made his copies from the actual working drawings. It was evident that he copied what he wanted to reproduce, with such modifications as occurred to him. His drawing of the figure was peculiar, and appeared to be a method of free-hand copying, by dividing the subject into geometrical outlines, by which means he could dispense with a knowledge of anatomy; however, with all their faults, his figures were better drawn than they would be by the majority of living architects. Under the present system, drawing of the figure seemed to be quite neglected. Instead of being educated as an artist, the student was placed in an office, and told to pick up what he could; the result was, that instead of one good work on which he might display all the resources of his genius, he was often forced to produce some fifteen or sixteen small and insignificant churches.

Mr. PAPWORTH said that De Honnecourt's book was far more interesting than the preface or introduction to it by M. Lassus, the editor, who claimed for France the merit of almost all the great architectural works of the period, including even Burgos Cathedral. Indeed, all that was really good in the preface was taken from Pugin's 'True Principles of Pointed Architecture.' The book and the preface were, in fact, directly opposed to each other, for M. Lassus urged that no new style of architecture could be arrived at; that there must be either an entire retrogression or the adoption of a *rifacciamento* of former styles. Mr. Papworth showed that, in opposition to the exclusive devotion given by each section of the profession to its favourite period of Pointed Art, De Honnecourt's mode of study was literally eclectic, as was proved by his imitations of Classical and Byzantine art, and by his studies from the life. The principal reflection which had occurred to him after looking at the contents of De Honnecourt's Album, was that architects in the present age attempted to know a great deal too much of everything beyond their own real business. It was too much to expect that architects, besides making their own working drawings, should be good painters, sculptors, and, in addition, masters of all handicrafts, whether incidental or not to the execution of a building.

Mr. M. DIGBY WYATT observed that the work under consideration was one of the highest interest historically, if not æsthetically, for it established three facts, of which doubts had been generally entertained until the discovery of De Honnecourt's treatise, viz., that in certain instances in the north, as had constantly been the case in Italy, the architect and the sculptor, or the designer of the sculpture, were combined in the same person, —that the architects and sculptors of the middle ages studied from animate and inanimate nature freely,—and that the whole tendency of the Mediæval style during its purest period was to extreme simplicity of design. The parts were repeated in regular succession and reduplication, without eccentricities, to create the picturesque, as was shown by the sketches before the meeting.

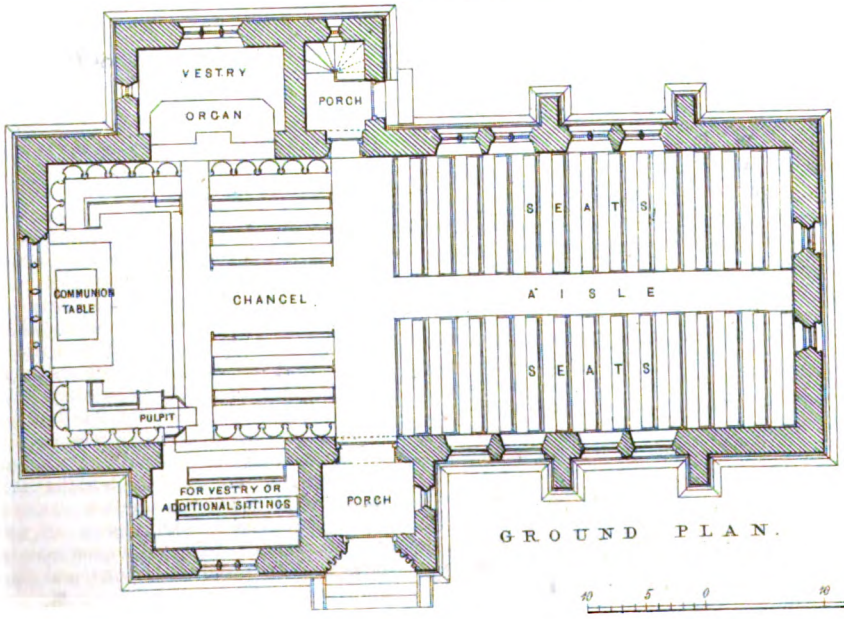
Mr. G. GILBERT SCOTT observed, that it was interesting to see something, however little, of the interior of the studio of an artist of any great period. It would, for instance, be of the greatest use if we could learn how and in what spirit the Greek architects expressed their ideas in private. Mr. Garling's paper was one which ought to excite interest, if only from its important bearing upon the history of their art; and even if M. Lassus' suggestions were somewhat conjectural, it should be remembered that mere conjectures had their value. The idea that De Honnecourt introduced French Gothic architecture into Hungary, was an interesting subject for investigation, although the grounds on which M. Lassus argued the point were rather slender. But passing by these conjectures of the editor respecting the origin of De Honnecourt's mission to Hungary, upon which the artist himself had not thrown any light, he would mention, as one of the most interesting points in De Honnecourt's book, the manner in which he appeared to have seized upon everything he saw at all likely to aid him in his art, and the marvellous facility with which he sketched it Speaking generally, he (Mr. Scott) did not believe that architects of the present day could draw the figure so well as De Honnecourt. Mediæval drawing might be considered quaint, and that of our own day excessively pretty; but, quite apart from the sketches of De Honnecourt, he would suggest what had long pressed itself upon him as a very important practical consideration, that in all great periods in architecture the amount of skill in drawing, whether more or less, was directed to the great object of rendering the work itself artistic, particularly in its decorative features, and very little of it to making pleasing pictures of the building, either before or after its execution; whereas at the present day the reverse was the case; the artistic attainments of architects, whether Classic or Gothic, being, with some exceptions, mainly devoted to making pictures of buildings, and only in a secondary degree to the perfecting of the artistic portions of the actual work. He could mention several gentlemen of both denominations who could draw in a most magnificent manner; but he had long felt the want of schools for artistic training, in which students should be systematically instructed in those higher branches of art which do not bear upon mere picture-making, but upon the actual art to be expended on the works themselves.

Mr. MARRABLE differed from the concluding remarks of Mr. Scott, as to the incapacity of modern architects to make correct drawings from which the men could work. According to his experience, every architect worthy of the name was capable, and many of them were indeed artists who could represent their designs in an artistic and pleasing way, without confining themselves to such rough and rude drawings as those of De Honnecourt. He could not but regret that so much time and patience had been devoted to preparing a paper which was more interesting in an archæological than in an architectural and practical point of view.

Mr. M. DIGBY WYATT observed that the history of art was the best lesson to set before the student, old or young, and without going so far as Mr. Scott, in depreciating the practical artistic works of the majority of the architects of the present day, as compared with those of the older architects, he believed that a very great and valuable lesson was to be learnt from any traces of their mode of practice and study which could be rescued from the past. On these grounds he certainly believed that Mr. Garling's paper had been judiciously brought before the members.

Mr. PENROSE said that the Institute had often received papers that were too strictly archæological, but the present, though treating of what was old, was architectural. It touched moreover closely upon realities, and was essentially valuable as giving an insight into an ancient studio. It was in fact a paper of practical importance; and thanks were fairly due to Mr. Garling for the pains he had taken in bringing it forward.

REPTON SCHOOL CHAPEL.



(With an Engraving.)

AT the tercentenary of the school, celebrated on the 11th and 12th of August, 1857, liberal subscriptions were promised for a memorial fund; the majority of the contributors giving preference to a chapel, as being at once the most appropriate and the most likely to contribute to the future interest of the school, and the maintenance of its present high position. A committee was formed, and a correspondence entered into with many old Reptonians and well-wishers of the school, in order to carry out this object. The committee being unable to obtain a site in the Priory ground, secured a most eligible piece of land on the brow of the hill leading up from the railway station. The foundation stone of the new chapel, of which we present a perspective view and ground plan showing the internal arrangements, designed by Mr. J. H. Stevens, of Derby, was laid by the Rt. Hon. Earl Howe, on August 26th last, and is now roofed over. Below the cornice on the outside of the building are panels for inscriptions; one describing the object of the building is as follows:—DEO . SERVATORI . HANC . ÆDEM . SCHOLÆ . REPANDVNENSIS . PER . ANNOS . CCC . INCOLVMIS . PRÆSIDES . ALVMNI . AMICI . POSVERVNT . A.D. MDCCCLVIII. The estimated cost is about 3000*l*. The walls internally are faced with stone, and the fittings are of oak.

THE MAIN DRAINAGE OF THE METROPOLIS

(*Concluded from p.* 392.)

The result of the objections put forth by the Metropolitan Board of Works, was that the Referees addressed a further communication to the First Commissioner, bearing date Nov. 12th, 1857, in which, while defending the major part of their recommendations, they modified their scheme in the following particulars:

The main outfall sewers which were to have been open for the greater part of their length, were now proposed to be covered except near their lower ends.

For the purpose of avoiding the "depressions" alluded to under the term syphons, the depth of the sewers was to be increased so as to enable the several streams to be passed without any depression of the bottoms.

Instead of the respective widths of 39 and 37 feet assigned to the channels on the first plan, they were now to be 25 feet and 22 feet wide at the head respectively, gradually increasing to 60 feet and 57 feet in width at the outfalls; the depths being increased by 9 ft. 6 in. and 10 feet respectively at their upper ends, and at their lower ends by 3 feet and 3 ft. 6 in.; they were also to be brought to an uniform fall of 6 inches to a mile. These sewers were now proposed to be made tidal throughout their whole length, the tide entering from their lower ends.

In defending their selection of the points of outfall the Referees urged, in reply to the objection of the Metropolitan Board, that the gain by going fifteen miles lower down would be partially lost in consequence of the discharge taking place at or near low water; that the discharge of the sewage in dry weather would take place during the greater part of the ebb tide, and that the sewage would not be returned up the river with the rising tide to the extent apprehended, because the currents at the points selected are very strong during and until the last of the ebb tide, while a considerable period of slack water occurs at the commencement of the flood tide; and from the set of the currents, a very limited portion of the sewage would have a tendency to move up the river.

The Referees describe the outfall channels of their second plan as being designed upon the principle of tidal creeks, the object in so designing them being to fix a level little above that of high water in London, as the point to which the sewage should gravitate in the metropolis.

At the upper end of the channels gates would be constructed to admit water from the Thames, whenever the level of the water in the river was higher than the level of the water in the channel.

The channels were proposed to be worked in either of the two following ways, viz.:

"1. Gates would be placed at a point 20 miles from the head, so constructed as to allow of the egress of the sewage whenever the level of the water in the channel was higher than that of the river at that end, but to exclude the ingress of the tide beyond that point.

"According to this arrangement, the gates would close soon after low water, and the water from a reservoir at the upper end, of about 20 acres in extent and 5 feet deep, filled at the previous tide, would be allowed to flow into the channel for about three hours, at a rate including the sewage flowing in of from 500 to 600 cubic feet per second, by which means a velocity of about 2·75 feet per second would be obtained at the upper end. When the tide had risen at the upper end to a level higher than the water in the channel it would flow in; and by the time of high-water it would occasion a velocity of upwards of 3 feet per second at the upper end. This water would accumulate at the lower end sufficiently to stand above the level of the river at that end at about two hours after high-water, when the sewage would commence to discharge, and continue doing so during the remainder of the ebb tide.

"By the second method of working, the channel would be left open at the lower end to the ebb and flow of the tide."

In this case the water from the reservoir at the upper end was proposed to be admitted at about one hour after the period of low water, occasioning the same velocity at the upper end as in the former case; and as the tide would not flow up the channels so rapidly as up the river, it was calculated that the water entering into the channels at the upper end, and flowing down, would meet the water from the lower end at about the fifth or seventh mile. "The velocity at the head would then be upwards of 3 feet per second, and the flow for the first five or seven miles would always be maintained in the direction of the outfall."

The reservoir on the north side was now proposed to be situated in Channel Sea Island, and that on the south side in Greenwich Marshes.

The outfall channels modified in the manner explained were calculated to add the sum of 550,000*l.* to the amount originally estimated.

The main point of difference as affecting the dimensions of the sewers, is the large amount of rainfall within the metropolitan district which the Referees considered it essential to provide for.

It was proposed in the plan of the Metropolitan Board of Works to remove one-fourth of an inch from the urban districts, and from the suburban districts a quantity varying in the different localities from one-eighth to one-sixteenth and one-thirty-second of an inch, in a period of twenty-four hours—these proportions being calculated to prevent the sewage from flowing into the river at all times, except during twenty-eight days in the year on the average. It appears that this average was derived from observations made in 1855.

The Referees objected that the average rainfall in London is one-fourth greater than the rainfall of the year selected by the Board of Works; and that from the quantity of rain which fell in 1851, the number of days on which sewage would have overflowed into the Thames would probably have been three or four times the number of days given by the Board as an average; and further, that the question of the amount of rainfall to be removed without polluting the river cannot be governed by the amount which falls spread over a period of twenty-four hours, but by the amount which falls during the period of eight hours when the sewage is flowing at its maximum.

The real reasons, however, which appear to have influenced the Referees in determining the amount of provision to be made in the sewers for the rainfall, seem to have had reference to the attainment of the amount of dilution requisite to give to the sewage the volume necessary to the maintenance of the theoretical velocity, upon which the proportions and fall of their main outlet channels were designed.

In regard to the objection that the removal of the rainfall from the Thames to the extent recommended would take away a powerful agent in scouring the river, the Referees observed: That the drainage area of the basin of the Thames above Woolwich is about 4640 square miles in extent, from which they propose to remove a portion of the rainfall taken from an area of about 350 square miles in the tidal portion of the river, amounting to nearly 8,000,000 cubic feet per hour during the period of the eight hours of maximum flow, and about 11,500,000 cubic feet during the average flow. If the latter quantity could be placed at once into the Thames at high water, it would occupy a layer in the tidal part above Woolwich about half an inch in depth, and on this assumption the effect of its removal would be inappreciable.

In answer to an application of the Metropolitan Board of Works for further particulars, the Referees suggested a third plan by which the reservoir on the south side was proposed to be placed near Deptford creek on the north side of the Greenwich railway station; and the course and sections of the outfall channels were modified in various essential particulars.

The north reservoir on this plan is described as to be of 15 acres area, and the south reservoir 10 acres; and both were to be 12 feet in depth below Trinity high-water mark.

The north reservoir was proposed to be capable of running into the channel about 500 cubic feet per second at spring-tides, and about 320 cubic feet per second at ordinary neap-tides, for a period of four hours, commencing at the time of low water at the outfall.

The south side reservoir would have run about 350 cubic feet per second at spring-tides, and about 220 cubic feet per second at neap-tides for four hours.

These quantities, together with the calculated mean dry-weather discharge of sewage (180 cubic feet per second on the north, and 160 on the south side) give the following quantities for four hours each tide; viz.:

	Spring Tides. cubic ft. per sec.	Neap Tides. cubic ft. per sec.
On the north side	680	500
On the south side	510	380

By these arrangements it was calculated that scouring velo

Digitized by Google

cities would be obtained at the heads of the channels, and for 6 or 8 miles towards the outfalls, of 2 ft. to 3 ft. 6 in. per second, according to the state of the tide and the quantities of sewage.

About the time that the reservoirs would become exhausted, viz., four hours after flood-tide at the outfalls, the tide would have attained the level of the sewage at the head of the channels, and would pour in during the remainder of the time up to high water, causing a scour through the upper 12 miles of the channels, varying from 4½ feet per second at the head, to 2½ feet per second at 12 miles. At high water the reservoirs would be shut up, and the water reserved for the next scour at low water.

The dimensions suggested for the outfall channels in the first plan having been calculated in error for too large a storm-flow, the Referees in their third plan altered the dimensions accordingly; a modification which they calculated would reduce the cost by about 350,000*l*.

Having in their observations, dated 12th November, 1857, described a double method of working the outfall channels, the Referees, in reply to the specific inquiry of the Metropolitan Board of Works, replied, that gates should be provided at the lower end, and that in their opinion it would be found advisable generally to keep the gates closed on the flood-tide, but that it might be found occasionally desirable to admit the tide.

The Metropolitan Board of Works entertaining strong objections to some of the recommendations of the Government Referees, and anticipating insurmountable difficulties in the execution of the schemes proposed by them, resolved to refer "The Reports of the Board on the Main Intercepting Drainage of the Metropolis," and also "The Reports of Messrs. Galton, Simpson, and Blackwell upon the same subject," to the engineer of the Board, together with two other civil engineers, with instructions to report to the Board as to the best means of carying out the main drainage of the metropolis.

Messrs. George Parker Bidder and Thomas Hawksley were associated with Mr. Bazalgette for the above purpose.

On the 6th April, 1858, these gentlemen presented their report upon the Main Drainage of the Metropolis.

This report gives a complete comparison and analysis of the various plans, reports, observations, and experiments of the Government Referees, with reference to the various parts thereof, and as bearing upon the plan submitted to the First Commissioner of the Metropolitan Board of Works.

The Metropolitan Board of Works having already determined upon the adoption of a system of main intercepting drainage, and it having been decided upon generally approved principles, that that drainage should, as far as practicable, be carried out by lines of arterial sewers, running parallel with the river Thames on both sides of the river, the Referees of the Board did not consider themselves called upon to investigate the merits of the various proposals that have from time to time been presented to the public. The points which remained to be definitely settled, and on which they considered it their duty to report, are, however, of the highest importance:—The area to be drained; the amount of sewage and rainfall to be provided for; the dimensions of the sewers; the points of outfall, and the mode of reaching them; and the possibility of purifying and improving the river, received the most careful investigation from the Referees of the Board themselves, and from other gentlemen whose aid they sought on collateral matters not falling strictly within the sphere of their own professional avocations.

As the result of their examination of the report of the Government Referees upon the outfall sewers, Messrs. Bidder, Hawksley, and Bazalgette direct attention to many errors and discrepancies, which, in their opinion, tend to weaken the recommendations of the Government Referees in reference to the dimensions and construction of the main sewers and the locality of the points of outfall.

At the threshold of the inquiry they consider that the experiments of Mr. Blackwell, which afforded the data upon which the Government Referees determined the velocity requisite for the main outfall channels, do not apply to the case of accreted deposits in sewers and rivers, which are formed under conditions totally different to those which had place in the experiments in question. The substances to be moved were placed on a wooden floor, were for the most part isolated, and were not cemented together by the matter of the deposit in the manner of the substances which are usually to be found in the beds of even quickly-moving streams. The result of the experiments was to the effect that heavy substances of various sizes could be moved on a boarded floor by a stream having a velocity of 2½ feet per second. Any one, however, may observe on the Thames bank fine deposited mud resisting the action of currents of 4 feet and even 5 feet per second, and in the River Mersey sandbanks are formed, although the tidal velocity is 8 or 9 feet per second.

In the plan first proposed by the Government Referees, the two great outfall sewers were to have been partially uncovered, and partially tidal.

The sewage in these uncovered sewers was to be diluted by six or seven times its own bulk of water, to be derived occasionally from storm-waters, and at all other times from reservoirs to be filled by the Thames.

These reservoirs were proposed to be placed—1. On the north side at Plaistow;—2. On the south side in the valley of the Ravensbourne.

By the Government Referees' second plan,—1. The outfall sewers were materially altered in size and shape;—2. They were now to be covered, excepting at the lower extremities;—3. Their levels and inclinations were varied;—4. They were to be "tidal" throughout. The inverts of the sewers were also to be lowered nearly 10 feet at the upper end, and 3 feet at the lower end.

The reservoirs were now to be placed—1. On the north side of Channel Sea Island;—2. On the south side in East Greenwich Marshes.

By the third plan the following changes were proposed—1. The sewers were to be reduced in size and again altered in shape;—2. They were again to be "tide-locked;"—3. The inverts were to be still further lowered. The reservoirs were reduced in size, and that on the south side removed from East Greenwich Marshes to Deptford Creek.

In regard to these various plans and modifications of plans, Messrs. Bidder, Hawksley, and Bazalgette observe:

"The information afforded with respect to all these plans is throughout imperfect, and in many respects contradictory or discrepant. The general design is to convey the sewage by long lines of outfall channels, terminating at points very remote from the metropolis; to provide for the removal of the sewage of a prospective population, estimated at what it may be forty years hence, at the rate of 7 cubic feet of sewage per head per diem, and for a rainfall equivalent to many times that amount of sewage. But as to the particulars of this project the greatest uncertainty exists. The long lines of outfall sewers are at one time to be uncovered, at another to be covered. The levels are different under each plan. The inclinations are variable under one plan and uniform under another. One set of plans provides for a certain specified flow, but another set for a "revised flow," on the allegation that the earlier plans were adapted for too large a flow. In the several plans the sewers are varied in form and area, and the position and magnitude of the reservoirs are altered. Having reduced the dimensions of the sewers, their direction is also greatly varied, although the first proposed was stated to have been made upon the most careful surveys. Last of all these plans vary in the essential particular as to whether the tide is, or is not, to be admitted into the outfall sewers. Upon this point even the first plan is indistinct. A difficulty of a similar kind is also experienced as to how the water of the Thames is to gain admission into the outfall channels, seeing that even at ordinary high water the level of the surface in the sewer is to be above the level of the surface in the river. By pumping only could the proposed object be attained; and yet no provision for the cost of the machinery and buildings, and for the working expenses, has been made in the estimates."

The difficulties which the remote outfalls involve in the valley of the Thames are sufficiently evident on a consideration of the plans proposed by the Government Referees. The construction of outfall works for the drainage of a *low* district by *gravitation* to a *remote* point, where the only attainable fall is a portion of the difference of level between high and low water marks, is only possible at an enormous sacrifice of time and money. The small declivity of the channel, incident to great length, necessitates large dimensions, and these again involve a proportionately large outlay.

In order to carry out the principle of drainage by gravitation aided by dilution, it became necessary to make large portions of the channels more than *eight* times what would have been the required capacity upon any reasonable calculation for the drainage of an enlarged metropolitan area, extending to Hanwell and Richmond, as they estimated such an area would be populated forty years hence.

Digitized by Google

The stream of water adequate to give to these sewers the hydraulic depth requisite to insure a sufficient velocity to keep them in a working state is only provided by nature on a very few days in the year. The Referees were consequently forced to suggest reservoirs at the head of each of the outfall sewers, in order to supply the deficiencies in the rainfall. These reservoirs involve not only additional difficulties, but even if practicable would entail such enhanced first cost and subsequent annual outlay, as to render the project extremely objectionable.

The quantity of water required for the dilution of the sewage as calculated by the Referees (see table, p. 275, vol. xxi.), amounts to no less than 183,059,370 cubic feet per diem. The difficulties of obtaining this supply in the localities originally proposed for the reservoirs would be considerable, but the difficulty of locality would by no means have been the greatest difficulty affecting the plan for these reservoirs. The level adopted by the Government Referees for the top water line of their outfall sewers, being a little above that of the highest tides, viz., 5 feet above Trinity high-water mark, it is obvious that the reservoirs could not be supplied from the Thames with water at a level high enough to flow into and fill the outfall channels. Except then when the rainfall proved sufficient for the purpose, the whole quantity of water required for the dilution of the sewage would have to be pumped up.

The pumping power required was calculated by Messrs. Bidder, Hawksley, and Bazalgette, as follows:—The level of the water in the outfall sewers being 5 ft. 6 in. above Trinity, which is 9 feet above the mean height of the water in the reservoirs, the water must be lifted a medium height of 14 ft. 6 in., and a maximum height of 23 ft. 6 in. Machinery, therefore, must be provided for raising 61,000,000 cubic feet of water in eight hours to a height of 23½ feet. This duty would require engines of the aggregate power of 5600 horses. As, however, half the daily flow of the sewage would pass off in eight hours, the quantity flowing into the sewers within that period would be 50 per cent. in excess of the mean flow. In order therefore to dilute the sewage to the extent proposed by the Referees, the dimensions of the reservoirs, sewers, and engines must be proportioned to one-half more than five times the ordinary sewage, or to 210,000,000 cubic feet per day instead of 183,000,000 cubic feet as stated by the Referees.

Messrs. Bidder, Hawksley, and Bazalgette give it as their opinion that to construct reservoirs of the necessary extent would, if practicable, involve an immense expense, and that the annual interest upon outlay, the cost of cleansing out the deposit left by every succeeding tide, and the expense of maintaining and working the machinery could not be expected to entail a burden upon the inhabitants of less than 100,000*l.* per annum, equal to a rate of 2*d.* in the pound on all the assessable property within the metropolis.

In the second and third plans projected by the Referees, the inverts of the main outfall channels being lowered, the reservoirs were to be filled direct from the river at high water; and as we have seen, would discharge into the sewers for a period of four hours, commencing at the time of low water at the outfall, and after the reservoirs became exhausted, the tide would pour in direct from the river during the remainder of the time up to high water.

Upon this arrangement Messrs. Bidder, Hawksley, and Bazalgette remark,—that reservoirs of the extent proposed could not receive the quantity of water required for the sewer;—that the outfall channels would be tide-locked at their lower ends;—that a large deposit of mud would follow, and that the velocity of the current at the lower end would be insufficient for its removal.

A general examination of the Referees' estimates showed considerable deficiencies in the quantities, and the absence of adequate provision for many works necessarily involved in the execution of the plan. The amount set down for land compensations appeared to the engineers consulted by the Metropolitan Board too small, and the result of a detailed valuation by a professional valuer showed a deficiency of 440,000*l.* under this head alone.

Having re-estimated the works proposed by the Referees on their different plans, Messrs. Bidder, Hawksley, and Bazalgette put down the approximate cost of

Plan No. 1, at	£11,000,000
Plan No. 2, at	9,000,000
Plan No. 3, at	7,000,000

A material element of excess in the scheme of the Government Referees is the large provision made for the combined sewage and rainfall.

As to the sewage alone, there is in fact little discrepancy between the estimate of Mr. Bazalgette and that of the Referees, so far as regards the maximum amount to be removed, if the enlarged area suggested by the Referees be excluded from consideration. The assumptions however, upon which the respective results are attained, appear to be very different. The Referees assume the flow of sewage at 7 cubic feet per person per diem, while Mr. Bazalgette adopts in his calculations 5 cubic feet as the standard. The Referees assume that one-half of the whole diurnal flow will pass off in eight hours of maximum discharge; Mr. Bazalgette on the contrary estimates that one-half will flow away in six hours. The Referees provide for the wants of a population thirty or forty years hence of 3,578,089 persons, while according to Mr. Bazalgette's views, the total prospective population is 3,448,500. But the general result of the various hypotheses on the determination of the maximum flow is as follows:

	cubic ft. per min.
Referees' maximum flow	26,100
Mr. Bazalgette's ditto	23,694

the difference being only about 9 per cent., while the increase in the total diurnal discharge of sewage consequent on the extended area provided for by the Referees amounts to little more than 7 per cent.

But while there is this sensible accordance with respect to the maximum flow of the sewage, a great difference exists with regard to the amount of rain to be carried off. The provision for rainfall made by Mr. Bazalgette amounted to a diurnal fall of ·25 inch for the northern districts of the metropolis, and from ·125 to ·25 inch from the peopled districts south of the Thames, giving a result of about 34,000,000 cubic feet per diem.

The Referees proposed to carry off as much as ·867 inch of rain in 24 hours from that portion of the metropolitan area (about 50 square miles) situated on the north side of the river; and a daily rainfall of ·387 inch from the remaining area of 68 miles on the south side, producing together 160,500,000 cubic feet per diem. In addition, provision is made for carrying off from the district termed prospective by Mr. Bazalgette about 6,000,000 cubic feet, and from the enlarged area projected by the Referees, in round numbers some 16,500,000 cubic feet, making a total rainfall of 183,000,000 cubic feet per diem.

The sewers proposed for discharging this large rainfall, together with the daily sewage of the districts included by the Government Referees, would suffice to carry off double the dry-weather yield of the Thames, and are adequate to the conveyance of the sewage at the maximum rate from more than the whole population of England.

Messrs. Bidder, Hawksley, and Bazalgette think it important to draw attention to the distinction between the rain to be carried off, and the actual fall of rain on the drainage area; the former being only the residual quantity which finds its way into the sewers after the gross quantity has sustained a large but variable diminution by domestic use, absorption, and by evaporation.

The Referees urge with great correctness that the quantity of rain-water to be estimated for is not to be reckoned from the hourly proportion of the diurnal fall, but from the quantity which may fall during the period of the maximum flow of the sewage, and they give it as their opinion that a less proportion than five times the maximum flow of the sewage would not prevent the frequent discharge of storm-waters into the Thames, and that the storm-waters would at these times be so highly charged with sewage matter as materially to interfere with the purity of the river.

Messrs. Bidder, Hawksley, and Bazalgette take a different view of the case. Estimating upon the Referees' own data, that the total amount of sewage which would flow off an urban district is equivalent to a depth of 52½ inches per annum over the whole surface, and assuming the mean annual rainfall to be 25½ inches, of which as much as 17½ inches would find its way into the sewers, it follows, that to relieve the Thames of all sewage impurity, the whole $52\frac{1}{2} + 17\frac{1}{2} = 70$ inches must be annually intercepted. But to effect this, the capability of discharge must be adequate to effect the withdrawal of an extreme storm-flow, that is to say, a flow produced by a fall of 2 or 3 inches of rain in twenty-four hours, or it may be in three or

Digitized by Google

four hours. Hence to insure the removal of all the rainfall, though in the aggregate amounting to only one-third of the combined flow, would require sewers of a discharging capability at least twenty times greater than that needed for the ordinary sewage of the prospective population of the metropolis.

As sewers even of the dimensions of those projected by the Referees would be incapable of carrying off the whole of the rainfall during heavy storms, it becomes a question for consideration whether the mere diminution of the number of days in the year on which the storm-waters would overflow into the Thames, would not be too dearly purchased at the expense of the enormous works suggested; especially if continued experience should confirm the opinion held by many practical and scientific men as to the distinctive decomposition of sewage matter, without the aid of the putrefactive process, which speedily succeeds upon its admission into a large quantity of fresh and flowing water.

In comparing the plans for the internal drainage of the metropolis, the engineers consulted by the Metropolitan Board of Works observe, with reference to low and high level sewers,—

"If the metropolis were to be left dependent for its drainage on low-level sewers alone, it is manifest that such sewers must be constructed at a depth adapted to the efficient relief of the basements of the houses of the lowest districts. This depth would be for the most part below the level of low water, and consequently any such tunnel sewers would be incapable of discharging themselves by gravitation. In other words, the whole of the sewage of the metropolis, no matter from what elevation it might descend, must eventually be raised by mechanical power, to effect its discharge into the river. The sewers must also be capacious enough, and the engines large enough, to deal with the whole volume of rainfall and sewage intended to be conveyed to a distant outfall; and even this provision would not prevent the reaction of a flood proceeding from a high level."

It would be more economical, as well as more convenient to the public, that high-level intercepting sewers should be constructed for the purpose of receiving the waters of the more elevated districts, and conveying them by gravitation to points of outfall, at which they can be discharged, either without mechanical assistance, or with the smallest possible amount of such extraneous aid. The Referees were of the same opinion, and accordingly proposed works based on this principle, but gave a much larger application to it than was designed by the engineer of the metropolitan board.

The route of the high-level sewer on the northern side has received the approbation of all parties.

Mr. Bazalgette by his middle and low level sewer divides the populous district intervening between the high-level sewer and the north bank of the Thames into two distinct areas,—the higher to be drained by gravitation, and the lower by the aid of mechanical power. The Referees upon their system proposed to dispense with both of these sewers, and to substitute two other sewers,—the one to drain eastward to Abbey-mills, and then to discharge by gravitation into the northern outfall sewer,—and the other to drain westward to Battersea, and crossing the river to discharge by steam power into the southern high-level sewer. Independent of other objections advanced against the latter scheme, it is inferior to that of Mr. Bazalgette in the point that by adopting a more elevated contour he is enabled to discharge the whole of the water from his gravitating area into the river, even at high tide,—an advantage which the scheme of the Referees does not possess.

Mr. Bazalgette has proposed two schemes for the northern low-level sewer,—one to include the western portion of the metropolitan area,—the other to exclude that area. The whole question of the drainage of the very low lands between Chelsea and Hammersmith is one of considerable difficulty. The water must either be pumped, or be deodorised, or be suffered to flow into the river as at present. The engineers consulted by the Metropolitan Board having rejected—as would appear, without sufficient reason—the proposition of the Referees to carry the sewage of this district across the Thames to their pumping station opposite Battersea, come to the conclusion that no mischief will arise to prevent the Counters-creek, the Eel-brook, and other minor sewers of the western district, to continue to discharge for the present into the river below low-water mark.

On the southern side there is comparatively little difference between the plans of the Referees and the plans of Mr. Bazalgette. They both comprise a high-level and a low-level sewer, and both propose to concentrate the sewage at Deptford. The Referees' plan, however, includes a lift at Battersea for the Putney and Wandsworth waters. The engineers of the board, however, are unable, for reasons stated in their report, to see any advantages in the extension of the sewers westward along the southern bank of the river, and urgently recommend the adoption of Mr. Bazalgette's plan.

The total maximum flow and rainfall provided for by the Board of Works' plan, has already been stated at 47,913 cubic feet per minute, during six hours' discharge. On account, however, of some additions made to the area, of a higher estimate of the progressive increase of population in certain districts, and of a larger allowance for rainfall, Messrs. Bidder, Hawksley, and Bazalgette calculate on a total delivering power of 79,900,000 cubic feet per diem.

On the subject of the points of outfall, the engineers of the board express a clear and decided opinion that the remote outfalls proposed by the Referees are unnecessary for effecting the objects of the 135th section of the Metropolis Local Management Act. They unhesitatingly select, as points of outfall, Barking Creek on the north side, and Crossness Point on the south side, as fulfilling all the favourable conditions that are attainable on either side of the river. Both are situated in dreary marshes, where neither the works nor the sewage can give reasonable cause of offence. The mean sectional area of the river at those places is four times as great as at London Bridge, and the average volume of tidal water about *four hundred times* as much as the volume of sewage to be admitted into it; and the river is fresh, or nearly so, at low water, and only moderately mixed with salts of marine origin at high water. As compared with the outfalls proposed in plan B*, the points indicated, they consider, will answer better in a sanitary point of view; and the diminution in the length of the outfall channels they calculate will save a sum of not less than 350,000*l*.

The sewage is proposed to be discharged into the river during the first two-and-a-half hours of ebb-tide, the outlet being by submerged pipes terminating below low-water mark.

Reservoirs are proposed to be constructed at the terminus of each of the outfall channels into which the sewage is to be received. The reservoirs will be arched and turfed over, so as neither to permit the escape of effluvia nor to present any unsightly appearance.

It is intended to construct the reservoirs so as to enable the precipitation of the sewage matter to be effected by the application of lime; although the process is not recommended for adoption on account of the large quantity and unsaleable character of the deposit.

The formation of a public road, 40 feet wide, is recommended through the marshes on the north side, under which shall be built a triple culvert of brickwork, each culvert to be 9 feet diameter. This road would afford a convenient communication between the pumping station and reservoirs, and would, it is believed, become a road of much importance to the extending districts at the eastern extremity of the metropolis.

On the north side the low-level sewage is proposed to be raised at Abbey Mills, by mechanical power, to the height of about 34 feet, and will thence flow by gravitation into the reservoirs; and on the south side the whole of the sewage will be similarly raised into the reservoir near the outfall, from a depth of 25 feet.

If it had been possible to have drained the whole of London by gravitation, there is no question that such a plan would have been immeasurably superior to either of the schemes under consideration; but inasmuch as any plan which proposes the relief of the low-lying districts on the banks of the river, and the exclusion of the sewage from the Thames, must adopt mechanical aid for raising the sewage, the extent and economy of such application becomes a question solely for the consideration of the practical engineer. Meanwhile, should the metropolitan drainage be executed in the most efficient and successful manner, our satisfaction must ever be alloyed by the considerations that in addition to the first cost of so great an undertaking, a constant and to some extent uncertain outlay must be incurred in its maintenance; that wide districts will be under bondage to machinery which an accident may at any time derange; and that in the possible future, the great plan now designed for the drainage of the metropolis, may become the means of converting it into a swamp.

THE PANAMA RAILWAY.

By V. Wyatt, C.E.

There are but few public undertakings which have so much interest attached to them as the Panama Railway; connecting as it does the two large oceans of the world—the Pacific and the Atlantic—and traversing the backbone of an isthmus which hitherto had been deemed insurmountable; passing to and fro the commerce of the eastern and western parts of the world, and opening up the riches and glories of the Pacific,—this railway bids fair to assume great commercial and general importance. India, Australia, California, British Columbia, and the rich provinces of Central and South America, on the Pacific side, have had a new and direct overland route opened to them by the construction of this isthmus railway.

A casual inspection of the American isthmus and the demands of commerce would seem to dictate that a canal between the two oceans, by which the shipping of the two seas could be interchanged without breaking bulk, would have been a far more useful and commendable work than a railway. So natural is this conclusion that from time to time various and diversified have been the projects for a ship canal between the two seas, and these projects date as far back as the Spanish Conquest. Shortly after Columbus had cruised about and discovered the Central American waters, and when the enterprising Spanish cavalier, Nunez de Balbao, had actually mounted the Andes, and espied, for the first time by a European, the Pacific ocean, more than three centuries since,—the world became convinced of the necessity of some great work on the isthmus. There have been proposed from time to time two different ship canals at Nicaragua—one with a Pacific terminus at San Juan del Tur, and another at Realejo in the Pacific, where the summit level in the former case is 615 feet above the sea, and in the latter about 212 feet. The latter route is somewhat circuitous and uncertain in its data. The Panama crossing of the isthmus has also been advocated, presenting equally favourable features for a canal as it does for a railway. There are no abrupt elevations and depressions; the distance can be made the shortest possible across the isthmus, being only about 30 miles in a straight line; and its greatest elevation above the mean level of two oceans, by careful selection of country, need not exceed the highest point of the Panama Railway, which is only 263 feet, and this summit height being of very short continuance. Then there are the Darien and Atrato routes; the former of which is much controverted, and its assumed data are insufficiently supported by reliable surveys, the summit being stated by one exploring party to be all that the mind can desire, and by another and more recent exploration as beset with mountain ridges and insurmountable obstacles; the latter route (the Atrato) has the objection of lockage up the rivers which descend from the summit each way, and it is very circuitous. There is no difficulty about the level of the two oceans, as the mean tide level of each are identical, the only difference being that the spring tides in the Atlantic are only about 18 inches, whereas in the Pacific they are from 10 feet at San Juan de Nicaragua, to about 18 feet at Panama Bay.

The climate of the coast of Central America and the isthmus of Panama is of the most unhealthy character, and quite unfitted for Europeans. The atmosphere is hot, steamy, damp, miasmatic, and fever generating. The European when he lands on this coast feels his energies relaxed, and his whole system depressed. This was the greatest difficulty the pioneers had to contend with in the construction of the Panama railway. The railway works were of a light character, and would have been deemed trivial in healthy spots; but when the theatre of operations was the isthmus of Panama, then the problem was, not merely to organise men for their work, but how to keep workmen alive in such a pestilential place, continually attacked as they were by intermittent fevers and agues. Every gang of men was being continually broken up by disease, desertion, and excessive mortality. It has been stated that 10,000 men lost their lives in the making of this railway, and that the sleepers in the line count the numbers of bodies buried there; but this calculation, like many other popular rumours, is of course over estimated. It is very certain however, that the company did import on to the isthmus during the time the works were going on more than 3000 Americans, Irish, Chinese, and Negroes, besides the casual supplies of labour which found its way to the works from time to time. The major part of these men fell victims to the isthmus fevers; the Chinese committed suicide to a wholesale extent; many succumbed to their intemperance and irregularities under a tropical sun; and some, including many shrewd Americans, "cleared off," and departed from the isthmus as soon as the seeds of disease or the horrors of the spot became apparent to them. The inconveniences and risk of working in such a climate may be imagined from the fact that the temperature on the isthmus is from 82° in the morning to 90° mid-day Fahrenheit in the shade, and this continued all the year round, with no greater variation than 5° or 6°; and accompanied with this is the unhealthy steam from a tropical rainy season extending over eight months in the year. The sea water in the two oceans adjacent to the isthmus, taken at ten feet below the surface, averages 84° Fahrenheit.

The Panama Railway starts on the Atlantic side from Navy Bay, at a point called by Europeans and New Granadians Colon, and by the people of the United States, Aspinwall, after one of the railway promoters. Colon or Aspinwall town, which has been created by the railway, has a very backwoods-settler look about it, being composed of wooden houses, stores, shops, and hotels, and has only one permanent looking structure, viz., the railway freight and store house, built of stone with an ordinary iron roof of 78 feet span. The American engineers point to this as the very *chef d'œuvre* of engineering. Aspinwall is on the eastern side of Navy Bay, on an almost submerged coral reef, standing only about 3 feet above the Atlantic. It is a wet, swampy, and aguish-looking spot; the rains are incessant; and yellowish-white unhealthy looking faces are visible everwhere amongst the railway employées and residents. Panama is considered a wet place, but in comparison with Colon or Aspinwall, it sinks into insignificance; the railway rain-guage at the latter place showing a register in one rainy season of eight months of 110 inches of rain. England is called wet with an average of 26 inches of rain for the year. Behind Aspinwall is a rotten swamp for miles, the miasma from which salutes the nostrils of the voyager when landing; and he is moreover advisedly informed that a residence of more than 24 hours for a new comer, will probably introduce him to a tropical fever. The old outlet on the Atlantic side for the mule travel of the isthmus was at Chagres, situated to the west of Navy Bay, being at the mouth of the Chagres river; and a never-to-be forgotten place by Californian travellers, who have so often left the bones of their friends on its miserable shores.

The railway after leaving Aspinwall crosses the dismal swamp before alluded to for a distance of 7 or 8 miles ere it reaches terra-firma; it then escapes from this floating bog, with all its rotten, rank, tropical vegetation. The greatest amount of mortality resulted on this part of the line in the first construction; here not only from the unhealthfulness of the situation, but also from a total absence of any properly organised commissariat to supply the men with the necessary and proper comforts; and also allowing the free circulation on the works of the raw spirits so cheaply imported on to the isthmus from the West Indies. Various were the expedients adopted by the American engineers in this swamps to form a foundation for the road, and to economise labour, time and expense. Crib-work (the American term for large wooden boxes, formed of large timber logs, which are loaded with stones or gravel and sunk into position), fragile and temporary trestle-work, and staging on piles. All these methods have rotted and nearly disappeared, as might be expected in a climate where the durability of timber is estimated by months instead of years; and this fragile and temporary work is being substituted, or rather buried up by a filling-in of good, hard, dry, rocky material, with occasional tips of clay to bind the whole together in one mass, enclosing in its bulk the original piled staging and crib-work; the material being obtained from side cutting on the Panama side of the swamp. There is one merit however in the swamp part of the railway, which is that it is the only direct and straight part of the line; most of the rest being very circuitous, and laid out in a succession of serpentine curves, on precipitous sidelong ground.

The clearing of the railway from bush and jungle was attended with considerable risk, having to be done two or three times over during the progress of the works, the growth of vegetation being so prolific here. Now that the line is completed and opened, the clearing is still a work of some expense, and has to be done twice a year by negroes, or the course of the line would be grown up and invisible. In the first attempts at clearing away the

Digitized by Google

jungle, the pestilential insects were an insufferable nuisance to the men; and frequently have they been driven from their work before a cloud of mosquitoes, sand-flies, garropatas, and venomous tropical insects.

From the dismal swamp the railway winds its course tortuously, and in the shape of an almost succession of reversed curves through the summit, and all the way to Panama. These curves are reversed 4°, 6°, and 8°, (which is the American notation for curves of the respective radii of 1432, 955, and 716 feet,) without any straight line to ease the reversal, and not always with the outer rail elevated. The winding course of the line may be conceived of from the fact that the isthmus in a direct line is only about 30 miles wide, but the distance by railway from Colon to Panama Bay is 48 miles. The course is very ingeniously picked out in the vicinity of the summit, taking every available ravine and opening to its assistance; running sidelong on the banks of the Chagres river in dangerous proximity for miles, and turning at times to every conceivable point of the compass, giving the traveller occasional views of tropical luxuriance; taking awful twists and bends to avoid cuttings of 8 or 10 feet in depth; and at last clearing the summit of the isthmus 10½ miles from Panama and the Pacific, with a cutting only averaging about 20 feet in depth and 500 yards long. The greatest grades are 60 feet to a mile, the curves are anything you like, and the maximum elevation to which the locomotive ascends is 263 feet above the mean tide levels of the two seas. Before the railway was explored and constructed, the isthmus had been surveyed by various scientific individuals, who maintained that a less summit could not be found at Panama than about 400 or 500 feet above the sea. But railway engineers soon destroyed the hypotheses of learned explorers (who so often write about nature, but do not attack her,) and by a good deal of pluck and energy, and a small amount of science, brought the project to a practical issue.

The isthmus presents many picturesque tropical beauties between the Aspinwall swamp and Panama. There are the varieties of palm trees, more than twenty in number, with their clusters of scarlet berries; the cocoa-nut tree with its graceful feathery branches; the gigantic flowering tropical lilies and cactus; the plaintain, prickly pear, and gay flowering shrubs and creepers; and the impenetrable jungle or tropical thicket, clothing the ravines with a dense cover of vegetation, and giving to their undulations a gorgeous clothing.

The earthworks upon the railway are but trifling; there are no large cuttings, (the largest being the summit one mentioned above) and no very large banks. The bulk of the material for the banks was taken from patches of side cutting taken at the nearest and most convenient points, regardless alike of appearance or finish. Necessity was the order of the day, and style and order had to succumb. The slopes are not trimmed, or even formed at all like slopes, the cuttings being taken out vertically and allowed to form themselves, and they have formed themselves truly, with the assistance of the tropical rains, into very wild shapes. Nature, here so prolific, however, steps in frequently and clothes their deformities by a tropical covering of vegetation. The tops of the banks are shaved down in too many cases to a nicety, being not more than 10 or 12 feet broad at the top, and cut into and guttered up severely by the tropical rains, for want of a proper sodding. Near the summit this deficiency of embankment gives the line a very dangerous look, and especially so where its slopes are washed by the Chagres river. Diversions of the line, and sacrifice of good alignment are visible in some places where work has been cut down to its minimum, and pushed through at any sacrifice.

The bridges which were first constructed upon the line were of the true wooden, temporary, and American type, having a very stagy look about them, and not intended for inspection by posterity. They were in some cases nothing more than trestle-work of the rudest description, and quite unsafe for trains of more than four or five miles per hour. These, however, thanks to the rapacities of a tropical climate, have gone the way of all that is perishable, and crumbled into dust and tropical mildew. Wrought-iron boiler-plate girder bridges, both for large and small spans, resting upon stone abutments, have been substituted. They are of the simplest character, and have a lean, skeleton appearance. Each bridge is only composed of two ordinary girders, placed directly under each rail, with nothing over them but the common cross-sleepers of irregular lengths, and the rails then spiked to these. No planking, no parapets (although the bridges are frequently placed on very ugly curves, and the train jumps as it mounts them), and the bridges *in toto* resembles an ill-constructed gridiron. The masonry is bold, rough, and good, prepared from a blue granite and whitish freestone which are found on the line, in the execution of which negro labour, as in all other classes of work on the isthmus, is largely employed under white superintendence. These bridges have cost a heavy sum, as they have all been constructed on the wrecks of the old ones, since the opening of the line in 1854, and whilst the ordinary traffic has been going on. The iron bridge over the Chagres river, about half way across the isthmus, is the largest and most important work on the line; it has six openings of 100 feet span each, spanned by as many pairs of boiler-plate girders, arranged in this example to form the parapets, with small cross-girders, and upon these last the longitudinal timbers are fixed to carry the rails. The whole, however, is left grid-iron shape, without planking or finish. It is adapted for a single line only. The upper sides of main girders are curved, which gives to the upper lines of the bridge a wavy and unpleasing appearance.

The permanent way is of the roughest character; being laid and maintained by negro labour, its correctness as to line, level, and finish may be easily judged. The rails are, however, generally good, and of the bridge-rail section, weighing 68 lb. to a yard. Some short distance of the line is laid with the common Yankee foot-rail, or, as it is sometimes termed in England, the contractor's rail. The rails are fastened to the intermediate sleepers by common spikes weighing less than a lb. each, and at the joints are secured very roughly by a small boiler-plate chair (8 lb. weight) and four spikes. This is the universal American system of fixing rails. The rails might, however, have been slotted at one end, through which two of the spikes pass and secure the rail to the chair, and prevent it from sliding. The bridge rails used here were evidently intended for longitudinal timbers; for there are the holes in the flangesfor the screw-bolts which secure the rails to the continuous timbers. The sleepers now used are of lignum vitæ wood, fetched from Carthagena on the Atlantic side of the isthmus, and cost when delivered 6*s*. each. The sleepers originally used (pine) on the line have wholly disappeared; they only lasted from two to three years. The lignum vitæ sleepers are reported to be of no longer duration than about twelve years. The ballast was omitted from the line almost entirely in its first formation, and now it is not universally used throughout, being put on in patches from time to time, where it is found to be all important to keep the permanent way from being washed out of position by the tropical rains. It is principally formed of broken rock and coarse gravel, both of which are plentiful on the line; it is used sparingly however, the sleepers being generally on the soft material on their underside, with broken rock packed between.

The travelling on the railroad is very slow, averaging not more than ten or twelve miles per hour. The grades, however, are not excessive, not exceeding as above stated a maximum of 60 feet in a mile; but the locomotives are weak and asthmatic, and they frequently stick on these inclines with very ordinary trains, and the passengers sit under a broiling tropical sun at the bottom of a cutting, with only an inch board intervening between them and the sun, frequently for an hour together. This is not very pleasant when each passenger pays 5*l*. 3*s*. for the fare to cross the isthmus, and 6*d*. per lb. for all his luggage over 50 lb. weight, which, with something like an ordinary amount of luggage, comes to about 2*s*. 6*d*. per mile per head. The black negro engine-drivers too take a long time to pull up at an intermediate station, swinging backwards and forwards in its vicinity for about a quarter of an hour, like the pendulum of a clock. The locomotives and carriages are of United States build and fashion, only a shade worse. There is the bull-whistle to the locomotive, with its funny little wheels in front on a bogie frame, turning on a swivel-joint, and its broad-topped ugly funnel for wood-burning. The carriages are common and dirty, with no double casing to the top to screen the intense heat of a tropical sun, Venetian slides for windows, and hard seats. The station-houses along the line are mere palm huts (excepting at Aspinwall and Panama), and their vicinities have a wild uncivilised appearance, with the black, nude negroes hovering about in all the crudities of uncivilised life.

At Panama, the terminus of the line on the Pacific side, the station has no conveniences of any kind for travellers; no offices for washing, refreshment, and other purposes. The traveller from California to the United States often finds himself here in

Digitized by Google

company with some 1000 or 1200 persons, just arrived by a Californian steamer, suffering from tropical disorders, and no means of comfort at hand, not even civility.

The total cost of the line has been about 27,000*l.* per mile, and the engineer-in-chief from the commencement to the present time has been Colonel Totten, an American. The railway pays a dividend of 12 per cent. per annum, with its present undeveloped traffic.

INSTITUTION OF CIVIL ENGINEERS.

Nov. 23.—Joseph Locke, Esq., M.P., President, in the Chair.

The Paper read was "*On the successful working by Locomotive Power over Gradients of* 1 *in* 17, *and Curves of* 300 *feet radius, on Inclines in America.*" By Mr. T. S. Isaac.

It was stated, that the road which had decidedly taken the lead in the United States, in the application of locomotive power to steep gradients, and had been generally the pioneer of improvements, was that extending from Baltimore on the Chesapeake Bay, to Wheeling on the Ohio river, a distance of three hundred and eighty miles, through a region of considerable difficulties, especially in the various ranges of the Alleghany mountains. This company was incorporated in 1827, being the first chartered in America, and a portion of the road was opened in May 1830. At first it was worked by horses, but locomotives were employed as early as August 1830,—prior to the opening of the Liverpool and Manchester Railway. Legislative and financial difficulties prevented the commencement of the western section until the year 1849, and it was not until 1851, or three years previous to the opening of the Sömmering incline, that the great incline over the main range of the Alleghanies was completed and worked by locomotives. This latter had an inclination of 1 in 45½ for eleven continuous miles, and after winding amongst the summits of the mountains for twenty miles, it descended on the western side with an inclination of 1 in 45½ for nine continuous miles. The passage of this mountain chain involved altogether sixty miles of railway, twenty miles of which had a gradient of 1 in 45½, and nine miles of 1 in 50, both worked by locomotive power at a speed of from fifteen to twenty miles per hour for passenger trains, and from ten to fifteen miles per hour for goods trains. The curves were frequently 600 feet radius. Although it was one of the main thoroughfares of American commerce, no extra provision was made for working these inclines beyond increasing the number of engines. The engines had eight wheels, all coupled, the diameter of the cylinders being 17 inches, the length of the stroke 2 feet, and the diameter of the wheels 4½ feet. The engines weighed 24 tons each, and the tenders 13 tons each.

In 1852, difficulties were encountered at two different tunnels, which rendered temporary inclines necessary, in order to accomplish the passage of the trains. This system was frequently adopted when it was required to surmount hills where the tunnels were incomplete, in order to enable the iron and other materials for the permanent way to be delivered along the line. There was a maximum gradient over the Kingwood tunnel of 1 in 10, and this incline was in operation for several months, the iron and other materials for upwards of forty miles of line, and the United States mails, having been conveyed over it by locomotive power. The same engine that was used on the other parts of the line was employed, and it drew a loaded car weighing 13 tons, and a tender weighing 12 tons, or a total weight of 25 tons, at the speed of 8 to 10 miles per hour. Over the Broad Tree tunnel there was a series of zigzag inclines on which the upward motion of the train was alternately reversed, the engine at one time pulling, and at another pushing the cars. There were three of these inclines on the eastern, and five on the western slope of the hill. The total length was nearly two miles and one-third, and the gradients varied from 1 in 18 to 1 in 15½, with a minimum radius of curvature of 300 feet. The ordinary freight consisted of two loaded cars weighing together with the tender 37 tons. Mr. Latrobe, the chief engineer of the line said, in his report for 1853, that as many as fifty cars containing 400 tons and two passenger trains had been taken over this hill in a day by four first-class locomotives; and that during five months there had been no accident involving more than a trifling detention. These two inclines, although unprovided with engines especially adapted for the purpose, fully demonstrated the feasibility of traversing gradients altogether unprecedented by the locomotive alone. The experience gained in working them not only established the fact, that a rise of 300 feet per mile and curves of 300 feet radius could be worked with comparative facility, but seemed to point also to a limiting gradient beyond which it was impossible for the locomotive to go with any useful effect, even for a temporary purpose.

Steep gradients and sharp curves had since been adopted on the Virginia Central Railroad on a more extended scale, and had been in successful operation for upwards of four years. The mountain top incline on this road crossed the Blue Ridge mountains at Rock Fish Gap, in Virginia. It was four miles and one-third long, with a ruling gradient of 1 in 18·87. But on the lower half-mile of the eastern slope, the gradient was 1 in 17·86 on curves of 570 feet radius and upwards, and the minimum gradient on curves of 300 feet radius was 1 in 22·22. The length of the eastern slope was 2·37 miles, with an average gradient of 1 in 20½; and of the western slope 1·89 mile, with an average gradient of 1 in 22·22. The whole distance worked by the mountain engines was 8 miles, over which the average gradient was 1 in 29½. The engines were mounted on six wheels, all coupled and set close, the outer wheels being only 9 ft. 4 in. apart from centre to centre. The diameter of the cylinders was 16½ inches, the length of the stroke was 20 inches, and the diameter of the driving wheels was 3½ feet. A tank was provided over the boiler capable of holding 100 cubic feet of water, and above this there was placed 100 cubic feet of fuel, an additional quantity being stored under the footboard, which was lengthened for the purpose. When supplied with wood and water sufficient for a trip of eight miles, each engine weighed about 24½ tons. The usual weight of a mountain train was 45½ tons, the speed being limited by regulation to a maximum of eight miles per hour. The consumption of fuel was three-quarters of a cord of wood westward and half a cord eastward. Greater loads had been conveyed, but those given were the results of ordinary working. For accomplishing the descent, all the cars were provided with a break to each wheel of sufficient strength to lock the wheel if necessary, and a breakman was stationed at each end of the car. The breaks of two cars were found sufficient in ordinary weather; but when the ground was covered with snow or ice, recourse was had to the air cocks of the engines, and sand was applied to the breaks. The author considered that a judicious combination of these two methods was preferable to the exclusive use of either. There was nothing in the motion of the train itself, except a diminution of the speed to indicate that such steep gradients or sharp curves were being traversed. It had now been in operation for upwards of four years without a single accident.

The author believed that the resistance of the curves had been underrated in America. On the mountain-top incline it was proved that the resistance of the curve exceeded 25½ lb. per ton of engine and train. Mr. Latrobe had calculated that the resistance to traction on a level was doubled by a curve of 400 feet radius; and he assumed 13 lb. per ton as the additional friction of a train on a curve of 300 feet radius, whence the additional friction of the engine, due to such a curve, must have exceeded 49 lb. per ton of its own weight. Two expedients had been resorted to for diminishing this friction. On the Baltimore and Ohio incline, for a speed of ten miles per hour, the outer rail had been gradually raised on a curve of 300 feet radius from 2 inches, the height given by the ordinary formula, to 9 inches. On the mountain-top track inclines, for a speed of 8 miles per hour, the outer rail had an elevation of 6½ inches; and a sponge saturated with oil was kept in contact with the flanges of the two forward wheels of each engine. These expedients had so far reduced the friction on the latter road as to cause no perceptible diminution of speed on leaving a straight portion of the track with a gradient of 296 feet per mile, and entering a curve of a radius of 300 feet having a gradient of 238 feet per mile.

The Virginia Central Company had also constructed a shorter incline about 100 miles further west, which was one mile and a-half in length, with gradients varying from 250 feet to 300 feet per mile, and curves of a minimum radius of 400 feet. Over this incline which had been in successful operation for two years, the common freight engines on eight wheels, four of which were coupled, giving 16 tons for adhesion, had taken a load of 36 tons at a speed of five miles per hour.

The ordinary performances of the engines on the mountain-top track showed an exertion of 181½ horse power, including the engine in the load, or 118 horse power not including the engine;

Digitized by Google

giving, in the latter case, 4·8 horse power per ton of motor, the resistance due to the speed and the gradient being 121·64 pounds per ton.

On one or two occasions, on the incline of 1 in 10 on the Baltimore and Ohio line, the weight of the engine being four and three-quarter times the resistance of gravity and the friction of the load, when the rails were very greasy the engine and train slid backwards with locked wheels from near the top to the bottom of this incline, without damage. The wheels of these engines had chilled tyres, a circumstance which considerably decreased their adhesion. The engines on the mountain-top track with an ordinary train exercised an adhesive power of one-sixth of their weight, and this could always be maintained in the severest weather by the use of a fine clean sand.

In conclusion, the author remarked that there were probably few mountain passes that could not be overcome by the introduction of gradients of 1 in 17, and experience had satisfactorily proved that the locomotive could draw a load nearly double its own weight up such a gradient at a speed of eight miles per hour. The working of the mountain-top track furnished additional evidence to that already gained from other sources, of the superiority of light engines with light loads over heavy engines with heavy loads.

Hall's Apparatus for Working Railway Breaks.—After the meeting, a model was exhibited of an apparatus by which railway carriages were coupled together, so as to render the action of the breaks continuous throughout the train, and thus render it possible to apply three or four breaks simultaneously. A longitudinal square bar was suspended under each carriage, the connection being made by a universal joint coupling. In making up a train, the break blocks of the break vans were screwed up close to the rims of the wheels, and then the coupling was effected, so as to avoid the possibility of slack. The break blocks were so arranged on the carriages that two operated in each direction, so that the carriages might be moved either backwards or forwards indiscriminately; but this was not the case with those attached to the tenders and the break van. The mode of applying the power was similar to that ordinarily in use. There was a worm wheel on the spindle of the handle from the van, working into a cog wheel fast on the longitudinal shaft. On this shaft there was also a screw working in a loose collar, to which was attached the ends of one pair of levers, operating the arm of a lever on a fixed shaft, also carrying the levers to which the blocks were attached.

Nov. 30.—Geo. P. Bidder, Esq., V.P., in the Chair.

The whole of the evening was occupied by the Discussion of Mr. Isaac's paper on "*Steep Inclines in America.*"

It was explained that on the Baltimore and Ohio Railway, the ordinary goods engines had cylinders of 19 inches diameter, with a stroke of 22 inches; they had eight driving wheels, of 3 ft. 7 in. diameter, all coupled. The passenger engines principally employed on the inclines of 1 in 45½ had cylinders of 19 inches diameter, and 22 inches stroke, with six driving wheels, 4 ft. 2 in. diameter, all coupled, and a leading truck, or bogie, on four wheels. Peculiar arrangements were made for facilitating the passage over curves of small radius; the centres of the front and hind wheels were only 11 ft. 3 in. apart, and the intermediate wheels were without any flanches, the springs being so adjusted as to equalise the weight.

It was stated, that the adhesion of driving-wheels had been shown from experience in the United States to be beyond the limits usually assigned. Instances were known where the effective adhesion had been as much as two-fifths of the nominal weight on the driving wheel; it being assumed that this varied much when running, as compared with the actual weight ascertained by the weighing machine when at rest.

On the Cleveland and Pittsburgh Railway, on the 1st August, 1857, a train of fifty loaded waggons, each on eight wheels, and weighing with the engine and tender 800 tons, was drawn up a continuous incline, 2 miles in length, of 1 in 132. The engine weighed 26·8 tons, with only 19·2 tons on the six coupled wheels. The gravity of the entire train would be 13,575 lb., whilst the friction, which could not average less than 5 lb. per ton, would increase the amount to 17,575 lb., or to more than two-fifths of the weight upon the driving wheels.

In making a series of trials for the New York and Erie Railway, Mr. Zerah Colburn drove a train of eighty waggons, each on eight wheels, weighing with the engine and tender 1270 tons, up a continuous incline of 1 in 480, with curves of 1145 feet radius. The gravity being 6000 lb., and the other resistances 8300 lb., the entire resistance was 14,300 lb. The weight on the driving wheels of the engine at rest was 40,500 lb.; hence the adhesion was 0·35 of the insistent weight.

An engine, when on a severe incline, changed its position so much as to alter materially its running condition, which should be provided for in building engines expressly for working inclines.

It was stated, that at the time of construction of the Mountain Top Incline, it was found necessary to place a tank on the eastern slope, on a gradient of 1 in 18·87. During the first two or three summers the ascending trains were in the habit of stopping daily, and the engines were able to start again without difficulty. There was one engine on the mountain on eight wheels, all coupled; the cylinders were 18 inches in diameter, with a length of stroke of 22 inches; the wheels were 3½ feet in diameter, and the gross weight of the engine was 27 tons. This engine had crossed the mountain six times in one day, with a load of 49 tons each time; making the trip in one hour from Turntable to Greenwood, and in one hour and a quarter from Greenwood to Turntable; although it was very rigid, and was not adapted to the curves. One of the lighter engines had taken a load from Turntable to Greenwood in half an hour. Mr. Ellet had published a statement of the cost of working, based on the fuel and oil consumed, and the wages of the workmen. Fuel on the mountain cost two dollars per cord. It was difficult to make a just comparison of the various fuels, and to obtain correct information as to the water evaporated. The same cause that prevented the experiments on the resistance of curves, prevented comparative experiments on fuels, and accurate statements of the water evaporated. At first, pine was used, but oak had been extensively adopted latterly. The effective pressure of the steam above that of the atmosphere usually amounted to from 100 lb. to 120 lb.

It was remarked that whereas on most English railways, the results of experience showed a resistance of 12 lb. per ton gross on a level, yet some of the statements which had been made as to the working of railways in the United States, seemed to indicate a resistance of not more than 5 lb. per ton gross after allowing for gravitation on the incline; whilst the permanent way of American lines was notoriously inferior in all respects to that of the English lines. The first of the results named in the paper showed a traction resistance of about 150 lb. per ton gross. In contrast with this it was stated, that on the Great North of Scotland Railway, near Aberdeen, the Kitty Brewster incline of 1 in 59, and full of quick curves, had been worked for the last three years by two tank locomotives, having cylinders 15 inches diameter, with a length of stroke of 24 inches, and four wheels coupled, each 4½ feet diameter, at a steam pressure of 150 lb., the load on the driving wheels being 15 tons, on the leading wheels 10 tons, and the gross weight in working order 25 tons. The trains were started from the foot of the incline. One of these engines could take up nineteen waggons, weighing when loaded about 11 tons each—making a total gross weight of train behind the engine of 200 tons—at ten miles per hour. The greatest load that had been taken was twenty-one waggons, of a gross weight of 230 tons, at 5 miles per hour. The average ordinary train taken up the incline consisted of eighteen waggons, each weighing 8 to 11 tons gross; the total weight being, say 160 tons gross, at 10 miles per hour; but excursion trains of loaded carriages, weighing when empty 5½ tons each, and 7½ tons when loaded, making a gross load of, say 200 tons, had also been taken up. The resistance of the train indicated on the piston, after allowing for gravitation on the incline, amounted to 13 lb. per ton gross of engine, tender, and trains, which contrasted favourably with the estimated traction-resistance of 150 lb. per ton gross on the American incline.

With reference to the influence of curves upon resistance, it had been found that at a speed of 45 miles per hour the traction-resistance was greater by 20 per cent. on a line having curves under one mile radius, at the rate of one curve in 2½ miles, than on a practically straight line.

It was remarked, that the Whitstable branch of the South Eastern Railway, on which there was a gradient of 1 in 30, had originally been worked by stationary engines and rope traction; but as the traffic was intermittent, it had been determined some years ago to substitute locomotive power, and this application

Digitized by Google

had been quite successful. Bury's four-wheel coupled engines, having cylinders 14 inches in diameter, with a length of stroke of 24 inches, the wheels being 4 ft. 6 in. in diameter, were still in use on this branch. Four trucks of coal were taken up the incline of 1 in 30, the gross weight, including the engine and tender, being about 50 tons.

On the Folkestone branch of the same line, which had an inclination of 1 in 30 for upwards of three-quarters of a mile, four-wheel tank engines, constructed on Mr. Crampton's plan, were employed. The four wheels of 4½ feet diameter were all coupled; the cylinders were 16 inches diameter, with a length of stroke of 24 inches; the weight of the engine was 26½ tons, and the pressure of the steam was 120 lb. per square inch. These engines had taken up the incline a load of fourteen carriages, equal to a gross weight of 100 tons, including the engine.

It was believed, that the peculiar construction of the engines and carriages in the United States, tended to lessen the resistance of curves. It was well known, that in New York and in other American cities, the railways were brought into the streets, horse-power being then employed, and that the trains were conducted round the turnings of streets with great facility. As to the cost of construction of American railways, it appeared from official returns, which had been carefully compiled, that in the state of Massachusetts the cost of the principal lines had amounted to 10,599*l.* per mile, or 9489*l.* per mile exclusive of rolling stock. In the state of New York these figures were respectively 11,200*l.* and 9762*l.* per mile. It should be stated that a large proportion of the American railways consisted of single way, and that their cost ranged between 5000*l.* and 14,000*l.* per mile.

The Manchester, Sheffield, and Lincolnshire Railway, with a gradient of 1 in 130 for upwards of 22 miles, was mentioned as a case of a main trunk line, upon which there was a large traffic, necessitating the employment of heavy engines. Ordinary inside-cylinder engines were employed, the cylinders being 18 inches in diameter, with a length of stroke of 24 inches, the wheels being 5 feet in diameter, all coupled. They weighed, when in working order, 31 tons, were worked at a pressure of 130 lb. to the square inch, and would draw a load of forty waggons, weighing 130 tons, independent of the weight of the engine and tender.

The great feature in the paper under discussion was thought to consist in the statement, that two-fifths of the weight of the engine had been obtained as adhesive capability; whereas in this country one-fourth had been considered as much as could be relied on in all states of the rails. On the West Cornwal Railway, loads of about 13 tons had been conveyed up an incline of 1 in 13, for a distance of from a half to three-quarters of a mile. The engine had four wheels coupled, and cylinders 13 inches in diameter. This plan had been considered preferable to the employment of stationary power. On the South Devon line there were gradients varying from 1 in 41 to 1 in 51, with S curves of 15 chains radius. As a practical fact it might be recorded, that the engines would take seven loaded waggons up an incline of 1 in 41 on straight portions of the line, but when they came to curves of 15 chains radius, one of the waggons had to be removed.

It was stated, that on the Lickey incline of 1 in 37½, an engine had been allowed to attain a speed of 30 miles in descending, and it was then brought up in 30 seconds by the application of a peculiar kind of break to the wheels of the engines,

With regard to zigzag inclines for traversing mountains, it was stated that the late Mr. George Stephenson had suggested their adoption thirteen years ago on a line in Spain. Mr. Drane had also recommended that this method of crossing high mountains should be adopted in Ceylon. And more recently, as was well known, Mr. I. J. Berkley, M. Inst. C.E., had carried out the system successfully on the Great Indian Peninsula Railway, for ascending the Bhore Ghaut. It was thought that they were only desirable under special circumstances, and in peculiar positions where it was impossible to make a continuous line except at great cost, or by the introduction of excessively sharp curves.

Probably the steepest gradients in this country, over which a large traffic was conveyed, were on the line between Manchester and Oldham, a distance of 7 miles. For a mile and a quarter there was an inclination of 1 in 48 or 1 in 50. The line was then tolerably level, until on approaching Oldham, gradients of 1 in 30 and 1 in 39 were encountered; and for about a mile and a quarter 1 in 27. This latter incline had originally been worked by stationary power and rope traction; but about five years back the locomotive had been substituted, and no difficulty was found in taking up considerable loads.

In closing the discussion, the circumstances under which steep inclines could with propriety be adopted were considered, and it was remarked that as a mechanical question, there was no difficulty in apportioning the power of the engine to the amount of adhesion required to traverse a particular gradient. But inclines of 1 in 10 or 1 in 17, or even 1 in 40, would only be resorted to from necessity, as such gradients were attended with a heavy cost for working expenses. On a branch of the Stockton and Darlington Railway, where there was an exceptional gradient of 1 in 40, although the traffic was all down-hill, the whole of the receipts of that portion of the line, taken at one penny per ton per mile, were absorbed by the working expenses. If the loads had been up-hill, it was believed that the working expenses alone would have amounted to threepence per ton per mile, and with gradients of 1 in 17, it was thought that this must reach one shilling to eighteen-pence per ton per mile. In fact, it was questionable under such circumstances whether horse-power and carts would not beat the locomotive in point of economy, though of course on a long line of railway it would be most undesirable to introduce a break of guage. It was undoubtedly more economical to employ locomotive power on the Whitstable branch, where the amount of traffic was so inconsiderable; on the Oldham incline, the necessity of preserving an unbroken communication was a justification for the use of the locomotive, the cost of which in such a case must be considerable. On the incline of 1 in 26 near Liege, a perfect system of stationary engines had been in use for many years. The Belgian Government feeling the inconvenience of that system, had abandoned it, and substituted the locomotive; but such was the uncertainty of the power in meeting the inequalities of the incline, that the stationary engines had been again resorted to.

Dec. 7.—Joseph Locke, Esq., M.P., President, in the Chair.

The paper read was, "*A Description of a Breakwater at the Port of Blyth, and of certain Improvements in Breakwaters, applicable to Harbours of Refuge.*" By Mr. M. Scott, M.Inst.C.E.

This communication was divided into four parts, the first referring particularly to the breakwater at the port of Blyth, the second to the theory of waves, the third to the theory of hydraulic construction, including form and methods of building, and the fourth relating exclusively to the author's designs, including his assumed improvements in the construction of breakwaters, which had been suggested by his experience in connection with the work at Blyth.

The port of Blyth was described as being situated on the coast of Northumberland, about ten miles north of the river Tyne. The whole surrounding district was rich in coal, comprising a large virgin field of steam coal in the immediate vicinity. Until recently, a small class of vessels only could trade there, and a great part of the coal raised in the neighbourhood was transmitted by rail to the Tyne for shipment. But a few years ago a company was formed, and powers were obtained for improving the harbour; Mr. J. Abernethy, M. Inst. C.E., being appointed engineer-in-chief, and the author undertaking the construction of a portion of the works. This part of the coast was exposed to a very heavy sea, and gales sprung up with great suddenness. For the length of a mile, the river was exposed to the action of the sea, so that no vessel could then lie in what was now the harbour. Along the seaward side of the river there was a rocky reef, and upon the base thus provided by nature, the breakwater had been erected. The work was originally intended to be, and for a length of 1800 feet was constructed entirely of stone; but a failure in the supply of material induced a change. Mr. Abernethy proposed to employ timber and stone after the manner adopted at Boulogne and at Calais. These views had been carried out in a part of the breakwater which had been completed for some time, which consisted of a framework of timber filled with stone, arranged thus:—First, there was a sole piece resting on the ground. Under each end of the sole, there was placed a block of stone, to which it was fastended at one end by a bolt; the chief object of this bolt being to act as a guide in erecting the frames. Upon this sole were raised two uprights; the one next the sea being supported by a strut from the sole piece.

Digitized by Google

Cross bearers, or half-balks embracing the uprights, carried the roadway above, which was protected by a simple handrail. The frames thus formed, were placed at intervals of 10 feet from centre to centre, and were tied together longitudinally by wailings, two on the sea face and one on the river face, and also by the open planking; the space within which was filled with rubble stone. In the first section this space was triangular, the planking on the river face being on the strut. The object of this arrangement was partly to provide a sloping surface, and to leave the uprights on the river face isolated, opposite the entrance of the proposed docks, for the purpose of destroying as much as possible the swell which passed up the river. In the second section, the exposure and consequent strength required being greater, the planking was put upon the river upright, and the whole space between was filled with rubble, covered with an open flooring of horizontal timbers. The work had added more than 4000 feet in length of the river to the harbour, where there was still water; it not only effectually broke the waves, but acted as a training wall to direct the current, and to confine and intensify within the new limits the action of the tidal scour. The cost of the work had been, on an average, about 10*l.* per lineal foot. The site of this pier was either dry, or nearly so, at low-water spring tides; but as it was to be continued into a depth of 5 or 6 feet at the lowest ebbs, and about 22 feet at high-water of spring tides, it was necessary to modify the plan; and as early as January 1857, the author succeeded in the application of timber to deep-water sections, in the manner hereafter described.

Under the head Theory of Waves, the author availed himself of the labours of Messrs. Scott Russell, Airey, Robertson, and others. He called attention to the two kinds of waves—the one long, low, but extending deep, which was the wave of translation, or wave of the first order; the other kind short, high, and superficial, being the wave of oscillation, or wave of the second order,—and laid down certain principles belonging to each class. He concluded this section by remarking, that if a wave in deep water, when the mass was great and the velocity of the particles small, travelled into shallow water, the quantity agitated was less, but the energy of the motion was increased. Therefore, *cæteris paribus*, the destructive energy was less against the wall vertical from the bottom, than against a wall built with a slope. When the foreshore caused a wave to break upon the wall the destructive effect was greatest. Waves would be broken by any slope having an inclination of less than 45°, but from that angle to the perpendicular, the wave would not be broken, unless it was nearly upon the point of breaking when it reached the slope.

In the third part, under the head Theory of Work, including the theories of form and of construction, the published views of General Sir Harry Jones, Sir William Denison, Prof. Airey, Captain Vetch, &c., were freely made use of; and it was remarked, that when waves could be reflected they ought not to be broken, and that when, from shallowness of water, the wave must break, the operation should be spread over the largest surface, and over the longest time possible. It was desirable, if practicable, so to direct the water, that the force of one portion should tend to neutralise the destructive energy of another portion; it being better to effect the object of stilling the water, by changing the direction, than by absorbing the force of the water in motion. The first condition would be fulfilled by a vertical wall, and the second by a slope. The third was more difficult of attainment. Under the term vertical wall might be included steep slopes, say from 60° upwards. It was thought, that as the vertical face in deep water did reflect waves, the seaward face of breakwaters, especially near the entrance to a harbour, should be built nearly vertical; for should it be a slope, the risk to a vessel approaching the entrance would be increased. With regard to the inner, or harbour side of the breakwater, it was obvious that a vertical face was the best; inasmuch as the work then constituted a valuable quay, alongside which ships might lie to load and unload passengers, cargo, or stores, whereas in the case of a slope, no vessel could approach. With regard to slopes the author considered the true principle to be, that they should be employed only for the purpose of directing or guiding the waves to neutralise one another. This he sought to effect, at least to some extent thus: first, the slope formed of timber was not to join the ground at the foot; there was to be no toe to be injured, but a space through which the water would freely pass. Secondly, the surface of the slope, instead of being continuous, was to have horizontal open spaces, like a gridiron, through which part of the water would fall in its passage upwards, and part on its recession.

The combination of vertical wall and slope, as carried out at Alderney, at Holyhead, and at Portland, was then alluded to, and it was believed that as, even during a very heavy sea, there was but little agitation at the depth of 15 feet under the surface, this section would present nearly, if not all, the advantages of a vertical wall carried up from the bottom of the sea. The quantity of stone used in these works was however very great, so that there were many situations where that method of construction would be inapplicable. There were other disadvantages attaching to this form. First, these breakwaters were not available as quays. Secondly, the seaward profile was such, that the waves must break upon the wall with all their violence, and hence the weight of material and the nature of the work necessary to resist such a shock were no criterion of that required in a vertical face, from which the waves were reflected, and against which they did not break.

The subject was next investigated under the head Theory of Construction—Stone-work, and it was argued that the faces of works exposed to the sea should either have their joints sealed, to prevent the entrance of air, or the work should be so open as to allow the air to pass out with facility. Continuity of face was most important in breakwaters, particularly with vertical faces, for without this the strength of the work, as a whole, would be dependent upon, and be measured by, the power of resistance of the weakest part. Hence arose the necessity of exercising great care during the construction, as the displacement of a single stone might lead to the destruction of the whole work. The author knew of no case on record of a breakwater being carried away or being overturned bodily; and therefore the question was not so much the strength as a whole, which could readily be calculated, but the action of the sea upon an individual portion, which could not be calculated. And if this obtained as regarded the finished work, for the same reasons the danger during the process of construction must be great, especially in the case of a vertical wall.

The fourth section of the Paper was occupied with a description of the author's improvements in the construction of breakwaters. He divided these works into two classes—those intended for deep water being wave reflectors, and those for shallow water being wave breakers. Excepting what was called the wave screen, the reflectors and breakwaters were of a similar character, consisting of a timber casing filled with stone. The stone hearting constituted the power to resist removal as a whole, and the timber facing secured the stone from being disintegrated or carried away in detail, so that if the work was moved it must be bodily. Further, the work was so connected together that each part supported its neighbouring portions;—and there was no tie between the work and the ground. It simply rested on the surface, and the stability depended wholly upon its weight. Other leading features of this arrangement were then noticed, and it was stated that the lower tie would accommodate itself so perfectly to an uneven surface, that the erection might proceed on sand and clay, as well as on rock—on broken as well as on even ground, almost indifferently. The manner in which the round ends at the entrances to harbours were constructed was then described; and it was shown that the planking was arranged like basket work, by which both strength and elasticity were obtained. It was said that the work was not liable to be breached during erection, and that this had been proved at Blyth, where the stone wall had been repeatedly damaged; but the new construction had remained uninjured, although exposed to heavier seas. The frames were put together complete on shore, and were then floated to their place; and it was remarked that the 9 or 10 lb. of oil per cubic foot used in preserving the timber, materially reduced the floating power; so that it was found by calculation for a depth of 10 fathoms, supposing the whole of the timber to be immersed, the total buoyancy would only be 15 cwt. per foot run; but as the timber was not wholly immersed, there was no buoyancy. At half-tide, when standing on end, each frame would have a weight or downward pressure equal to 8 cwt. to sink it. The timber work when finished would have a downward pressure of 25 cwt. per foot run. Thus, it appeared that the weight to be lifted was but little, and that the frame in position could easily be made to gravitate sufficiently to steady itself until secured. In the direction of the length of the breakwater, the frames were kept parallel by sliding ties, which were simply balks of timber with chocks between them, embracing two frames, and being secured together above water, they were slid down to the bottom. Various other details were

Digitized by Google

then given of the mode of carrying on the work under this arrangement, and it was remarked, that the systems pursued at Dover, Alderney, Portland, and Holyhead, did not appear to secure rapid execution; whilst, in illustration of what could be done by this plan, although of course on a comparatively small scale, it was mentioned, that of the work at Blyth 130 lineal feet had been erected in five days.

With regard to the power of the work to resist waves, it was stated that, in the section for a depth of 10 fathoms, the stability was double the greatest force which could be brought to bear upon it. To afford protection to the footings of a wall, or to the toe of a slope of stone in the recoil of breaking waves, a screen had been designed, the construction of which was explained.

In reference to the questions of durability and cost, the author was of opinion that properly prepared timber would last twenty years, and that the section of a depth of 10 fathoms would cost completed about 70*l.* per lineal foot; whereas the stone breakwater at Alderney was said to have cost 190*l.* per foot, and that at Portland 150*l.* per foot. This difference in first cost was so great as to leave, it was considered, an ample margin for the renewal of the timber when it decayed. The manner in which this renewal might be effected was then described.

Finally, it was shown that even if the new arrangements were regarded merely as a means for forming the backbone, as it were, of a more permanent structure, it was the best and cheapest way of attaining the object desired; for viewing the timber only in the light of a temporary staging, the following were some of the advantages claimed for the system—rapidity of execution; a good staging from which to build the stone facing; and the rubble hearting, having been exposed to the sea for years, would be thoroughly consolidated, and form an impenetrable backing.

The author then proceeded to describe the method proposed for completing one form of the permanent work. There were some peculiarities in the mode of setting the face blocks, the objects in view being mainly two; first, for affording increased facilities for handling heavy masses, and secondly, to place within easy reach of the divers, the means of moving the stone in every direction, without the necessity of communicating with anyone above water. This was effected by a system of hydraulic and other machinery, which was then described in detail, for moving masses weighing 25 tons each in six different directions, either down, up, forwards, backwards, to the right, or to the left.

In commencing the discussion, some extracts were given from the Report of the Select Committee on Harbours of Refuge; the tenor of these observations was, that of the three modes of construction of piers brought before the committee, that of tipping the material as "pierre perdue" was that most generally employed, and had hitherto proved most successful. From these passages it appeared, that the general opinion was not favourable to the building of nearly upright walls for piers projected into the sea. It was however contended, from the experience of some years at the Harbour of Refuge works at Dover, that by the use of improved machinery, and by the employment of helmet-divers instead of men in diving-bells, large block work could be accomplished almost as easily, and nearly as quickly, as above the water line.

The machinery for the proposed modification of the present system, was described to be,—having a powerful stage consisting of trestles, as at Dover, or by substituting for timber, cast or wrought iron tubular uprights, with the upper extremities made to slide in order to level the stage in case of the subsidence of the feet. Trussed beams supported the rails for the travellers carrying the steam boiler and engine, with the air pumps for supplying the divers: and for lifting and laying the blocks, to which it was proposed to give very much increased dimensions, such as 15 feet long by 10 feet wide and 6 ft. 8 in. deep; which, if made of brick and cement, would weigh about 50 tons. It was contended that two thousand of these blocks could be laid during each year; and an advance forward of 900 feet per annum of a pier whose total sectional area was 3082 superficial feet; and this with brick and cement blocks at a cost of about 180*l.* per foot lineal; if of rubble stone blocks and cement about 110*l.*; and if of concrete about 101*l.*

If smaller blocks were used, the plant and machinery might be reduced in bulk and cost, and even still greater progress might be made; an instance of this was given by allusion to the pier now being constructed in Rye Bay, of concrete blocks weighing 10 tons each; up to the present time, it had perfectly resisted storms from the south-west, to which it was much exposed.

The further consideration of this subject was then adjourned until the evening of Tuesday, January 11, 1858, when it was hoped the members and visitors would come prepared to discuss this interesting question.

After the meeting, Mr. C. Defries exhibited and explained some specimens of his Improved Railway Carriage Roof Lamps.

Three objects were sought to be accomplished in these lamps. First, by admitting cold air into the burner, thus preventing the oil from boiling, the overflowing of the oil in the glass, so common in other lamps, was prevented. Secondly, a simple method of fixing the glass was adopted, so that by having a stock of glasses at different stations, a broken one might easily be replaced; instead of, as at present, it being necessary to send the damaged lamp to the repairing shops in order that a new glass might be soldered in. Thus a much smaller stock of lamps would be required, and less expense would be incurred for repairs; in addition to which, the chance of breakage in the transit from the stores, would be entirely removed. Thirdly, the interior of each lamp was made in one piece, instead of three or four pieces, as customary. This tended to increase the light, which was remarkably clear and brilliant.

Annual General Meeting.

Dec. 14.—The Report of the Council for the past Session, which was read, commenced by regretting that there had not been a general resumption of works of public utility and of private enterprise in the United Kingdom; a large proportion of the professional engagements being still in foreign countries, or in the British colonies. In India the suspended works upon the different railways had been resumed, and it was fair to conclude would now be pushed forward with vigour. On the continent but little progress had been made, except in the construction of branch lines. The opening of the Caen and Cherbourg Railway, constructed by Mr. Brassey (Assoc. Inst. C.E.), was mentioned, as on that occasion Mr. Locke, M.P., the President of the Institution, who was the engineer-in-chief of the line, had been raised to the grade of Officer of the Legion of Honour. The line traversed a rich and fertile district, inhabited by an enterprising and industrious race; the total length was 225 miles, and the works comprised about 4500 yards of tunnelling, seventy bridges across rivers, and three hundred and ten road bridges.

The various Spanish railways in operation, or in progress of construction, were then noticed; and it was stated, that in Austria, the Lombardo-Venetian Company, under the able direction of M. Paulin Talabot, had united the majority of the principal lines, with a view to the ultimate formation of one comprehensive system, which would be one of the most considerable in Europe, as it would consist of nearly 1900 miles of railway, connecting Austria, Hungary, and Southern Germany with Trieste and Italy, and extending in an unbroken line from Vienna to Milan, and from the Bavarian frontier to Florence.

In Piedmont, where railways were so early introduced, but little had been done for some time past, beyond completing to the foot of the mountains on either side the Victor Emanuel line, and commencing the herculean task of tunnelling through the Alps. Meanwhile, it was proposed to construct a line of railway along the Cornice road, bordering the Mediterranean, from Nice to join the railway at Voltri and thence to Genoa; for the accommodation of the traffic between France and Piedmont until the Alpine tunnel should be completed. In Portugal arrangements had been made, under the direction of Mr. Fowler (M. Inst. C.E.), by Sir Morton Peto, Bart. (Assoc. Inst. C.E.), for the immediate construction of a main line from Lisbon through Coimbra to Oporto. In Russia, the engineers of the Credit Mobilier of France were pushing forward the vast network of lines comprehended within their scheme; and on the Riga and Dunaburg line, under Mr. Hawkshaw, V.P. Inst. C.E., rapid progress was making by Mr. T. Jackson, the contractor. In the East, the Ottoman railway between Smyrna and Aidin, under the direction of Mr. Edwin Clark (M. Inst. C.E) and Mr. Meredith (M. Inst. C.E.), the consulting and the resident engineers, was being vigorously proceeded with; whilst the line from Cairo to Suez had just been completed by M. Mouchelet.

In the Southern Hemisphere the colony of Victoria might be referred to as making great advances in engineering works. Un-

Digitized by Google

dertakings of considerable magnitude had been designed, some were in progress, and a few were completed. The most prominent of these were macadamised roads, railways, water-works, shipping wharves, piers, and slips for heaving ships out of the water. The railway from Yarra Yarra Bridge to Sandhurst, with a deep water pier in Hobson's Bay for ships of 500 tons burden, was completed and in full activity; although as costly, mile for mile, as the London and Greenwich railway, it yielded a profit on the capital of 10 per cent. per annum. From this line a branch had been opened to St. Kilda, which was found to be of great convenience to the suburban and residential traffic, and a prolongation was about to be made to the Sandhurst railway. The Geelong railway had been opened to Williamstown, and had only been delayed from reaching Melbourne by the non-completion of the Government line to Williamstown. The Government lines required to maintain the intercourse with the distant parts of the colony were in progress, large contracts having already been let. The Yan Yean Waterworks for supplying the town of Melbourne were finished; the water was collected in artificial reservoirs, and was conveyed through a system of pipes 40 miles in length to the town. As the town was not subdrained, the disposal of the waste water was even now a serious question, there being only 4 feet tide in the Yarra-Yarra River, which drained into Hobson's Bay an almost tideless lake. At some future, and probably not very distant period, this would render the question of dealing with the sewerage as difficult as that of London. The deep-water piers and slips at Williamstown were in an advanced state of completion, and would be useful auxiliaries to the commercial marine resorting to Hobson's Bay. The system of macadamized roads leading from Melbourne to Maryborough, Sandhurst, Castlemaine, Ballarat, and other important places, had been completed in many cases under very difficult circumstances, but were now so efficient that travelling was almost as rapid and convenient as on the English roads, before the introduction of railways.

In reference to telegraph matters, it was stated, that the attempt to lay the cable between Candia and Alexandria had for the present proved abortive, in consequence of a severe gale, which rendered it necessary to cut the cable and to buoy it when 228 miles had been payed out in a depth of 1400 fathoms. This proceeding was so successful that the cable was fished up on the subsiding of the gale; but the insulation being apparently injured it was not considered advisable to continue the operations during the present advanced season. Candia, Syra, Chio, and Cape Hellas were, however, successfully connected by submarine cables under the superintendence of Mr. Liddell. Another attempt had been made to establish submarine communication between this country and the United States. The English and American steam-ships, with their respective portions of the cable, commenced paying out about mid-channel, and, after some casualties, the shore-ends were landed; but unfortunately the insulation proved so defective, that no intelligible messages could now be transmitted, and, on account of the advanced state of the season, all further attempts to remedy any defects were adjourned. The cable lost in 1855, and a portion of that lost in 1856, off Cape Spartiventi, Sardinia, had been recovered by Mr. Liddell and Mr. F. C. Webb (Assoc. Inst. C.E.) The Channel Islands were now put into telegraphic communication with the English coast, by means of cables laid by Messrs. Newall and Co., from Portland to Alderney, and thence to Guernsey and to Jersey. A cable with four wires was laid down by Messrs. Glass, Elliot, and Co., from Dunwich to Zandvort, but the communication through it had been delayed by an accident, which occurred whilst endeavouring to repair one of the wires;—and a cable with two wires had been successfully laid from the English coast to Emden, likewise by Messrs. Glass, Elliot, and Co.

At home an important feature in the railway extensions in the vicinity of the metropolis was the Victoria Station, Grosvenor-basin, Pimlico, under Mr. Fowler (M. Inst. C.E.) This site was peculiarly fitted for a railway, as from the previous formation of the roads and bridges, the levels of the rails could be so arranged as to avoid interference by inclined approaches with the adjoining streets or properties, whilst affording extensive frontage upon wide streets at present not encumbered with traffic. The works, including a bridge across the Thames, consisting of four arched spans of wrought-iron of 175 feet each, were now in progress.

One of the important hydraulic innovations of the past year had been the new mode of lifting ships, introduced by Mr. Edwin Clark (M. Inst. C.E.), and which had been successfully applied at the Victoria (London) Docks. The apparatus consisted of thirty-two hydraulic presses with cross-heads and suspension links, similar to those used in lifting the tubular girders of the Britannia Bridge. These presses were arranged in two parallel rows, leaving between them a space to receive a gridiron 320 feet long and 60 feet wide, in a depth of water of 27 feet. By an ingenious arrangement the presses were enabled to act in three separate groups, so as either to act simultaneously upon the gridiron, or to lift one or more points; in order, if necessary, to give a certain extent of inclination to the body which was lifted. It was stated that the original cost of a system of docks of this description would only be about one-fifth of that of ordinary graving docks; the operations of lifting and lowering were very rapid, a vessel of 1000 tons burthen only occupying the docks for about thirty-five minutes; and the facility for making the repairs was very great.

In supplying towns with water the only important work of the past year was at the South Staffordshire Waterworks. The object of this undertaking was to supply the towns and districts of Lichfield, Walsall, Wednesbury, Westbromwich, Tipton, and Dudley, where hitherto there had been a serious dearth of good water. The spot selected by Mr. J. R. McClean (V.P. Inst. C.E.) for establishing the pumping engines was at Lichfield, where (in addition to a large surface supply taken above the contamination of any sewage) by sinking down to the sandstone-rock, and driving a tunnel upwards of a mile in length, an unlimited quantity of pure soft water was obtained. This was raised by a pair of James Watt and Co.'s powerful pumping engines, and forced through a 2-feet main of cast-iron pipes to a single standpipe at Brownhills, whence the water proceeded by gravitation through the remainder of the main, 22 inches diameter, which was laid for a distance of nearly 14 miles, chiefly alongside the rails of the South Staffordshire Railway to the reservoirs of Walsall, Wednesbury, and Westbromwich, situated at the respective heights of 180 feet, 240 feet, and 260 feet above the main at the engines. The total contents of the storage reservoirs was 90,000,000 gallons. The ultimate length of the main pipe would be upwards of 25 miles, and it was given as a remarkable instance of care on the part of the Messrs. Cochrane and Co., the iron-founders, and Mr. Aird, the contractor for laying them, that out of seven thousand pipes only two should have exhibited any defect when laid, and these defects were each remedied within an hour.

The principal papers read during the session were then noticed; and it was remarked that, as usual, the discussions occupied a longer time than the reading of the papers, and would be found to add greatly to the interest of the Minutes of Proceedings.

The members were strongly urged to continue to present copies of scientific and professional works for the library, without which its utility for reference and consultation could not be maintained.

Special attention was directed to a very interesting series of photographs of some important structures in the City of Washington, U.S. America, now in progress or recently completed under the direction of Captain Montgomery Meigs, U.S. Engineers, by whom the views were presented to the institution.

The Washington Aqueduct, the most important, though not the most costly of these works, was intended to supply the city of Washington with water from the great falls of the Potomac. The source was 150 feet above the tide. The aqueduct was a circular conduit, generally built of rubble masonry laid in hydraulic cement. The diameter was 9 feet in the clear; the masonry being 14 inches in thickness. Its fall was 9 inches in 5000 feet, and its discharge at 8 feet depth of water was 67,596,000 American standard gallons in twenty-four hours. The lowest discharge of the river in summer droughts was 63,000 cubic feet per minute; at its highest it was a flood like Niagara. There were eleven tunnels upon the line, of which two only were incomplete. Of the 12 miles of conduit about half a mile remained to be executed. There were several bridges of masonry, including one elliptical arch of 75 feet span, and one single granite arch, segmental in form, of 224 feet span, crossing a ravine 100 feet deep, with rock abutments. A bridge of 200 feet span of iron crossed the creeks between Washington and Georgetown; the iron pipes, 48 inches in diameter, doing duty as arched ribs to support the bridge, and also as mains to convey the water under pressure. They were lined with staves of wood as a protection against frost. The reservoirs had a collective area of about 90 acres of water, and stored up many days' supply. The work was completed except the dam, the second reservoir, the larger bridges, and two tunnels, one of which would be finished during this winter, and the other in July next. The bridges would pro-

Digitized by Google

bably be all completed by the 1st of August, 1859. The estimated original cost of the 7-feet conduit was 1,921,000 dollars; of the 9-feet conduit, 2,300,000 dollars; and the probable cost when finished was estimated at 2,550,000 dollars. The masonry aqueduct was 12 miles long. The pipes to be laid by the Government to the public buildings, navy yards, &c., would cost about 400,000 dollars.

The Capitol of the United States was a building 750 feet in length and 70 feet in height. The centre was looked upon in America as an old building, having been built about thirty years. It was of sandstone. The wings upon which Captain Meigs was now engaged were faced with blocks of white marble, and slightly veined with blue, but not sufficiently coloured to affect the appearance at a short distance. In this building were the Halls of Congress. The Hall of Representatives in the south wing was 139 feet long, 93 feet wide, and 36 feet high. In it the voice of any ordinary speaker was said to be audible, without effort, in every part of the room, and this without regard to the place from which the orator addressed the audience. Its ventilation was satisfactory, and throughout the variable winter there were no complaints of too much cold. The north wing would be occupied this winter. The porticoes yet remained to be erected. The centre building was crowned by a dome, partly of brick and partly of wood, modelled after that of the Pantheon at Rome. The portico of this building was also a copy from the Pantheon, but raised upon a basement with a noble flight of steps in front. The old dome had been removed, and some progress had been made in erecting the new one, which was of iron, 300 feet in height; the diameter of the peristyle being 124 ft. 6 in. The cost of the old building of the Capitol was about 3,000,000 dollars; the new wings would cost between 5,000,000 and 6,000,000 dollars, and the dome nearly 1,000,000 dollars.

The Post-office building was of white marble. The columns were monolithic, from Carrara. The rest of the marble was similar to that in use at the Capitol.

The Washington Aqueduct was entirely under the direction of Captain Meigs, but in the architecture of the Capitol and the Post-office buildings he had the aid of Mr. Thomas U. Walter, who had been associated with him since he took charge of these two buildings. In the heating and ventilating of this building he had the assistance of Mr. Joseph Nason. The works involved a total expenditure of nearly 10,000,000 of dollars. They were now drawing towards completion. The buildings were occupied; the porticoes and the dome remaining unfinished, and some interior decorations were still in progress.

The deceases of the members during the year were announced to have been:—Rear-Admiral Sir F. Beaufort, honorary member; Messrs. R. Garrett, A. Grève, R. Hopkins, A. S. Jee, H. F. Mackworth, and J. Seaward, members; and Sir G. Cayley, Bart., and Messrs. T. W. B. Blakemore, M.P., and J. Hodgson, associates. The memoirs of these gentlemen were given in the appendix to the report. The resignations of four associates were announced, and it was stated that the effective increase during the year (after deducting the deceases and resignations), amounted to 22, whilst the total number on the books was 857 members of all classes.

The statement of the receipts and expenditure showed an increase of receipts and a diminished expenditure, and that there was a balance of upwards of 1000*l.* in the hands of the treasurer. The financial position was in every respect so satisfactory that the council intended to apply a portion of the surplus funds to the improvement and extension of the library.

During the year the second part of volume vii., and the whole of volume xvi. of the Minutes of Proceedings had been published and issued. There now only remained to complete the series of seventeen volumes, extending over twenty-one years, the second part of volume viii. and volume xvii. for the past session, both of which were nearly ready for issue.

The report concluded by congratulating the members on the general satisfactory state of the institution, which to some few still among them had been from its humble beginning in 1818 an object of solicitude. Ample funds, volumes of proceedings printed rapidly, well attended meetings, and crowded *conversazioni*, were the outward signs of prosperity, but they also indicated the greater necessity for increased exertions on the part of all who would insure the permanent prosperity of an institution which had done so much good, and might still continue to be so useful if it was adequately supported by the members of a profession which took no mean part in the labours of the present century.

After the reading of the report, Telford medals were presented to Messrs. J. A. Longridge, G. Robertson, J. Henderson, R. J. Hood, Maj.-Gen. G. B. Tremenheere, and A. Giles; Watt medals to Messrs. G. L. Molesworth and T. S. Sawyer; council premiums of books to Messrs. C. H. Brooks, F. C. Webb, S. A. Varley, R. C. Despard, A. Wright, and J. Brunlees; and the Manby premium in books to Mr. G. L. Molesworth.

The thanks of the institution were unanimously voted to the President for his attention to the duties of his office; to the Vice-presidents and other members and associates of council for their co-operation with the President, and constant attendance at the meetings; to Mr. C. Manby, secretary, and to Mr. Forrest, assistant secretary, for the manner in which they had performed the duties of their offices; as also to the auditors of the accounts and the scrutineers of the ballot for their serviees.

The following gentlemen were elected to fill the several offices on the council for the ensuing year:—Joseph Locke, M.P., President; G. P. Bidder, I. K. Brunel, J. Hawkshaw, and J. R. McClean, Vice-Presidents; W. G. Armstrong, J. Cubitt, J. E. Errington, J. Fowler, C. H. Gregory, T. E. Harrison, T. Hawksley, G. W. Hemans, J. S. Russell, and J. Whitworth, members; and J. A. Ransome and A. Slate, associates.

INSTITUTION OF CIVIL ENGINEERS OF IRELAND.

An ordinary general meeting of this institution was held on the 14th inst. at Dublin. Mr. M. B. Mullins, President, in the chair.

The paper read was on "Beams and Girder Bridges," by William Anderson, associate, being in continuation of former communications on the same subject. Having in them shown the manner in which the strains in the several parts of uniformly loaded beams were determined, he now concluded the theoretical part of his subject by considering the effect of passing loads. The analytical investigations were illustrated by numerous coloured diagrams, and many of the propositions were proved by means of an accurately constructed model of a lattice beam, the property of Trinity College, Dublin, and lent by Professor Downing for the occasion, the several bars composing it being replaceable at will by spring balances. The theoretical deductions received the most direct proof of experiment. The paper concluded by a recapitulation of the conclusions which had been established.

REVIEWS.

On Telegraphic Cables. Excerpt Minutes of the Proceedings of the Institution of Civil Engineers. Vol. XVII. 8vo. 1858.

On the Mechanical Conditions of the Deposit of a Submarine Cable. By G. B. Airy, Astronomer Royal. 'Philosophical Magazine,' July 1858.

On the Atlantic Cable. By William Gravatt, F.R.S. 'Philosophical Magazine,' July 1858.

Several papers were read in the course of the past year on the subject of Submarine Cables at the Institution of Civil Engineers, of which abstracts appeared in due course in this *Journal*. These papers are now published, by the authority of the Institution, in a collected form, together with notes of the discussions which followed them.

The first of the papers in the volume before us has been rewarded by the Institution by a medal and prize, and is entitled —"On Submerging Telegraphic Cables. By James Atkinson Longridge, M. Inst. C. E., and Charles Henry Brooks." It is to this paper in connection with the engineering questions connected with submarine telegraphy that we shall at present confine our attention. The authors propose to solve several problems of the highest interest and importance to the telegraphic engineer, and investigate, among other things, the tension of the cable, the effect of paying it out at a velocity greater than that of the ship, the effect of currents, and the effect of the vessel pitching in a heavy sea. The paper is accompanied by tables showing numerically the principal results of the mathematical formulæ which are separately investigated in the appendix. Of course reliable formulæ relating to the subject mentioned would be of great value to the engineer, but it may be added that, as the theory

Digitized by Google

of those subjects is comparatively new, no results ought to be adopted without strict scrutiny of the steps of the investigation by which they are arrived at.

Great discrepancies exist among the theories hitherto published. Many of them, including some read at the British Association, and noticed by Messrs. Longridge and Brooks, are so obviously the production of persons who have not the requisite knowledge of dynamics as to be undeserving of serious attention. We observe also a wide divergence between the results expressed in the paper just mentioned and those of the Astronomer Royal, who has also investigated the problem of the sinking cable. In the discussion at the Institution of Civil Engineers, recorded in the volume before us, Prof. Airy expressed (p. 80) his dissent from the principal conclusions of Messrs. Longridge and Brooks. Of course the weight of the authority of the Astronomer Royal should prevail only so far as to occasion inquiry and scrutiny; but the question is not one to be settled by reference to authority, nor is it one even of opinion in the usual sense of the word. A person thoroughly acquainted with the principles and process of a mathematical investigation does not form an opinion of its accuracy; when he has mastered the steps of the reasoning he knows it to be either true or false.

Undoubtedly, the most important problem in the first paper before us, and that on which its conclusions mainly depend, is the Problem 3, on "The general equation to the curve assumed by the sinking cable." The following are the forces taken into account:—1, the weight of the cable in water; 2, the tension acting in the direction of the curve; 3, the tension at the bottom acting horizontally; 4, the resistance of the water; 5, the friction of the water on the cable. The fourth force (the resistance of the water) is assumed to act "at every point of the cable in a direction bisecting the angle formed at that point by the cable and the horizon," that point in the cable being assumed to move in the same direction. This is stated to be the necessary condition in order that the cable may be laid in a straight line without tension. It is however no more than a very inartificial way of stating that the velocity of paying out the cable is equal to the horizontal velocity of the vessel; which is obviously the only case in which the cable could be laid without coils and without tension at the bottom of the sea.

The authors assume also that the curve is invariable in form, and moves uniformly parallel to itself. It is stated that the mode of considering the problem thus adopted "enables it to be treated *statically* as regards the form of the curve."

Here we arrive at the first point on which we have to express our dissent. Assuming everything that the authors have assumed, we consider that nevertheless the problem ought not to be treated statically. There are dynamical considerations which cannot properly be overlooked in discussing the form of the curve. We object to the expression "centrifugal force,' for many reasons, but we do not know any way of briefly stating the nature of the error which arises from treating the problem statically, than by saying that the authors have neglected the effect of centrifugal force. To speak more precisely, the nature of the error may be explained as follows:—Each particle of the cable moves in a curve, and by a known proposition in dynamics the sum of the external forces resolved along the normal to the curve is equal to the quantity usually called the centrifugal force *i.e.* the *vis viva* of the particle divided by the radius of curvature of the curve. Now, this centrifugal force the authors have neglected, and have in effect treated the sum of the normal forces as zero. This error, if there were no other, would in our opinion deprive their investigation of the value of an accurate demonstration.

The next point on which we differ from the authors of the problem in question is one not of a mechanical, but of a purely analytical nature. By a process needlessly complex they arrive at certain differential equations, numbered (3) and (4), involving the tension (t) at any point of the curve, the corresponding length of it, the angle (A) at which its tangent at that point is inclined to the horizon, and the coefficients of resistance and friction. Eliminating t between these two equations, a differential equation to the curve is obtained. It is clear that in this equation A must be a variable. But in integrating it A is treated as a constant. It need scarcely be added that the result obtained is erroneous.

One particular case of this result deserves attention as being that assumed in most of the other investigations of this paper, viz., that when a cable is laid without tension at the bottom, it will descend *in a straight line*. Now, the cable may possibly assume this form, but will not generally do so; in technical language the equation to a straight line is a singular (or particular) and not a complete solution. The case in which the form of the descending cable would be a straight line is obviously this—where the resistance perpendicular to that line is equal to the effect of gravity resolved perpendicularly to that line. Such a case might happen, because whatever the weight of the cable, the resistance may be varied to any extent by varying the velocity of the vessel. In such a case there would be no deflecting forces, but in all others there would be, and the form of the cable would therefore be a curve.

Before leaving this subject we may remark that the conclusion arrived at by the authors in Problem 3, is directly opposed to the conclusion at page 9 of their paper; for there it is stated that "there is no reason *à priori* for concluding that the line of the cable is straight. Indeed, a little consideration leads to an opposite conclusion." The argument which follows is a strange jumble of statical and dynamical ideas, which we do not propose to analyse, but merely notice the discordance between the paper and its appendix, as an illustration of the evils of joint authorship.

In Problem 4, the object proposed is to ascertain "what are the relative velocities of the cable and of the paying-out vessel requisite to reduce the strain or tension to any given amount, and what will be the consequent waste of the cable." Here again, as it seems to us, an error occurs which entirely vitiates the conclusions arrived at. At page 36 it is assumed that when the velocities of the ship and the cable differ, the friction along the cable varies as the square of the velocity of the ship only. But it is clear that the friction depends on the velocity of the cable also; it is the *relative* velocity with which the cable passes through the water which determines the friction.

We have found it convenient and conducive to perspicuity to arrange our remarks in an order not corresponding to the order in which the problems occur in the paper under review, and to examine first the problem which is most important. We proceed now to consider Problem 2, which is founded on the consideration that "if a rod of any material heavier than water is placed in water in an inclined position, it will be found on letting it go that it does not sink vertically, but moves diagonally downwards to the lower side. In fact it runs down an inclined plane between the vertical and its own direction" (p. 6). Certain equations for the motion of such a body are then given. They suppose the body to be a small plane disk not subject to any forces but gravity and the action of the water. They suppose further, that if the body be placed obliquely in water it will descend, moving parallel to itself, and every part of it moving with uniform velocity in a straight line. But the two suppositions are inconsistent with each other, for if the body be subject to no forces but those mentioned, it will rotate, the velocities will not be uniform, and the path of its centre of gravity will be curvilinear. The uniform rectilinear motion assumed in the equations of Problem 2 can only occur when the motion is constrained; and the omission of the constraining forces vitiates the equations and all the deductions from them.

In a corollary to this problem it is attempted to show what will be "the waste of cable when it runs out at a given angle (α) free from tension;" that is, the motion of a small inflexible disk is assimilated to that of a long flexible cable. Of course the equations for the motion of the disk (even if they were correct) would not represent the real motion of the cable, for the several parts of the cable influence each other's motion by their mutual tensions. If it be replied that the corollary is limited to a cable "free from tension," the rejoinder is that such a cable is a pure abstraction. To suppose the telegraph cable to descend free from tension is simply absurd; and we have no hesitation in saying, that the tables given at page 7, showing, in the cases of the "Atlantic cable" and a "light cable," the waste per cent. of cable paid out, are not entitled to the least reliance.

The fifth subject of the paper before us is entitled, "What is the effect of currents and the consequent waste of cable," and relates to Problem 6, "the equation to the curve assumed by a flexible line stretched across a current." In this problem the effect of gravity is omitted, and, if we rightly understand it, the cable is supposed to be lying in a horizontal plane. But it is not explained how the result of such a problem can be applied to the case of a cable acted on by gravity, and descending. If such a cable be acted on by currents transverse to the plane of the ship's

Digitized by Google

motion, the curve will be of double curvature, and a mode of investigation altogether different from that of Problem 6 must be adopted. Some connection seems to be assumed between the form of the curve when the forces are all in one plane, and its form when there are forces acting in more than one plane. But though it is found that the curve of a cable acted on by a current but not by gravity is a common catenary, it does not follow that any relation to the common catenary remains when gravity acts. For instance, it does not follow that the horizontal projection of the curve of double curvature just mentioned is a common catenary. Some curious remarks on this problem are given at page 17, of which the only one of which the meaning is plain, is erroneous. It is said of the form of the cable acted on by a current that "if it is not a straight line, but a curve, it must be a catenary, but it cannot be a catenary without tension at the bottom, consequently the line is not a catenary, but a straight line." It is not correct to say that a catenary cannot exist without tension at the bottom, for by a proper disposition of forces a cable may be made to assume any form whatever, and to be without tension at any assigned point. In Problem 8 the object proposed is to find the form the cable will assume, and the tension, in case the paying-out vessel and the paying out should be suddenly stopped." Here as in a former case, there is an attempt to solve a dynamical problem by reference to purely statical considerations. It is said that immediately on the stopping taking place the curve will begin to rise, and "to assume a catenarian form." What is meant by, beginning to assume a catenarian form? The tension and curve are computed just as if there were equilibrium, but the tension arising from sudden stoppage of motion is obviously very different from a mere statical strain. On the sudden stoppage of the vessel and paying out there would be an impulsive tension or jerk communicated in different degrees to all the parts of the curve, and causing them to move with velocities and in directions which it would require an elaborate dynamical investigation to determine.

The last problem which we shall notice, and that very briefly, is Problem 11:—"To find the variation of motion due to the motion caused by waves." Here again the solution is altogether erroneous. The first equation expresses the angular acceleration of the sheaves of the paying-out machinery due to the tension; and it is assumed that that acceleration is measured by $(T - R)r$, where R is the tension when the ship is at its mean level, T the tension at any other time, and r the radius of the sheaves. The correct expression instead of that just mentioned is $T \cdot r$. In the differential equation for the angular acceleration at any time, the forces acting at that time only ought to enter.

We do not wish to say one word more in condemnation of this paper than is strictly necessary. We give the authors credit for taking great pains; and if they have failed, they have the consolation of knowing that the history of mathematics is full of examples of mistakes in attacking new problems, which have been committed by the most renowned mathematicians. But considering the disastrous consequences which would result from reliance on erroneous investigations of this subject, and considering the warning which Professor Airy had given to the Institution of Civil Engineers respecting this paper, we think we are fully warranted in saying, that the Institution should have subjected the paper to competent revision before issuing it to the world stamped with their approval and authority.

(To be continued.)

Text-Book of Modern Carpentry; comprising a Treatise on Building-Timber. By THOMAS W. SILLOWAY, Architect of the New Capitol, at Montpelier, Vermont.—Boston, U.S.: Crosby and Co. London: S. Low, Son, and Co. 1858.

To use a modern phrase which Lord St. Leonards has introduced, this is a "handy-book," for, without diving deeply into the mysteries of science and mechanical construction, it presents in a concise form the results of a vast amount of experimental and mathematical investigation. For the student who would elaborate the subject, no work is preferable to "Tredgold," albeit it is perhaps getting rather antiquated, except in its more modern guise as edited by Professor Barlow; but the little volume before us (which is of American origin) will be found to contain an amount of practical information which many more ambitious-looking volumes fail in supplying. It may be presumed that the author—who appears to be a man of some professional experience, since he was architect to the new Capitol at Montpelier, Vermont—would necessarily resort in some degree to European precedents, but though this has certainly happened, he gives the reader the benefit of transatlantic experiments also; and some of the particulars thus gleaned have doubtless stood the test of time in a country in which timber is so abundant a material, and one entering so largely into the requirements of every-day life. The portion of the treatise devoted to building-timber, states an average of results arrived at through numerous experiments and much observation. The authorities on the subject are many, and the field wide; but in the few pages allotted to the subject, the writer seems to have condensed the most instructively practical portions of the works of Hutton, Barlow, Du Hamel, Perronet, and many other writers both in Europe and America. A copious "glossary" which is appended to the book has evidently been compiled with considerable care, and, as the definitions are usually amply explained, it will be found essentially serviceable. There is also a goodly number of engraved illustrations which do their part towards the completeness of the whole.

The subject of carpentry is divided into—the nature and properties of timber, the different kinds of timber in use, instructions as to felling and seasoning, the preservation, durability, and strength of timber, with rules for determining its tensile, cross, and compressive strength. Several elementary problems in geometry are next introduced, and the general topic is then resumed by a consideration of the equilibrium of strains on timber, the various modes of scarfing, and the construction of floors and trussed beams. Some excellent hints are given on the framing of roofs, and amongst matters more cursorily touched upon, are domes, bridges, arch centering, and iron work.

Speaking of *American timber*, the author says—

"There are but five kinds of wood in common use for carpentry in this country. These are spruce, pine, oak, hemlock, and chesnut.

"*Spruce*, (Abies) is indigenous to the colder parts of North America, where it grows in great abundance. For most qualities which constitute good framing timber, it is excelled by no other wood in use.

"There are two varieties, which are familiarly known as black or double (Pinus niger) and white or single spruce (Pinus alba). Of these the black is of most value; it being much tougher than the white, and may be procured in much larger sticks. The foliage of this variety is darker and heavier. The white spruce is of a comparatively small growth; but the wood may be worked much smoother than the other variety. Spruce-wood, when seasoned, is of a clear yellowish white, the annual rings being distinctly marked by a darker tint of the same colour, and having a silk-like lustre. A cubic foot, when seasoned weighs thirty-one pounds and a half. It shrinks in seasoning about a seventieth part of its dimensions, and loses a fourth of its weight.

"The principal defects of this wood are its liability to twisting and splitting in the sun, and its tendency to decay in all damp situations; but, where due attention is paid to these points, and proper care is exercised to prevent the exposures named, little else need be done to insure the permanency of work composed of this wood.

"*Pine* (Pinus) is next in value as material for a frame. Of this wood there are many species. The family (Conifera) to which it belongs is large, and comprises all that ranges from the most compact and hard spruce to the softest white pine. But two kinds, however, will claim our attention; the others, as framing-timber, partaking largely of the nature of spruce. Remarks relating to that wood may be applied with nearly the same propriety to all the harder varieties of pine.

"The two varieties most in use are known as white pine and Carolina pine.

"*White Pine* (Pinus strobus) abounds in all the northern portion of the United States, and is the tallest of our native trees. It is remarkable for the straightness of its trunk, which is often found a hundred feet high entirely clear of limbs. The whole tree frequently attains an altitude of two hundred feet. It is the same as that known in England as Weymouth pine. In forests, all excepting the top branches decay early; and these, being above all other trees, make it conspicuous as far as it can be seen. Pine is of rapid growth, and, in favourable situations, increases an inch in diameter and two feet in height in a single year. The bark of trees which are less in diameter than fifteen inches

Digitized by Google

is very smooth, and of a bottle-green; being, through the warm season, covered with an ashy gloss.

"The color of the seasoned wood is a brownish white. A cubic foot weighs twenty-four pounds and three-quarters. Its decrease of dimensions in seasoning is slightly more than spruce.* It has little tendency to warp or twist; and, for such parts of a frame as are liable to be exposed to dampness and continued wet, it is preferable to spruce. The wood being softer it is more liable to indentation at the joints; and, being less stiff, it is not for general purposes entirely equal to spruce. As a whole its average value for framing purposes may be considered as nine to ten.

"For finishing-lumber it excels all others, and sustains the same relation to joinery that spruce does to carpentry. None is better calculated to withstand the effects of the sun and weather than this; for with the exercise of proper care in seasoning, and reasonable protection afterwards, it will retain its natural strength and vigour as long as the best of oak.

"*Carolina Pine* (Pinus australis) is in most respects entirely unlike the wood last described; being very compact, and thoroughly saturated with a resin or pitch, which is remarkable for its intense fragrance. It grows in great luxuriance in all our states south of Virginia, and is familiarly known at the north as southern pine. Timber of almost any reasonable length and dimensions may be easily obtained. The wood is seldom cut up into small joists; but when not sawed into large framing-timber, it is used for planks and floor boards; the solidity of the wood, and the fineness of its grain, making it of great value for the purpose last named.

"In all dry situations it is exceedingly durable; but in wet or even damp places it loses its vigour, and soon moulds and decays. Its tensive strength, compared with oak, is nearly equal, while its weight is much less. This quality, added to its peculiar stiffness and resilience, has of late years made it a rival of oak, where a lighter and yet solid wood is required. It is, however, very brittle, and liable to fracture by a sudden blow or concussion; making it inferior to oak where toughness is needed.

This wood when newly planed is a rich yellow; the resinous parts giving it a finely variegated appearance. The average weight of a cubic foot, when seasoned, is not far from thirty-eight pounds and a quarter. It decreases a fifth of its weight in seasoning, and a sixty-fifth of its dimensions; shrinking something more in the direction of its length than either of the other woods in common use.

"*Oak* (Quercus) is a wood, like all others, existing in many species. Only two, however—those commonly known as white oak and yellow oak—are in general use for building purposes. It is a native of temperate climates, and is found in great perfection and vigour in the United States, from Virginia (the northern limit of the growth of Carolina pine) to Canada line. The wood is very durable when kept immersed in water; and while remaining in a perfectly dry situation it has lasted more than a thousand years. When subjected alternately to the action of water and air, together with more than ordinary warmth, it is subject to early decay. Oak-wood is hard, yet elastic and tough. Its texture is alternately porous and solid; the porous sections being the lighter coloured portions of the annual ring. The wood of young trees is much tougher than that of old ones, and is more difficult to work. That of old ones is often quite brittle; while at the same time in many other respects it appears to retain its natural qualities. It is the case with oak as with all trees—that the wood taken from the body and large limbs is stronger than that taken from the small branches. The sap is possessed of a peculiar odour and taste. It contains gallic acid; and, in consequence, turns black or purple when brought in contact with iron.

"The color of the wood is a whitish brown in the white species, and a yellowish brown in the yellow. A cubic foot, when dry, weighs forty-eight pounds. It shrinks in seasoning a thirty-sixth part of its dimensions, and loses a third of its weight.

"For many purposes—such as strengthening-pieces, keys, trenails, &c.—oak is indispensable; though of late years as a general framing timber it has been little used. For the first two centuries after the settlement of this country it was employed almost to the entire exclusion of other wood; but spruce and pine have gradually supplanted it, till now a new piece of oak framing is but seldom seen. When used to any great extent it is for open timber-roofs of churches, or something of the kind. The natural beauty of its selected wood for a rich finish-lumber, and its great strength and durability as a framing timber insure the usefulness and value of the 'monarch of the forest.'

"In addition to the foregoing, the two next in value are those familiarly known as the black oak and the live oak. The former is nearly allied to the yellow oak; and is, in many respects, of equal value. Live oak is principally used in ship-building. The wood is nearly identical with white oak; but the nature and habits of the tree tend to produce only small and very crooked timber. For the various purposes, however, for which the timber is used it is an important member of the Quercus family.

"*Hemlock* (Canadensis) is often used in the cheaper kinds of carpentry, It is indigenous to nearly all places which are favorable to the production of spruce and light pines. In dry situations, when the wood has been properly seasoned and is carefully protected from the action of the sun, it may be considered as a fourth-rate wood. Its peculiar structure, tending to twistish or cleftish grain, makes it entirely unreliable for large timbers where either tensile or compressive strain is required. It decays quickly in damp situations; and if exposed in an unseasoned state its heart-wood cleaves from the surrounding wood by the action of either sun or wind.

"Considering these tendencies (existing even in the best specimens), it is usually cut into small studding joists or common boards. Hemlock possesses one quality in common with oak and the other hard woods; viz., the tenacity with which it adheres to a nail. An ordinary tenpenny cut nail, if driven into the wood half its length, will part before it can be drawn out. This quality is one of its first recommendations for common or rough boarding, as it firmly holds the nails of shingling, slating, clapboarding, &c.

"The sap is possessed of an intense and somewhat unpleasant odour. It is unfit for use while in an unseasoned state, as it corrodes iron immediately at the part where it begins to project from the wood. The color of the wood is a light brown; and a cubic foot, when dry, weighs twenty-seven pounds. It shrinks in seasoning a little less than spruce, and loses one-fourth of its weight.

"*Chesnut* (Castana) is a wood of great value, and is in most respects nearly identical with oak, which it resembles in color, toughness, and solidity. It is a native of temperate regions, and is usually found growing side by side with its rival. For most purposes for which oak is used, chesnut is of equal value. While exceedingly durable in damp situations, it is equally so in those which are dry; and in places partaking at times of both it is preferable to oak. For posts set in the ground it may be considered good for a service of forty years. Like oak, the grain of the wood is compact; and that of young trees is very tough and flexible: but old wood is liable to brittleness, appearing sound and healthy without, while within it is decayed and rotten. Chesnut contains one valuable quality not possessed by either of the other woods; namely, when once seasoned it is but slightly susceptible of shrinking or swelling. The weight of a cubic foot of the wood, when perfectly seasoned, is forty-one pounds."

On the *preservation of timber* we read—

"Wood is liable at any time to change its nature, and part with its most valuable properties. In all timber, even if well seasoned, there remains a certain quantity of sap and vegetable matter, which, when the piece is shut up in stagnant air liable to be heated in summer, will mould or ferment, and an acid be formed decomposing the wood. In no instance should a piece of framing be so enclosed that fresh air cannot at all times come in contact with it.

* * * * *

"The next consideration is to protect it from the action of alternate moisture and dryness. If a stick of timber be exposed to a continued heat—as, for instance, over a baker's oven—it will in time lose its elastic power, and become brittle. If, on the other hand, a piece of the same timber, in all respects identical in properties and nature, be immersed in water, and remain submerged, it will retain the larger part of its properties for centuries. In fact, if not injured by insects or acids in the water, it may be considered as almost indestructible; but the reverse of this is the case if it be subjected to the alternate action of water and air.

"As soon as a piece of wood is exposed to the action of moisture the vegetable and saccharine matter begins to dissolve; and a

* It is the generally received opinion of carpenters, that all wood is liable to some shrinkage in length; though, in most instances, it is hardly perceptible.

Digitized by Google

slimy coating is formed wherever the solution exists. When exposed to the air this slime ferments; and from it grows a sort of fungus, which lives on the vital parts of the wood itself. A continual series of exposures of this kind soon induces a visible decay, which ends in the entire destruction of the timber.

"Every part of the frame should in some way be protected. No work should, therefore, be placed on or very near the ground where earth can in any way come into immediate contact with it; nor should any be subjected to the direct action of steam or vapour, without being in some way shielded. The artificial methods of preserving timber are numerous. Covering the work with boards is in many instances effectual. Sometimes, however, this is no protection, but, on the contrary, serves to retain moisture that would evaporate if left exposed, as is often the case with the sills of buildings, timber bridges, &c.

* * * * *

"The first step to be taken is to season the timber thoroughly. When this has been done the whole of the exposed surface should be covered with some preparation that will strike into the wood, and, as much as possible, harden the outside. Thus, by closing the pores, the piece is made impervious to the weather.

"A valuable practice for the preservation of timber is to heat it by burning charcoal, or something of like nature, beneath; and while it is in a heated state applying a hot solution of an ounce and a half of corrosive sublimate, or one of aqua-fortis (nitric acid), in a gallon of water. After this is done and the work well dried, it should be painted with the best quality of white lead and oil.

"A thin solution of hot coal-tar and whale-oil is of great benefit to all timber that is to be placed near the ground. If this operation be repeated two or three times, and finely pulverised clinkers from a blacksmith's forge, or the dust made from the scales of iron which lie about an anvil, be sifted upon the timber while the tar is newly put on, it will possess great durability, since wood prepared in this manner is scarcely susceptible of decay.

"Pyroligneous acid, or the liquor that drips from stove-pipes in which vapour condenses, also strong decoctions of soot applied hot, are recommended as good preservative agents. In all framing exposed to the weather, every mortise that can hold water, and their tenons, together with all the wood about them, should have a good coating of one of the preparations first named before the work is put together.

* * * * *

"When a piece of framing is to be permanently exposed to the weather, it should be treated with one of the solutions first described, and then thoroughly painted and sanded. Wood in a proper condition when felled, afterwards thoroughly seasoned, well saturated with diluted corrosive sublimate, and finally kept properly painted and sanded, is as durable as it ever can be.

"One caution it would be well to remember; namely, to refrain from applying paint or any preparation to wood before it is thoroughly seasoned; for, should the outside be coated so as effectually to prevent impenetration from without, evaporation will also be prevented from within; therefore, all moisture that may be in the wood will be retained, and rot the piece.

"Another suggestion is to use timbers as small as the nature of the work will permit. It is a mistake to suppose that large timbers will continue good longer than small ones. We may see an exemplification of this at any New England farmhouse. The light spokes of a wheel will remain sound and strong for years after the tongue of the cart to which they belonged has entirely decayed.

"If a timber is sufficiently strong when first used (the requisite allowance being made for permanent strain), all has been done that prudence would dictate, since no increase of the dimensions of the piece will insure its longer duration. And, finally, it should be scrupulously remembered, that timber will not certainly remain sound because a large portion, or even most of it, is in proper condition, and well cared for. Only so much as is actually protected will retain its qualities; and any part so exposed as to injure the whole stick will as surely injure or destroy the unprotected part. Therefore, the ends of timbers which are built into walls, also all surfaces in contact—as where the side or edge of one stick rests upon another, tenons, in mortises, &c.—should be supplied with air, kept dry, and in every way properly protected."

The following table is furnished as the result of experiments on the *strength of wood:*

"*Experiments on the strength of Woods.*

As we have stated, the framing of roofs is a matter freely discussed, and accompanied with numerous diagrams. Specimens are given either with or without tie-beams, and some in which iron tie-rods, &c. are introduced. Many of them have been carried into execution; perhaps the most noticeable is that illustrated in plate xi., which exhibits the design of a portion of the large trusses supporting the dome of the State Capitol at Montpelier. This was executed from drawings supplied by the author, Mr. Silloway, in 1857; and the trusses, together with the framing of the roof and dome, consumed 80,000 feet of timber. The span is 67 ft. 4 in. between the walls, and the trusses receive no support from below. The principle of its construction it would be difficult here to explain, but, in appearance, it resembles three ordinary king-post roofs (of equal span) combined, the tie-beam of one resting upon the ridges of the other two.

The several tables which are interspersed with the general letterpress, will be found valuable for reference; viz., the comparative weights of various thicknesses of iron—from which it appears that American iron is a seventieth heavier than English—computations of timber-measure, roof scantlings, and the tensile strength of different kinds of wood, as deduced from the experiments of Bevan and Muschenbrock; and the costly works of Rondelet and Belidor have not been examined in vain.

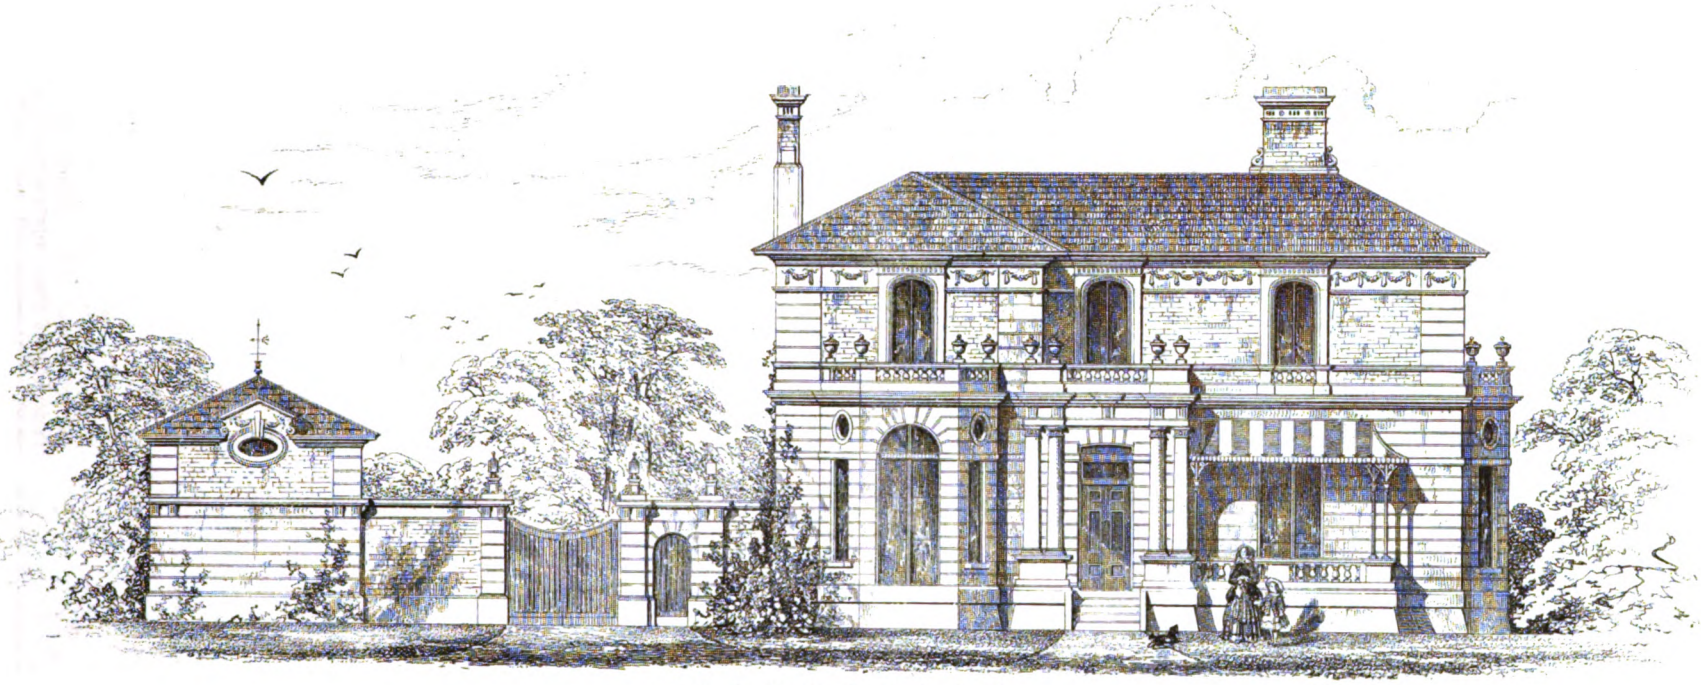
The Companion to the Almanack.—London: Knight and Co. 1858.

When, as in the case of the serial before us, a book can point to an existence of thirty-two years, it may be presumed to need no favourable introduction to public notice. Among the higher publications of its class, Mr. Knight's Almanack takes a distinguished place, and the mass of general information on subjects of mathematics, natural philosophy, natural history, chronology, geography, fine arts, public economy, &c., with notes on the recent enactments of the legislation, and public improvements, constitute a useful record for preservation on the library shelf, or for more ordinary reference. Among its contents, we have been accustomed for some years to meet with a well-digested essay on the architecture of the day, founded on a review of the principal buildings which have been completed during the previous twelvemonth, and the mere enumeration of these, with the running comment, is to some extent a chronicle of our architectural progress. Yet it is hardly possible that in a single year any great architectural progress can become demonstrable. It is only when we look back over ten or a dozen years that a comparative estimate can be formed. Nevertheless, inasmuch as year after year witnesses the completion of one or more important works, it is possible in almost a single glance to perceive the reflex of the dispositions and abilities of the age. "When in provincial towns we see municipal buildings, like the town halls of Leeds and Newcastle, erected at a vast cost, and with an unstinted amount of ornament, where a few years back, plain 'serviceable' buildings merely would have been constructed; and when, as in London, we see that the caterers for public amusement raise such splendid and artistically-decorated piles as Covent Garden Theatre and St. James's Hall, and in the same year churches are completed so ornate and so costly as those of Doncaster, Stoke Newington, and Richmond, we cannot but feel that it is an evidence of a growing popular appreciation of architecture as an art; and that, in other words, a building is expected now to satisfy the eye by its elegance, or dazzle by its splendour."

The writer proceeds to remark upon the leading competitions which have attracted public attention, such as the Government Offices, the Wellington Testimonial (the proceedings in connection with which are commented upon with not less severity than truth), the Nelson Column, the statues of Jenner and Havelock, the Guards' Memorial, and that erecting in Westminster in honour of the Westminster scholars who fell in the Crimea; with the statues, at Grantham of Sir Isaac Newton, and at Salford of Mr. Brotherton, M.P., and the handsome Crimean Monument at Sheffield. Among the "Public and Sanitary Improvements," we find reference to—first, the Thames (of course), then the main drainage question, and the proceedings of the Board of Works. Among local topics we find the extensive works for the improved water supply of Manchester, which are now brought almost to a termination, and the city is already supplied from the new source. We quote some other particulars.

"The water is obtained from a 'gathering ground' of nearly 20,000 acres; the reservoirs form a chain of ten artificial lakes, stretching for upwards of 4 miles, near Woodhead in Longdendale, and capable of containing 600,000,000 cubic feet of water. Only the pure water supply is conveyed to the city, the turbid water being stored in distinct reservoirs for mill purposes. The water, which is very soft, is carried 12 miles by means of large pipes and aqueducts to a reservoir at Godley, 8 miles from Manchester; it is thence conveyed to two service reservoirs at Denton, 4 miles from Manchester, whence the city is supplied on the constant-service system. When the works are completed, they will, it is estimated, be capable of furnishing 25,000,000 gallons of water daily. The entire cost has been about 1,500,000*l.* Like the gas-works, these works belong to the corporation..... One instance, that of Bourne, Lincolnshire, deserves special notice (though the works were completed in 1857) as showing how much may in skillful hands be accomplished under favourable circumstances at a small outlay. In consequence of the pollution of the stream from which the little town (of 4000 inhabitants) obtained its water, a company was formed for the purpose of procuring a new supply by means of an artesian well. The well was bored to a depth of 92 feet, and all the necessary works were completed at a cost of 1287*l.* The bore of the well is only 4 inches, and through this 567,000 gallons of perfectly pure water rise in twenty-four hours. No engines or pumps are employed, but the town is supplied at high pressure, so that from the fire-cocks or hydrants placed in the streets, water may be thrown by the natural force upon any house direct from the main, and of course without the intervention of a fire-engine. The houses of the poorer inhabitants are supplied at a charge of one penny a week each."

Churches, as usual, claim a large share of attention. Amongst those in or near London which are noticed, besides the three we have mentioned above, are new churches, at Blackheath, by Mr. Ferrey; Orchard-street, Marylebone, by Mr. P. C. Hardwick; and the iron temporary churches at Islington, Holloway, and near the Victoria Docks. The lists of provincial churches and restorations are very large, so that most of them are therefore only enumerated, without detailed remarks.



"Church restoration," says our essayist, "seems to be proceeding more rapidly and resolutely than ever: but as almost every kind of reparation, 'beautification,' and extension is now called restoration, it is not always easy to tell what ought to come under the received acceptation of the term. It is impossible for the lover of our old Gothic edifices not to regret the extent to which the process is being carried. Soon, hardly a church or cathedral will remain as it was left by the original architects. The entire surface of a majority of our finest ancient piles has been restored by replacement with modern work,—in our estimation scarcely less destructive a process than would be the restoration of the Theseus or Ilyssus, by having the traces of injury removed by the chisel of a stonemason. Of course it is necessary to repair an edifice that has fallen into decay, it may be even to restore by removing a portion of it; but such restoration should never be carried one line farther than is inevitable, and every part which has been renewed or rebuilt should bear upon its face an inscription to that effect in some conspicuous spot. New work in counterfeit imitation of old is, to our thinking, simply dishonest—the worst of architectural 'shams,' though it be in such marvellous favour with that section of gothicists which is always protesting against shams in architecture."

In discussing the "*Buildings for Public Purposes*," we read—

"The New Palace at Westminster is at length approaching towards completion, so far at least as the building as actually decided on is concerned; but Sir Charles Barry has always contemplated the removal of the present unsightly and inconvenient law courts, the continuance of the design along their site, and the rounding off of the whole by the erection of 'a great entrance gateway with flanking turrets at the corner of New Palace Yard, which would form the public entrance to the building, as distinguished from the royal entrance at the other corner under the Victoria Tower.' Indeed, some such finish seems absolutely necessary to the integrity of the design, and it is most earnestly to be hoped that as soon as the works now approaching rapidly towards their termination are out of the architect's hands he will be empowered to proceed with this part of his task: we shall then have what, with all its faults, will be, beyond dispute, the most magnificent building erected in this country for centuries.....Much has been said of the long time which the works have occupied, and their extreme costliness; but in truth, when the extent and solidity of the works, and the elaborate and sumptuous character of the ornamentation are considered, and it is remembered that every part, from the most massive masonry and the most ponderous iron-work down to the minutest details of the decoration and the fittings, has been executed in the best and most finished manner possible, the wonder rather will be that so much has been accomplished in the time. Probably no other building of similar extent and character has ever been erected in anything like so short a period, and carrying on the comparison with other works, the cost will not seem excessive. What its extent is few very clearly understand. The statement that it covers an area of upwards of 8 acres, comprises 1100 apartments (including the Houses of Lords and Commons, the Central Hall, St. Stephen's Hall, &c., each equal in itself to a building of no ordinary magnitude as well as splendour), above 100 staircases (many of which are of grand proportions), and more than 2 miles of corridors and passages, helps somewhat to a conception of its size. But to understand the enormous expenditure of time, as well as material—and with both, of course, money—which its construction has necessarily involved, it is needful to bear in mind how high it has reached, and how low it has delved, as well as how large an area it has covered; that its towers are among the loftiest as well as the most massive in Europe; and that its foundations, including the coffer-dams and river works, are among the most remarkable combinations

of engineering and architectural skill and energy employed in any modern civil edifices; and that to all this has to be added that the artistic decorations stand quite alone in any English work. From the laying of the first stone—the river-wall having been previously completed—in April 1840, nineteen years have not elapsed, and we have very far advanced towards the completion of one of the most magnificent and sumptuous of modern buildings. The entire cost to February 1858, according to Mr. Barry's statement, was, 'as far as the architect is concerned,' 1,768,979*l.*; but as this does not cover all the items, there can be little doubt that it has reached at least 2,000,000*l.* The original estimate was only 707,104*l.* 'But the building to which the original estimate applied, and that which now exists, are two different things.' From the river embankment to the flagstaff on the Victoria Tower, everything has been altered, and the effect of every alteration has been to increase the magnitude, the splendour, and the cost. Some of the alterations were made at the suggestion of the architect, but more originated with the various parliamentary committees and commissions, and some—and those of the costliest, too—were made against the architect's earnest protest; it is therefore manifestly unfair to hold the architect blameable for the increased cost and extended time. We must leave the subject now, however; we have from year to year traced its progress, next year we hope to be able to speak of the building as virtually completed, and to take a more general survey of it, and of its decorations."

Next we have the Leeds Town Hall, the Newcastle Corporation Buildings, and Covent Garden Theatre, respecting all of which, as well as some others which are mentioned, full accounts have from time to time appeared in our pages.

Street Architecture is treated rather summarily (stated to be in consequence of the length of the notice in the previous number); and Engineering works, such as Bridges, Docks, &c., form the concluding subjects of a well written and interesting article. The numerous outline illustrations which are interspersed are great aids to the textual descriptions.

Among other topics of which this volume treats, are a valuable paper on the "Museum of Practical Geology, its Educational Objects;" the "Practical Results of Sanitary Legislation in England;" "The Thames and London Drainage" (to which we shall perhaps again refer); and a description of the several "National Collections of Pictures,"—an interesting article, in which is condensed much information not generally known,—and some others which fall less within our province to notice. Altogether, this 'Companion,' though to our minds scarcely equal to the last, is a very readable and well-digested volume.

VILLA AT ALTRINCHAM, CHESHIRE.

(With an Engraving.)

The accompanying design was recently erected as a suburban residence, with some immaterial alterations, at a cost of 2300*l.*, by Messrs. Bowden, Edwards & Foster, builders, Manchester, from the design and under the superintendence of Mr. Horace Jones, architect, of 16, Furnivals-inn, London. The elevation is in red brick, with Portland cement dressings. The general arrangement will be gathered from the plan. The drawing room, which is 15 feet high, has a coved ceiling, and is well adapted for music; the hall is also lofty and architecturally treated, as also is the staircase. The interior finishings, including the chimney-pieces to principal rooms, are all executed in a style corresponding with the Italian character of the exterior. The site of the house is at Woodheyes, a large park recently laid out for building purposes, near Manchester.

ARCHITECTURAL UNION COMPANY.

The honorary secretary of the Architectural Exhibition and Architectural Union Company (Mr. Edmeston) is endeavouring to develope more fully and completely the advantages conferred on the public, and upon exhibitors of manufactures, &c., by the collection of all that is new in building inventions, in the way already put in practice at the Architectural Exhibition, on a small scale, and he has addressed a circular letter to those interested, in which he remarks as follows:

"As the Architectural Exhibition will henceforth be open during the height of the London season, the committee are obliged to incur a rental of more than three times the amount paid in Suffolk-street, and they will therefore be obliged to increase the rentals paid by exhibitors in the materials department, in a corresponding degree. They of course anticipate a largely increased number of visitors, and they have now the great advantage to be united in one house, and to be thus identified with all the architectural societies of London. The Exhibition will also be open for a much longer period than was the case in Suffolk-street. The spaces at disposal will, if against a wall, consist of 3 feet of floor space measured from the wall, and with perpendicular height of 8 or 9 feet, and it is proposed to ask for this a rent of 1*l.* 1*s.* per foot run, or 5*l.* 5*s.* per 6 feet, each exhibitor to fit and set up his own stall or means of exhibition. The space in the centre of one of the galleries may also be appropriated to works of art manufacture, under restriction as to the mode of setting up the articles exhibited, so as not to interfere with the light; the space may be 4 feet wide and with a height of 8 or 9 feet, and the rental required would be 1*l.* 5*s.* per foot, the stall, &c., being set up by the exhibitor.

"From the advantage gained by all exhibitors of materials in the Architectural Exhibition, and which many of them have repeatedly acknowledged to me, I am inclined to think that if the new galleries were filled during a part of the year (say for the months of July, August, September, October, and November) wholly with such an exhibition, it would be found of great benefit to all having anything to make known, and that it might be done at a small cost to exhibitors.

"Thus, let the Architectural Union Company provide a curator, and warming and lighting,—let the Exhibition be rendered as nearly free as possible,—let every encouragement be given to the public to resort to the galleries for the purpose of becoming acquainted with all that is newest and best in building inventions, and let the rent paid be only, say 1*l.* 1*s.* per yard run, or perhaps less for a larger space, and at small cost the very best advertisement will be provided for all inventors. Every architect in London, or from the country who may visit London, would be certain to see the Exhibition, and all would go there for anything they might specially require, or to become acquainted with progress in these matters; while it is quite certain that no one who has much business on his hands can afford to hunt up the different workshops and factories; and those who possess articles of value or of taste can only with the greatest difficulty make known their inventions or manufactures to those who can use them most."

We would specially direct attention to the two last paragraphs. We understand that very numerous applications have been made, and the advantages conferred upon those most interested, at a very small cost, are too obvious to need any recommendation from us; to country manufacturers especially a great boon is offered.

NEW WESTMINSTER BRIDGE.

"Sir,—In the description which appeared in your paper of Wednesday last, relative to the New Bridge at Westminster, it is stated that—

"'Mr. Page had the benefit of Sir Charles Barry's advice in the ornamental accessories of it, in order that its design might be as much as possible in keeping with the architectural style of the new Houses of Parliament.'

"As this statement is likely to produce an erroneous impression as to the extent of my participation in the design of this bridge, I have to request the use of a small portion of your columns to state that, although the usual and remarkable characteristics of the superstructure of the bridge, such as its spacious width, the lowness and easy gradients of its roadway, the proportions of the piers to the arches, and the curve and headway of the latter are in accordance with my design as adopted by the

Digitized by Google

late Sir William Molesworth, the elevation now proposed to be carried into effect is so much at variance with that design as to absolve me from all responsibility in respect of the questionable taste of its details.

"As to the bridge being in harmony with the style of the New Palace at Westminster, I have to observe that the elevation now proposed does not comply with that condition; but it is fair to add that I do not consider such accordance to be necessary, even if it were practicable.—I am, Sir, your obedient servant,

"Old Palace-yard, Dec. 10. CHARLES BARRY."

[The above letter appeared recently in the *Times*.—As far as we are acquainted with the proposed architectural decorations of New Westminster Bridge, we entirely assent to the condemnation of them expressed in this letter. We have seen sectional drawings of cast-iron mouldings intended to ornament the parapet of this bridge; and resembling the profile of Gothic mouldings in stone, but the resemblance is confined to the surface, as these mouldings, instead of being solid, are hollow internally. The taste for cast-iron Gothic has been deservedly ridiculed; the true ground for its condemnation being, as we apprehend, not the mere nature of the material, but the wrong use of it. The mode of artistic treatment which is proper for a material like stone is obviously improper for metallic substances, and of these again, those which are malleable require one mode of treatment and those which are cast another. A few years ago the mere superficial imitation of Gothic forms passed for Gothic architecture, but a purer taste demands not mere mimicry of its forms, but a comprehension of its principles, which have been utterly disregarded in the designs in question.—ED.]

IMPROVEMENTS IN EDINBURGH.

THE designs for the new street extending from the High-street, immediately opposite the Tron Church, to the south end of Waverley-bridge, have been approved of by Sir William Gibson Craig, the referee under the Railway Access Company's Act, and are being exhibited to the public at present in George-street Hall. Messrs. Peddie and Kinnear, the architects to the Railway Access Company, have, as may be seen from the designs in George-street Hall, been very successful in complying with the requirements of the Act, which sets forth the desirableness of preserving as far as possible the character of the buildings in the district through which the new street is to run. At the northern entrance, leading directly from Waverley-bridge, they propose to erect a large hotel of three stories and attics, circular above the third story, and terminating in a high crow-stepped gable. A turret, a balcony, dormer windows, &c., give to the building, which will occupy a considerable space of ground, a very picturesque appearance. As much will necessarily depend upon the aspect which the back of the northern part of the street will present when looked at from Princes-street, care has been taken by the architects to form an irregular sky line by breaking up the portions of the houses seen above Market-street. The buildings in the street itself are considerably varied, both in breadth and height, massed without producing an effect of heaviness, and relieved by the openings to the several closes as well as by variety of architectural detail. The houses are chiefly designed for shops with warehouses or saloons and attics above.

About the middle of the northern side of the street it is proposed to erect a public hall, capable of holding about 600 persons. This, which is to rise two stories above the shop front, is distinguished in the designs by a three-light window and a tall gable. There is no building in the centre of the town really available for public meetings, except the Merchant's-hall in Hunter-square. It is to be hoped that of whatever extent this place of meeting may be, means will be taken to guard against the serious mistake of having only one avenue of entrance and egress. The inconvenience experienced at crowded meetings in the two public halls in Edinburgh is not only excessive, but it points to serious dangers in the event of an accident taking place. The designs for some of the buildings on the south side of Lord Cockburn-street are not yet completed, but a good idea can be formed of the general appearance which it will present. The designs have been carefully prepared with a view not only to utility, but general effect, and give reason to hope that the new street will add to, rather than detract from the fine appearance of the irregular masses presented to the view of the spectator who looks across from the northern side of the railway valley.

COMPETITIONS.

Designs or models are invited for a Monument to the memory of the late Lieut.-Colonel Morris, C.B., on Hatherleigh Moor, Devonshire. It is hoped that between 400*l.* and 500*l.* will be collected; the subscriptions at present amount to 345*l.* The committee will not be held liable to pay for the preparation of such designs or models. The next meeting of the committee will be at the Subscription-rooms, Hatherleigh, on Jan. 20, 1859, at one o'clock, before which day the designs or models are requested to be sent to the care of Mr. Pearse, solicitor, Hatherleigh.

Plans or models are requested of a New Tabernacle at Newington for the congregation of the Rev. C. H. Spurgeon, on land situate near the Elephant and Castle, Newington. Premiums, 50*l.*, 30*l.*, and 20*l.* The drawings to show a plan of each floor and gallery—longitudinal and transverse sections—and elevations, drawn to a scale of 8 feet to 1 inch, and tinted in light brown Indian ink. One perspective view, tinted in like manner, may accompany each design; but bird's-eye perspective views and drawings in frames other than straining frames and glasses will not be received. The building to contain on basement-floor (which is to be 5 feet below the level of the footway) school-rooms, 12 feet high, for boys and girls, and lecture hall to seat 800 persons. The chapel above to seat 3,000 persons, and standing room for not less than 1,000, and with not more than two tiers of galleries; each sitting to be not less than 2 feet 6 inches by 1 foot 7 inches. Gothic designs will not be accepted. The plan of the Surrey Music-hall has proved to be acoustically good, and will be decidedly prefered. Provision to be made for baptistery, six vestries, waterclosets, urinals, &c. The total cost, including architect's commission, warming, ventilation, lighting, boundary walls, fences, paths, fittings, and every expense, to be about 16,000*l.* Each architect to state the commission he will require on outlay—such commission to include all expenses for measuring, superintendence, &c. The architects competing will be requested to undertake the task of acting as judges, and to award the first and third premiums. For this purpose the Committee will require the name and address of each competitor to be forwarded to them, per post, on the 1st day of February. The second premium to be awarded by the Committee; and no architect to select his own design. Designs to be sent by the 31st inst.

Designs are invited for the proposed Manchester Assize Courts, Lodgings for Her Majesty's Judges, Offices, Lockups, and all other accommodation which may be necessary or convenient for carrying on the civil and criminal business usually transacted at courts of assize. A premium of 250*l.* will be given for the best design, 150*l.* for the second best, and 100*l.* for the third best. The various buildings are to be erected on a plot of land, part of which was recently the site of Strangeways Hall, situate in Bury New-road, or Great Ducie-street, Manchester. A plan of the site and particulars may be obtained on application to Frederick C. Hulton, Clerk to the Manchester Assize Courts Committee, Salford, to whom the designs must be sent by the 1st March next.

The Havelock Testimonial.—The Havelock Testimonial Committee have decided upon giving to Mr. Behnes, sculptor, of Osnaburgh-street, Regent's-park, the carrying out of the Havelock statue at Trafalgar-square. Mr. Behnes's No. 4 model has been selected as the most suitable, both as regards attitude and likeness. The statue will be erected on the vacant site adjoining the Nelson column.

The American Steam Ram and Battery.—Stevens' Steam Battery is an iron vessel, now building for harbour defence only, under a contract with the late Robert L. Stevens. It is about 440 feet in length and 50 in breadth, and is built apparently for speed, being very sharp forward, with clean run, greatest breadth abaft the centre of length, and with flat floor. She is now built up only to about the light-load line, the "planking" being ½-inch boiler-plate double riveted to U-shaped angle-iron "timbers" about 20 inches apart; no "ceilings" as yet; "deck-beams" of U-shaped angle-iron are in for two rather low decks, and the hold has on each side a large iron tank, extending some 200 feet amidships, and leaving but about 20 feet of space between the two tanks on the line of the keel. Each tank appears to be independent of the other, and at the forward end has an inclined engine, very heavily proportioned, which seems to be arranged for condensing air into the tank. Over the top of the tanks are large pipes or boiler-plates, connecting the engine with the tank at several places, as if the tank were composed of subdivisions. No propelling apparatus is yet apparent. The plan, as report says, is to carry a heavy battery, of long range, as near to the water as possible, using the air tanks to secure safety from sinking if pierced by a shot below water, or from water which would wash into the low ports. The battery is to be covered by a sloping roof so that shot would glance off, and the vessel to have speed enough to be able to keep at long range. The original appropriation by Congress was 500,000 dollars "toward" the construction. The executors have claimed that a little over 800,000 dollars has been expended, and that about as much more will be required to complete the vessel, though whether this is to include equipment and armament is not definitely stated. There has been much doubt expressed if the thing will ever be completed, although Mr. Stevens did contract for a specific sum, and of which he had received on account the appropriation of half-a-million dollars, as above. At present there is only enough work doing to justify the expression that "the work is progressing."

Notre Dame.—The restorers of Notre Dame de Paris are now taking in hand the interior of the choir, and have already swept away the cumbrous marble arches, false in style and heterogeneous in material, which have so long defaced it. They are about, too, to complete the cathedral according to its original plan, by raising a pierced Gothic spire in the centre of the building.

THE PROPOSED STEPHENSON MONUMENT AT NEWCASTLE.

That the question, as to the best kind of public memorial to be raised as a tribute to the illustrious dead, ought in a great measure to be guided by circumstances, every one will admit; and it will on the other hand be granted that, in spite of the utmost preliminary care and deliberation, but very few, indeed scarcely any, even under the most favourable auspices, have realised the ideas of their projectors. Then again, to show the diversity of opinions which may exist upon the very same subject, we have only to point to the amusing contrasts which were afforded by the examination of the designs for the Wellington Monument to be placed in St. Paul's Cathedral, or even the multiplicity of schemes which have been actually carried out in commemoration of our deceased Crimean heroes. From the range of the contents of Westminster Abbey and St. Paul's down to the latest additions to Trafalgar-square, all partake of the same unsatisfactory heterogeneous character. What wonder is it therefore that the good people of Newcastle cannot agree as to what kind of monument they shall rear in memory of their late distinguished county-man George Stephenson. Yet in their case there is this advantage, that nothing is yet, we understand, really decided on, and therefore there is the greater hope that the discussion which is now afloat will have a beneficial tendency. It is a matter for congratulation to observe with what enthusiasm and energy the proposal to erect the Newcastle memorial has been met by those classes who, either appreciating the genius of Stephenson, or profiting by his industry, have taken the initiative in the promotion of this praiseworthy object. As Lord Ravensworth has remarked, "In this, the capital town of his native county, some enduring monument should be placed of a description which shall leave no doubt upon the minds of every passer-by that it is to the memory of George Stephenson."

In the present state of affairs the possibility (based on a resolution unexpectedly proposed and confirmed at what had been given forth as to be merely a preliminary meeting) is, that the whole will be confided to "some sculptor of eminence."

To such a decision there are many malcontents, and reasonably too, when the site it is remembered is to be an out-door one, and, if the most appropriate and eligible one be selected, is in the centre of a large open space—the locality suited above all others for some architectural attraction as a focus, and in which an insignificant bit of sculpture would be worse than useless. A life-size figure—perhaps sitting—placed on the spot referred to, within the area of the triangle formed by the junction of Neville-street with Westgate-street, on a pedestal equal to the height of the figure, would appear a mere pigmy in the locality of the Railway Station, the Literary and Philosophical Institution, the Surgeon's Hall, the Assembly Rooms, and St. John's and St. Nicholas' Churches, and would bear no more proportion to the area of that admirable site than it would to the wishes and expectations of the inhabitants. To obviate this objection however it may be urged that the monument might be colossal; to which we reply, that to be at all equal to the necessities of the case, it must be giant-like in its proportions, and this would inevitably destroy its *individuality* of purpose; besides it is by no means conceded that statues exposed to the rigours of the seasons are adapted to any climate, much less to one so capricious as ours.

In connection with this specific subject of Stephenson's monument a very able address* has been prepared by an architect resident in the vicinity, who naturally feels warmly interested in the issue of the contest. To this we are indebted for some of the foregoing remarks; and the following may be quoted as exemplifying the author's views on the comparative claims of architectonical and sculptural memorials generally.

"Monuments may be generically grouped into the architectural, sculptural, and architectural and sculptural combined. The sculptural monument is usually life-size or colossal, in stone, marble, bronze, or other metal; and, until more modern times, was rarely separated from its architectural parent. There are instances—as the Colossus of Rhodes—where statues were erected isolated and distinct from all buildings; but so far from these being examples of sound sense and true taste, the fact that they were more the product of boastful ambition than of pure sentiment, is a sufficient reason to deprive them of the reverence we are naturally disposed to give to precedent, especially when that precedent was contemporaneous with a high state of cultivation." .....And without entering into the nice distinctions of colour, some consideration is due to the effect produced upon the mind by beholding an exposed marble statue, bleached on one side and blackened on the other—results which atmospheric influences in Newcastle produce long before the figure has time to grow hoary with age—or of a deep brown bronze, without sun shadows, and bearing a strong resemblance to the natural complexion of a foreign and degraded race called by our transatlantic friends 'men of colour.'

* * * *

"Monuments of the architectural class, comprising pyramids, monoliths, tombs, or obelisks, constitute examples as foreign to the present object as those of the purely sculptural class. But from the earliest ages, rude hieroglyphic carvings, which afterwards developed into chaste sculptures, may be found in almost every example. The columns, triumphal arches, and choragic monuments of ancient Greece and Rome, were architectural structures sculptured by way of adornment. Architecture is, therefore, rather the parent of the art of sculpture than the elder sister; and never has sculpture been placed in position apart from architecture without suffering by the innovation. In London, the statue of the Duke of Wellington on horseback, for want of an architectural pedestal and covering, has been placed upon a triple arch, to the degradation of our national taste and the regret of every artist. In Liverpool and Manchester, the colossal figures of their local celebrities, and the statues of Wellington and Peel, are far from satisfactory, considering their cost, although, in these cases, the nature of the sites have doubtless had much to do with the character of the monuments; and, to the general public, they appear to serve no higher purpose than the Sebastopol guns at Sunderland or Stockton do. They are mere objects of wonder. Monuments of the combined architectural and sculptural class, including columns, triumphal arches, shrines, and tombs, constitute the best examples. Monumental columns, with colossal figures on the top, are in equal bad taste with merely sculptural monuments, and for the same reasons, with this additional reason—viz., that the figures are placed beyond the proper limits of sight. You know they are there, but that is all.....Those of the arch class are suitable only for conquerors, and the sculptured statues and bronzes record the history of their triumphs, and, as aids to history, are doubtless useful enough in their way. But this is not the form we want in Newcastle for George Stephenson. He, too, was a conqueror, but his conquests were peaceful. The results of the victories which he achieved have been beneficent, as the victories themselves were bloodless. The influence of his exertions and career is felt throughout the civilized world. Nations are learning their dependence upon each other, and the facilities for rapid communication are constantly becoming more numerous. The domain of commerce has been widely extended; and a new and nobler chivalry is succeeding the chivalry of war. The impulse which has been given to agriculture has resulted in its elevation to a science. The labour of the artizan has been lightened, and his comforts increased. Effective means for preserving life amidst the danger incident to the working of our coal fields are in general operation. With all these departments of human interest the name of George Stephenson will be for ever identified, and the impetus which has thus been given to the progress of society must continue to be felt to the remotest ages of the future. It is for the public taste to decide in what style the monument shall be, whether of Greek, Roman, mediæval, or modern character. Unquestionably, the finest specimens of modern monuments are Sir Walter Scott's at Edinburgh, and the Martyrs' Memorial at Oxford—the latter of pure mediæval character, the former of more original conception, though based on mediæval example."

* * * * *

"If a suitable monument to George Stephenson *could* be described, it would be described as an architectural canopy—nearer than the heavens—within which, on a sculptured pedestal dated by his inventions, artistically and perhaps somewhat emblematically arranged, would stand the man himself as he appeared in the midst of us. His whole form should be faithfully exhibited. His physiognomical expression should be represented with photographic fidelity in the marble; and even his peculiarities of dress and posture should also be accurately

* 'The Stephenson Monument: What should it be?' By Thomas Oliver, architect. Newcastle-upon-Tyne. 1858.

Digitized by Google

delineated. He should not be too young to appear a prodigy of success, nor too old to indicate natural decay. His attitude should be that in which his physical constitution rested, and his features should reveal his clear and manly intellect. Above him should be *our* work, erected by our labour and cost; around him emblems of his own work, and of his extraordinary success; while, symbolising the healthful influences of his example and career, streams of crystal water should issue in a perennial flow from granite fountains for the welcome benefit of all!"

WORKS AT EXETER COLLEGE, OXFORD.

Among the most important and extensive architectural works of the day are those now rapidly approaching completion at Exeter College, Oxford, under the superintendence of Mr. George Gilbert Scott. The great popularity of this college had rendered a great increase of accommodation necessary, and the old chapel had long been crammed with seats, arranged in no very decorous manner, and yet quite inadequate to the requirement of the members of the College, when it was determined about three years ago to build a new chapel and remodel the entire College.

The site, a very noble one, lying between Brasenose-lane and the Broad-street, and bounded on the west by the Turl, was chiefly occupied by two quadrangles—a large one, now commonly called the Old Quad, nearly square, the western side of which extended the whole length of the site in the Turl, and contained the tower gateway; and a smaller quadrangle called St. Helen's, from an ancient church and cemetery which formerly stood there. This quadrangle was separated from the Fellows' Garden by the library. Northward, towards the Broad-street, there was a great confusion of building, &c., consisting of additions to the rector's lodgings, in no particular style of architecture; the "Rector's Garden," an unwholesome little enclosure, carefully guarded by iron railings; the Old Buildings, less commonly known as the Prideaux-buildings, and built originally for the accomodation of foreign students; a fragment of the old city wall with an arch pierced through it; the "New Buildings," ashlar in the street and Gothic, but of brick and no style behind; a variety of offices, another little garden, and a fine row of poplars, the loss of which all old Exeter men regret to this day. The chapel and the rector's lodgings stood on the north, and the hall (a very fine specimen of the revived Gothic of the time of James I.) stands on the south of the old quadrangle.

Of these buildings nothing now remains but the east, south, and west sides of the Old Quad, and the original "New Buildings." All the rest have been swept away. The present arrangement is as follows:—On the site of the old chapel and the rector's lodgings rises the new chapel; the old library has been rebuilt on an improved plan; the St. Helen's Quadrangle has been enlarged by throwing back its north side, and on the site of the miscellaneous buildings and little gardens an entirely new quadrangle has been built, with a tower gateway opening into the Broad-street. The offices have been compressed into a much smaller area, and are entirely concealed behind the east side. The rector's new lodgings are in the south-east angle, and are extended eastward so as to form the north side of the St. Helen's Quadrangle. Lastly, it is intended to re-erect a portion of the old Prideaux-buildings in the gap between the Turl front and the house of Mr. Parker, the publisher; so that old Exonians will not be wholly deprived of the curious wooden oriels the memory of which must be so familiar to them. The arrangement of the site is certainly the best possible, and reflects the highest credit on the skill and judgment of the distinguished architect. The new works are:

1. *The New Quadrangle.*—The alterations were commenced and will for the present end with this. The first step was the destruction of the poplars and the erection of the Broad-street front, which has a very handsome *façade*, but is somewhat marred in its effect by an attempt to make it harmonise with some adjoining buildings which were erected many years ago in inferior Perpendicular. It is not possible to clothe the forms of one style with the details of another, without risk of failure. It would have been better therefore to continue the previous new buildings in Perpendicular of a superior quality. But we believe Mr. Scott is not responsible for the employment of Perpendicularised Decorated. At all events much credit is due to him for the manner in which he has overcome the difficulty; the work in less skilful hands would have proved a failure. The remainder of the quadrangle is of very pleasing character, and is not brought into contrast with the older buildings; the windows, especially those in the west side (now nearly finished) are very gracefully moulded. Within the rooms and stone staircases are admirably arranged and well lighted, and stained glass of a simple description has been introduced with good effect into the windows of the latter. The chapel bounds this quadrangle on the south.

2. *The Rector's Lodging* stands immediately to the east of the chapel. It is a very commodious house, well arranged internally, and highly ornamental to the College. The hall is 30 feet in length, and the dining-room and drawing-room are each about as long. The entrance doorway is a singularly beautiful composition, richly carved and moulded, and with shafts in the jambs. The portion in St. Helen's Quadrangle is very highly decorated, the drawing-room windows having tracery, and very pretty balconies with railings of wrought iron-work arranged in quatrefoiled circles.

3. *The Library.*—The old library was a poor building of a Classical style, and very inconveniently arranged, with clumsy galleries and cumbrous stairs within. The building which Mr. Scott has substituted stands upon the same site, and is acknowledged to be one of the most effective edifices of the kind in Oxford. It is divided by a floor into two rooms, the fittings of which are throughout not only very richly carved but most conveniently arranged. The upper room, which is lighted from above by stone dormers very skilfully treated, is reached by a newel staircase contained in an octagonal turret with a pyramidal capping. It has a fine roof of stained deal, and is of excellent proportions. A wing communicating with the main building on the north is partly used as an Undergraduates' Library. The walls are faced internally with ashlar instead of plaster, an architectural luxury rarely attainable in these days. There is a great deal of carving on the exterior, but no appearance of overcrowding. (A plate of the New Library was given in this *Journal* for August 1858, to which we beg to refer our readers.)

4. *The Chapel*, which extends the entire length of the north side of the great quadrangle, is worthy of a more particular description. Not only is it undoubtedly the finest ecclesiastical edifice in the University, but it is the *chef-d'œuvre* of its accomplished architect. The great roof of noble pitch towers high above the surrounding buildings, and forms a conspicuous object in the distant views of the city; while the tall and graceful *flèche* which surmounts it adds to the number of the towers and spires of Oxford, and is by no means unworthy of its place in that unrivalled group. The plan of the chapel is rectangular, the east end being extended into a pentagonal apse. Its interior dimensions are as follows:—Length 91 feet, width 30 feet, the height from the ground line to the ridge of the roof is 84 feet, to the summit of the vane 150 feet. The area is subdivided into an ante-chapel (the westernmost bay) 20 feet long; the chapel proper 56 feet, and the apsidal sacrarium 15 feet long. It is divided into five bays, including the ante-chapel, which are separated by buttresses of great projection, and well able to support the massive stone vaulting of the roof within. These buttresses are plain beneath, but are richly decorated above with crockets and finials (the carving of which is still in progress), and on each is a niche, intended to be filled with statues gradually as funds shall be provided for the purpose. There is a three-light window, with varied geometrical tracery, in each bay; the windows of the apse are of two lights, and three of the five are to be filled with stained glass of the richest description, which is now being prepared by the well known artists, Messrs. Clayton and Bell, who are old pupils of Mr. Scott. At the west end are a wheel window richly carved and one of two lights in the space between the roofs above. A constructional organ gallery has been built in the lower part of the west wall, which to our mind is the least successful part of the design, as it has an appearance of weakness; but the difficulties of cramming so much into so small a space were very great. Mr. Scott has overcome them as far as was possible. This gallery and the main roof of the building are approached by a newel staircase in an octagonal turret, which adds greatly to the external effect of the chapel, though every one must regret that the small spire with which Mr. Scott intended to have crowned it has been omitted for reasons of economy. The present square outline does not harmonise well with the other outlines of the chapel. The entrance doorway, with a rich pedimental head and tympanum prepared for carving, is on the south side of the ante-chapel. There are niches in the jambs which are to be filled

Digitized by Google

at once with statuary. The interior proportions of the chapel are very noble and striking by reason of the unusual height and the great richness and variety of the mouldings in every part. This will be greatly enhanced on the completion of the works by the proposed large use of shafts of polished marble in the jambs of the windows and as supports to the main ribs of the groining. Devon and Cornwall marbles alone will be employed, and indeed nothing can be more beautiful than the Lizard serpentines of the latter county; but it is proposed in this way to recognise the fact that this College was originally founded by Walter de Stapledon, Bishop of Exeter, for natives of his diocese, which consists of these two counties. A great deal of marble will also be employed in the arcades and reredos beneath the sills of the windows in the apse. The chapel will be divided from the ante-chapel by a stone screen of elaborate and costly workmanship, the munificent gift of the present set of undergraduates. But the main feature of interest in this chapel is the groined roof of stone, the span of which it will be remembered, from the dimensions already given, is no less than 30 feet. Vaulted roofs are rare indeed in modern times, on account of the great expense, and even risk, attending their construction. The few that have been built may be counted up on the fingers. Mr. Scott may well be proud of the Exeter roof, it is worthy of the men who vaulted over the glorious cathedral of the founder, Stapledon, in the fourteenth century. The filling in of the spaces between the ribs has been judiciously varied by the introduction of narrow stripes of a dark yellow stone, quarried at Guyting in Warwickshire, which affords a pleasing contrast to the somewhat monotonous tone of the Bath stone, of which the chapel is built, and will preserve the balance of colour above with that imparted to the walls by the marble shafts below. Externally the roof is covered with Stonesfield slates. The *flèche* is of wood, and will be covered entirely with lead.

Mr. Symm, of Oxford, is the contractor for all the works at Exeter College; and Mr. Buckeridge, architect, an old pupil of Mr. Scott, resident in Oxford, has superintended their execution from the beginning. Both are deserving of the highest praise for the manner in which they have carried out the intentions of the architect.

ON THE APPLICATION OF NATURAL FOLIAGE TO ARCHITECTURE.

By James K. Colling.*

(*Concluded from page* 8.)

After giving many instances of the judicious alterations which might be made in various leaves and flowers, the author said,—

I would particularly wish to point out that there are certain natural principles and forms running through both leaves and flowers, that they follow a regular geometrical distribution of parts, and that the form of leaf or flower follows naturally from the principle—or, if I may so say, from the anatomy upon which it is set out. Thus flowers radiate in threes, as the lily,—leaves grow in threes from the same point in the stem, and are in perfect harmony with the flower, as the anemone,—leaves divide in threes, as in the water avens, clover, and wood sorrel,—doubly triple, as in the columbine,—and further carried on to the greatest intricacy, as we see in the parsley. Flowers again are cruciform, as in the wallflower,—leaves also grow with the same arrangement, as we see in the lilac and the maple. It should be noticed too that that arrangement of the leaves in pairs (called "opposite leaved") extends through the whole anatomy of the plant or tree,—the leaf-buds being formed at the base of the leaves, they also are in pairs; the leaf-buds become branches, all of which are arranged to grow in an opposite manner, the same as the leaves. But there are many accidental circumstances (such as the leaf-bud being destroyed by insects) which in the case of branches prevent the opposite principle from being too strictly carried out, which, if it were, would give the tree too stiff and formal an appearance. So also in alternate leaved plants or trees, it follows through the whole system, and all the branches are alternate. But to continue from what I have called the cruciform arrangement.

We next come to flowers which are divided into five petals, or set out on the pentagonal principle, and this division is again seen in the leaves—they are first divided into five lobes, with a semi-radiation, simply cut out as in the ivy, divided with deep eyes as in the vine, which we again see in the flower of the hollyhock. The lobes again subdivided as in the maple and bryony, —or separated into distinct leaflets as in the Virginian creeper,— and running again into intricacy in the field geranium and other plants. Then we have the seven lobes in the hollyhock,—seven leaflets in the horse-chesnut,—eight petals in the coreopsis,—ten divisions as in the campanula and stellaria,—until we arrive at multiplicity in radiation, as we see in the daisy and sunflower, and in the leaf of the lupin. Further, we see leaves and flowers take leave of radiation altogether. Flowers run into a vast variety of forms (far too numerous for me to attempt to go into), such as the pea and bean tribe, and many others. Leaves branch in pairs from a central leaf stalk, as in the elder and rose leaf, which is carried further in the acacia and ash, and is again subdivided and carried into the greatest intricacy in the ferns. In the leaflets of the acacia we see also the heart-shape form which we observed in the petals of the strawberry and the primrose, —also again in the violet leaf, but formed the contrary way.

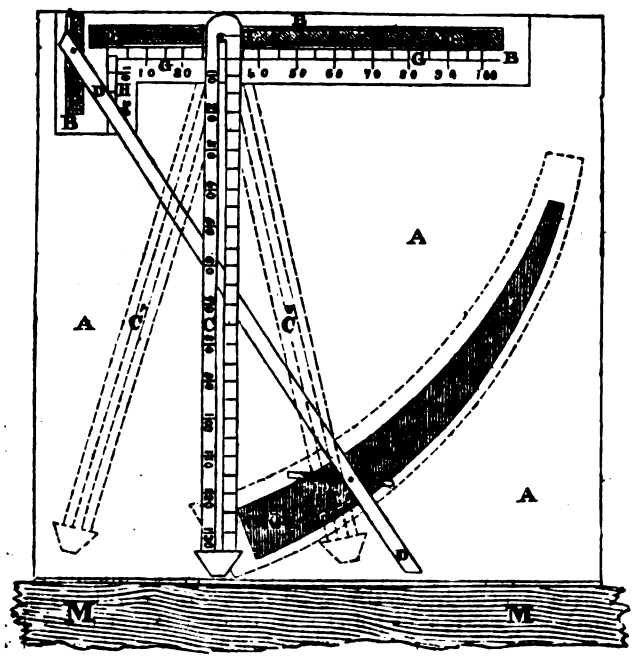
All these facts show that there are certain natural laws, by studying which the artist can produce what form of leaf or flower may best suit his purpose, upon perfectly natural principles, but without following any one leaf or flower in particular—thus giving him such a vast field to work in that there need be no limit to genius or invention.

There are also a vast variety of other forms and objects in nature, beyond those to which I have more particularly drawn your attention, which will present both agreeable and valuable means of study. The observing too of plants and flowers is at the same time one of the most agreeable and pleasant of occupations; in the words of Lord Bacon—"It is indeed the purest of human pleasures, it is the greatest refreshment to the spirit of man," for "God Almighty first planted a garden." Things are never too commonplace in nature for study and observation—

> "There's beauty all around our plants, if but our watchful eyes
> Can trace it 'midst familiar things, and through their lowly guise."

Elegant and graceful form may often be suggested by the meanest weed. What, for instance, can be more beautiful than the clasping of the leaf in the common sow thistle—with the ears of the leaf turned into a spiral form on each side of the stalk. The dandelion has a most peculiar formed leaf, which presents a good study of light and shade. There are also many other leaves particularly valuable for the disposition of the light and shade upon them. Heaths again present some elegant combinations and clusters of bell-like flowers. In other flowers we get suggestions of colour in the foliage or varieties in the form of their flowers; and in sea-weed, another field for study, what beauty and elegance we see obtained simply by branching and forking. One especially, the *fucus serratus*, appears to me to offer a valuable hint for the carver.

Thus we may go on, and let us but follow up this search into the anatomy of vegetation, and it will give us scope and power for invention. If we design fresh foliage, let it obey the laws of nature, and it will not fail of being beautiful. But what is the fact?—how often do we see in modern foliage the very first and simplest law of nature totally disregarded, and foliage made to grow two ways—growing out at both ends at once! What can be more absurd? Yet it is done every day, more particularly in Classic foliage. And as to any natural form or divisions in the leaves, it is never thought of; we are content to go on copying the leaves of the Greeks and the Romans, without ever thinking it worth while to make them at once more natural, or even to get any more variety in form. We look upon it as architectural foliage,—we are willing to accept the conventional forms as being the highest and most beautiful that can be attained; and we completely and purposely separate it, and cut it off from the original source from which those old artists took their ideas. We shut out nature, and go on every day further and further from her. Modern foliated carving should be based upon nature, and nature's laws, as all carving, whatever may be its style, has been originally; but we may and should take ideas from all styles of architecture, but let us not confine ourselves or copy from any. Copy nature in the vast variety she gives us and never-ending beauty of form; and let us have a little of this variety in our architectural enrichments. Its leading characteristics should be elegance of form and beauty of light and shade, whilst retaining all the quietness and repose necessary for its various positions as architectural enrichment.



* Paper read at the Liverpool Architectural Society.

THE KREMNOMETER.

THE name of the instrument, a drawing of which is annexed, is derived from two Greek words, whose combined meaning signifies to *measure slopes*. The purpose which the Kremnometer is intended to subserve is, the setting out the widths of cuttings and embankments on a sloping cross-section, and it may be described as follows:

A A A, the stock or frame of the instrument, consists of a piece of mahogany or other hard wood 9 inches square and 1¼ inch thick. B B B, is a thin plate of German silver, sunk flush with

the polished surface of the frame. C, is a plummet of the same metal ⅜ of an inch broad and $\frac{1}{40}$ of an inch in thickness, having a projecting piece of metal at the end to insure its hanging vertically. There is a slit in the centre of the plummet from end to end, and it is graduated into feet along its whole length, (the drawing shows only every fifth foot) 16 feet to an inch is a convenient scale, and sufficiently large for practice. D D, is the slope bar of the instrument, ¼ of an inch wide and $\frac{1}{50}$ of an inch thick. E E, is a groove cut in the frame, in which the pivot-block L—on which the plummet is suspended—moves up and down. F F, is also a groove at right angles to the other, in which the centre of the slope-bar moves. G G and H, are scales of the same graduation as that on the plummet. The scale G G must be perfectly parallel to the sole-plate of the instrument; and the scale H exactly at right angles to the same. K K, is a slit cut in the frame with a shoulder on each side, which, with the cross-bar shown in the engraving, serves by a clamp-screw to keep the slope-bar at any slope to which it is set. M M, is a straight-edge of wood, from 10 to 20 feet long, 6 inches broad, and ½ an inch thick. It is not attached to the instrument, but serves for placing it in proper relation to the slope of the ground.

The method of applying the instrument may be briefly described. First, fix the slope-bar at the required slope of the work to be set out; this is done by having a mark at the bottom of the instrument, perpendicularly under any point, say 30 on tha scale G G. Lay the plummet over this line; then place the slope-bar at the half-width of the formation level of the cutting or embankment, shown on the scale H. This half-width, added to the ratio of the slope to the base, will show the half-width of a horizontal cutting on the plummet scale at any depth of cutting to which the plummet is set. If, as in the engraving, the half-width of the formation level be 15 feet, and the slope 1½ to 1, then a cutting of 30 feet deep of a horizontal cross-section gives a half-width of 60 feet. The scale H, which represents the formation, is counted from a point the same distance from the edge of the groove E E, as the centre point on which the plummet swings. When the slope-bar is adjusted it is fixed by the clamp-screws behind the slits K K and F F. Unscrew now the clamp which holds the sliding block L, and place the plummet on the scale G G, at the depth of the cutting or embankment where the slopes are to be set out, and there screw it tight; then place the straight edge M M along the slope of the ground and set the instrument upon it. According to the amount of slope the plummet will hang, for example, at C, and the reading on the scale where it cuts the slope-bar is the width for one side measured—not horizontally but along the straight edge or slope of the ground. Now turn the instrument half-round, and the plummet will hang as at C″, and the reading on the plummet scale where it cuts the slope-bar, as seen through the slit in the plummet, will be the width for the other side. Proceed to the next point; and again setting the plummet to the depth shown in the section, lay out the widths as before.

It would occupy too much space to enter into an investigation of the principle on which the instrument is constructed. It may simply be mentioned that whatever arc of a circle the straight-edge or slope deviates from the horizontal, the plummet describes the same arc.

Those who are acquainted with the ordinary methods of setting out widths on sloping ground with the level need not be told how tedious the process is; and although the instrument described will not supersede the level in all cases, yet where the slope is regular or nearly so, which it generally is, the Kremnometer will enable at least twenty times more work to be done than could be done by the level alone.

Sir John Macneil's instrument for the same purpose, a drawing and description of which are given at the end of his Tables of Earthwork, requires that the angle of the slope be found for it by a separate instrument,—a process nearly as tedious as that of setting out the widths at once with the level.

The Kremnometer is the invention of Mr. A. S. Wilson, C.E., Aberdeen, and is manufactured by Messrs. Smith and Ramage, of that city.

DURHAM CATHEDRAL.

IT has been decided to restore the whole of the upper stage of the great central tower of this cathedral, and to replace the present parapet by one somewhat different in design, and more raised above the cornice. The four angles appear to have been intended to carry each a large pinnacle, but it is uncertain whether they ever did so; there are no prints extant which show anything of the kind, nor is it now intended to carry out this feature, inasmuch as pinnacles would at least interfere with, if not destroy, the simple grandeur of the tower as it now exists. Although the squinches and corbelling will of course remain within the belfry stage, externally no indications will be evident beyond building up a solid pier to the height of the new parapet, and capping it just above with a plain cope moulding. The new parapet will, like the old, be perforated. The lower parapet to an open gallery which runs round the outside of the tower at the foot of the belfry windows will be entirely new, and of more appropriate design than the present one, and it is intended thoroughly to restore the whole of the eight windows, and to substitute the best stone for the cement, with which the general facing of the walls and many of the architectural features have been repaired. From the great height of the tower these contemplated works will involve considerable practical difficulties, and be attended with a proportionate expense, roughly estimated at between 5000*l.* and 6000*l.*

THE ARCHITECTURAL EXHIBITION.

THE near approach of the period fixed for the re-opening of the Architectural Exhibition in its new, and let us hope permanent, quarters, appears to be stimulating the committee to renewed exertions in obtaining from the profession that important co-operation which will enable them to inaugurate the coming season with a goodly array of choice drawings. We earnestly hope that their appeal will be successful, and that the efforts which have been made, and so praiseworthily too, by a few thoroughly zealous individuals, will be cordially seconded out of doors. It is with no small satisfaction that we learn the pecuniary results of their last year's labours; for, despite of the unforeseen delay in opening (caused by the alterations in their *then* gallery being incomplete), the balance sheet for the season

Digitized by Google

is reported to exhibit, not merely a cancelling of outstanding liabilities, but a surplus in the honorary treasurer's hands of about 40*l*. This is indeed encouraging!

A recent inspection of the new galleries in Conduit-street, warrants the expectation that they will prove in every way suited to their purpose; for though the walls were mostly in a rough state, and very little appearance of finishing was anywhere discernible, it was not difficult to perceive that the proportions of area and wall space, and the all-important item of lighting promise well. The latter is derived wholly from above, by means of skylights—in a handsomely ornamented ceiling of curved form—which extend the whole length of each room, and which are filled with large sheets of deadened glass, imparting a subdued yet sufficiently cheerful tone. Concerning the other architectural decorations, &c. we must reserve our remarks till all are completed, but we may state that, externally, all has been done that was contemplated, virtually little more than a thorough renovation of the old building, which, being of the good old-fashioned school, and, moreover, the well-appointed residence of successive persons of distinction, possessed in itself several features of architectural though unobtrusive character.

SUGGESTIONS FOR THE IMPROVEMENT OF LONDON, AND FOR NEW PURIFYING SEWERS FOR THE THAMES.

An ingenious French architect, M. Horeau, who has now for some time been resident amongst us, has during the past month been submitting to the examination of members of the profession and others invited for the purpose, at the Hanover-square Rooms, a great variety of schemes devised to ameliorate the condition of our great city. Of these propositions generally it is enough to state that they evince an immense deal of study and patient application, so far as planning goes, with some amount of talent in the design of the different groupings (albeit the fanciful, and we should fear the unstable, engross a larger share); but that the magnitude of the schemes, and the enormous outlay that would be requisite in carrying them out, would alone present, we should say, insuperable obstacles to their accomplishment. Some of these ideas it may be remembered were embodied in the author's designs for the new Government Offices; these were now re-exhibited among the rest of the drawings, with an ingeniously written explanation. We observed also M. Horeau's designs submitted for the universal Exhibition of 1851, and a plan, sections, and elevation of that proposed for the Paris Exhibition. In all there were thirty-six drawings, all bearing the stamp of originality, while many possessed greater recommendations.

One subject to which the author seems to have paid much attention is the sewerage of London, and he has conceived a project for the construction of new purifying sewers for the Thames, which in these days of sanitary improvements it may not be amiss briefly to describe, without pronouncing any opinion on its merits.

Among the objects proposed to be attained are, to avoid the difficulties of levels; to avoid expensive engineering; to avoid the formation of an offensive deposit as well as the reflowing of sewage towards the metropolis. The intended sewers would consist of a vault of sufficient capacity to enclose four iron gutters or "rivulets" (two large and two small) supported by iron bearings independent of the construction of the vault; these rivulets to be constructed at different heights in order to facilitate their junction with the present sewers (which are at different levels) and to have a slight fall; they would also be divided into as many basins as would be required by fixed sluices, open only at their summits for the purpose of receiving deposits; this would not arrest the ordinary current. Moveable pipes or gutters would be provided to carry into the adjoining rivulets the first matters which are not to be received in deposit, either to remove the manure or to allow of repairs. The purified water which could be obtained in a short time at the summit of the deposits might be conducted into the Thames, especially should this water be made to pass into channels containing purifying agents. Underneath the purified water would naturally be found the liquid manure, and after this is drawn off there would remain at the bottom the deposit of solid manure; this should be covered with lime or alum to preserve its quality and facilitate its being put into casks, the casks, being raised by pulleys, could be placed on one of the three railways (with moveable floor) placed above each other between the rivulets. The railways might be made serviceable in various other ways. Six galleries (three on each side of the vault) would be appropriated to the inspection of the junctions of the old sewers, to the proper disposal of the raw matters to separate into the various rivulets, for fixing and repairing the numerous water and gas pipes, &c. &c. Moveable scaffolding, ladders, syphons, pumps, cranes, and the like, could be made available inside in different ways, thus avoiding to a great extent the obstructions along the public way which the present system usually entails. The sewers would be lighted by jets of gas, which could be further assisted by daylight, by reflectors, or by the apertures occasionally necessary above.

ON THE APPLICATION OF CHARCOAL TO THE VENTILATION OF SEWERS.

The subject of the ventilation of sewers has from its importance been constantly ably discussed by both theoretical and practical men as well as members of the engineering and medical profession for many years past, but does not appear even yet to have reached a satisfactory settlement. In a valuable report recently made to the Commissioners of Sewers by their engineer, Mr. Haywood, "on the application of charcoal to the ventilation of sewers," that gentlemen quotes the suggestion to the commissioners by their medical officer, Dr. Letheby, of the application of charcoal to ventilation, as follows,—

"Now in making a practical application of these facts, it is manifest that we have in common wood charcoal a powerful means of destroying the foul gases of sewers. How it is to be applied is fortunately a question of but little embarrassment; for let the sewers be ventilated as they may—either by open gratings in the street, or by the rain-water pipes of the houses, or by the pillars of the gas lamps, or by tubes carried up at the landlord's expense from the drains of every house, or by especial shafts in the public streets,—in fact, let the gases go out of the sewers how they will and where they will, you have but to place a small box containing a few pennyworths of charcoal in the course of the draught, and the purification of the air will be complete. As far as we know, the strength and the endurance of this power is almost unlimited, so that when once the air-filter has been set up it will last continuously for years. Its action also upon the draught is not particularly injurious; and I have no doubt that the temperature of the sewers, and the agencies which are now at work in circulating the air and ventilating them, will be sufficient to keep up a current of foul air through the filters; and if these were multiplied to a large extent, the friction of the gases upon the charcoal would be reduced to an insignificant amount."

Mr. Haywood proceeds to remark,—

"The system suggested is in fact to place a sieve or strainer of charcoal across every ventilator and gully to the sewers, through which the air shall be filtered and deodorised as it escapes. The effectual application of these sieves will, I apprehend, neither be so easy nor so cheap as may be anticipated.

I have shown in my report that the number of openings to the sewers within the city is 47,819: these openings are from ventilators, gullies, sinks, waste-pipes, water-closets, and rain-water pipes; through the whole of which at times, it is perhaps not too much to say, effluvium escapes into the atmosphere, and any system only half does its work which does not deal with the whole of them. There are 2810 gullies and 1065 ventilators in the public way; it is owing to the escape of effluvium from these that the public experience the greatest annoyance, and from the latter especially, because from their area it escapes in larger quantities at one spot. Whether these 3875 are worse in their effect upon the public health than the other 43,944 openings I offer no opinion.

The application of charcoal to the existing street ventilating gratings may be made in two ways:—

Firstly,—by reconstructing the ventilators at the heads in such manner that the air must pass through the charcoal sieves before escaping, the gratings remaining placed as now at the street level. A simple mode of reconstructing them for this purpose has already been suggested by the surveyor to the Hammersmith Board of Works (Mr. Bean), who, with the medical officer (Mr. Burge), some time since commenced experimenting upon the

Digitized by Google

prevention of the issue of effluvium from the street ventilators by means analogous to that suggested by your medical officer.

Secondly,—by removing entirely the present ventilating gratings, and connecting the shafts with pipes to go up the fronts of the houses to a convenient height, where they may terminate in chambers having charcoal sieves and escape outlets above; it would be a waste of money to carry these far above the street level, for unless the action of the charcoal is uncertain no nuisance can possibly accrue.

Of the two the first will be the cheapest in adaptation,—the second the readiest for the purpose of inspection, and I think, upon the whole, the best.

Dr. Letheby considers these charcoal sieves will not be particularly injurious to the currents which now circulate in the sewers and aid in ventilating and purifying them, and enable workmen to continue in them. Future experience must determine this; but I am of a contrary opinion, and think it more probable that three or four ventilators will be required where there now is but one, unless the sewers are relieved more freely by the house drains and untrapped inlets than at present.

To the increase of the number, should my opinion prove correct, there will be no practical difficulty; it will only be a matter of expense, but it will be found in all cases cheaper and more convenient to bring the additional ventilating tubes up in front of the houses than to terminate them at the street level.

But a better mode will be to adapt the lamp columns to the purpose, as not only would all question of the right of placing the tubes up in front of the houses be avoided, but the charcoal sieves might be made more accessible and less obtrusive, and the heat of the gas when burning would aid the functions of the shafts as eduction tubes, and, as these gas columns are about 750 in number, they will supply situations for that additional number of ventilators. To effect this the whole of the gas columns must be re-modelled, or rather gas columns of an entirely fresh design must be cast.

But, assuming that charcoal has all the virtues ascribed to it, it follows that stench of any sort need be no longer feared, as its destruction, when the charcoal is properly applied, is certain; and very large openings to the sewers might be made at convenient situations, many of which at once suggest themselves to me,—as near to the public urinals, and at the existing side entrances, and by special shafts erected at the intersection of streets, and by cab-stands, &c., so that all fears of preventing the circulation of air in the sewers may be allayed, and it will only become a question of how many openings will be needed, and their cost.

With regard to the gullies I see no means at present of applying it in such manner as that it shall be easily accessible, and not either impede their action or become impeded in its own purifying action, so that the gullies must remin as they are, and whatever harm they now cause to the public health will continue nevertheless. Nor can I suggest any convenient means of applying it to the thousands of inlets to private houses; something might be done by those inhabitants who would be content to erect special ventilating tubes from their house drains to their housetops, and undertake to have charcoal placed and maintained there; but I fear the large mass of the inhabitants will not take that trouble or go to that expense: and I can scarcely conceive that domiciliary visitation by officers to an extent to insure its being done effectually would be tolerated by the inhabitants of the metropolis, largely accustomed though they now be to official interference with so many of the physical conditions of their dwellings.

The cost of adapting the existing ventilators would be about £6400 for the whole city; the cost of constructing additional ones perhaps may amount to £15,000 more; the annual charge for inspection, reparation, and renewal can be alone determined by experience; but indeed the whole question of cost cannot be approached with anything like accuracy until an experiment of some magnitude, and carried on for a length of time, be made, nor does it seem to me that the results in any way can be satisfactorily arrived at without one.

Placing the charcoal sieves before one or two ventilators as an experiment will be practically of no value whatever, for the absence of effluvium in the streets is not the only thing to receive consideration; the nuisance must be remedied, if remedied at all, without rendering the interior of the sewers more heated or dangerous than at present. Reducing the nuisance from one or two street ventilators, and remedying a small local nuisance, will help you to but little, because you have it already, upon the authority of your medical officer, that stench of every sort and description, and of any magnitude, may be destroyed by the charcoal, and what you require to know is how to apply it.

But it should be clearly understood that this system, if applied, will only remedy a portion of the evil; it may prevent the issue of stench from the street ventilators, but nothing more; it will leave the house drains and all other inlets in the same condition as at the present time. If therefore the committee consider that the result to be gained will be commensurate with the estimated cost, the proper way will be to select a limited district, adapt the existing ventilators in the first place, add to their number, and perfect the system to such an extent as may be practicable, and watch and record the results before adopting it for the whole city; and this course I beg to recommend."

ON THE PAINTING OF THE ANCIENTS.*

By F. P. Cockerell.

I FEEL, as an architect, that in bringing before an architectural society the subject of colour, which, however graceful, must be considered the least important branch of architecture, rather than the graver considerations of form, proportion, composition, &c., I owe some apology; but, as a lover of the picturesque, and having in my travels given some attention to painting in its various branches, I venture to offer you some remarks upon this highly attractive branch of our art.

Though colour is not in all cases indispensable to architectural effect, yet its value cannot be doubted as affecting architecture in general, and the true understanding of its application is hardly less difficult than that of the more serious branches of the art. Yet it must be remembered that the great masters of architecture whose works are our text-books,—Alberti, Vignola, Palladio, Phillibert, de l'Orme, &c.—have treated it as a comparatively secondary art, in a measure separated from the more grave consideration, and leaving it to the painter and the decorator.

Vitruvius speaks of it at considerable length (7th book, cap. v. to xiii.), but it is in reference to interior and not at all to exterior decoration. This distinction is of the greatest importance to mark in considering the application of colour, for upon it the chief merit of the question may be said to turn.

The use of colour in interiors has been adopted in all times and countries, and the reasonableness of the practice cannot be doubted; but in the best times of art, in the northern countries, its use in exteriors has been rejected in a great measure.

The consideration of the subject of polychromy is of comparatively recent date: it is now the fashion of the day, and let us beware how we abuse it, or attempt to hide by ornament the want of art, subverting the practice of our forefathers, and attempting pedantically to introduce into our own practice that of countries whose conditions are entirely different from our own.

Therefore, in treating the subject of ancient polychromy, I do not mean to advocate its adoption in this country, but rather by considering the works of the ancients, those great masters of common sense, to endeavour to follow their reasoning, which is so admirably adapted to their conditions and climate, to draw some conclusions with reference to our own.

All good art may be said to be a translation, more or less direct, of the book of nature, and there is no chapter in that book so largely treated, or so imperatively forced upon our consideration, as that of colour. Nature is lavish of colour in all her works, and delights the eye with her harmonies in all her operations: from the golden glories of the rising or setting sun, to the pencillings upon the back of the tiniest beetle, all is harmonious and all variety.

The whole face of nature speaks to the lover of the beautiful by colour in the earth, in vegetation, in animal creation, and in the endless variation of accidental colour, in sunlight or in clouds. Even the unseen depths of the ocean are full of objects exquisite in colour—seaweeds, shells, and the glorious rainbow hues of fishes.

And the various objects of creation have further varieties in their own species. In man, how various are the combinations of colour: the dark hair and olive complexion, the blonde hair, blue eyes, and ruddy skin, the rich auburn and the golden red;

* Paper read at the Architectural Museum.

Digitized by Google

and the true artist will surely set aside the conventional contempt of dark skin, and will find in the negro and the Indian subtleties of colour hardly inferior to our own.

So lavish is nature in her distribution of colour, that she does not confine it to her own works, but even to the conventional works of man she imparts by a few years of exposure to her influences of atmosphere and climate, a complexion whose harmony no art can approach.

From the poles to the tropics all is colour, but as nature has varied the conditions of climate and situation, so she has graduated her distribution of colour.

In the poles, amid eternal snow and under a pale sky, nature has made all her objects pale or white,—there is no brilliant vegetation—birds and animals are all grey and white, and offer but little contrast to the surrounding scene. As we advance towards temperate climates, we find bright vegetation, and a greater variety and deeper colour in animal creation. In those countries where the sky is always blue, there is a further increase in colour, until finally in the tropics we find gorgeous flowers and brilliant birds, and great jewelled butterflies, dazzling to the northern eye. But, however opposite are the combinations of colour in the poles or in the tropics, the result is the same—harmony.

And this harmony, established by nature in each latitude, affects the eye of the inhabitants, and the result shows itself in their habits, and in their choice of colour in dress, and in all objects of every-day life.

When an untravelled person sees a case of South American birds, or hears a description of the gorgeous colouring of the jungle swamps, he imagines that such contrasts of colour cannot be otherwise than discordant; but the sober greens and greys of the north, his model of harmony, would appear tame and colourless under a southern sun.

Everyone who sees with a painter's eye will have observed that the relative value of contrasting colours under a grey or neutral light, and under a brilliant sun, are absolutely changed; and that contrast which, upon a cloudy day, would appear harsh and discordant, is subdued and harmonised by the rays of the sun. Besides, sunlight introduces a new element into colour—namely, light and shade, with its endless variety, from the cold-cast shadow lighted by the blue sky, to the warm reflection from a lighted surface; so that local colour loses a portion of its importance, and contrasts become less violent.

This is a consideration of the greatest importance in judging of the system of colour adopted in those countries where polychromy took its rise and reached its maturity, and which are now more particularly under our consideration.

Besides, in those countries the blue sky, the varied hues of the mountains, the sea, &c., form a background so brilliant that, unrelieved with harmonious colour, white in architecture would be ghostlike and crude.

Having then prefaced with these considerations, and recognised nature as our mistress and the source and fountain of all our inspirations, following her by analogy and not by direct imitation, let us proceed to consider the works of the ancients, and compare them as best we can with nature.

It is not our province here to attempt to deduce from her countless varieties any system, or to establish any rules, to reduce the infinite within the compass of the finite. This has been frequently and most ingeniously attempted by different authors, but the result has been necessarily insufficient, and such, that the first natural object that came to hand would furnish an exception to the rules laid down.

The prism is a measure that lays open to us nature's system of colour; but it is in itself a disquisition so profound that we can add nothing to it, nor can we vary it so as to suit our various requirements. Without stultifying its harmony, we must therefore humbly accept it as it is, acknowledging that we are incapable of appreciating all that it teaches, and that to imitate what we do appreciate is infinitely beyond our limited means of execution. A satisfactory theory, therefore, is a thing unattainable; let us, therefore, attempt to lay one down, but let us reverentially turn to the works of the great fathers of art, and endeavour, by following their progress from the earliest times, to discover—first, whether their works do agree with our hypothesis; and if so, what may have been their interpretation of nature's teaching.

We cannot pretend positively to follow the reasonings of the ancients, or to look with their eyes into the book of nature. It is possible that we may imagine analogies with nature where none were intended; but if such analogies can reasonably be instituted, it is some proof of the correctness of the principle contained in the work of art (and if the work be good, *vice versâ*). I would therefore only suggest, in following the development of art, such points as appear to agree with our hypothesis.

The earliest style of pictorial decoration known to us is that of the Egyptians. We shall, no doubt, find in their works a certain following of nature; but the analogy with her goes no further than that first principle which dictates that there shall be colour in everything. The mode of producing this colour is for the most part by copying of natural objects—as birds, beasts, serpents, &c., or heroic or domestic subjects. No doubt these early paintings (to the repetition of which tradition bound the Egyptians of even the later times) were the nearest approach within their limited means to a direct imitation of those objects. And though we must not lose sight of the fact that these objects were naturally chosen as entering into their religion, the comparative scarcity of conventional ornament, or the absence of a regular system of lines adapted to architectural forms, seem to show a rudimentary state of art.

Those ornaments which are conventionalised are still closely imitated from nature, as the lotus cap, the papyrus, the palm, &c. And though this cannot be considered otherwise than a merit, I point to it only in contradistinction to the refined conventionality of the Greeks.

The colours used are glaring, and in crude contrast, without gradation or harmony. The modesty of nature is lost sight of, and her principle of universal colour interpreted by the use of universal paint.

I pass over thus briefly the Egyptian period, because, although the art of the great times had its origin in the teaching of Egypt, there is very little in itself that shows a high artistic cultivation, or that can serve as an example for us. The striking quality of the monuments of Egypt is of another, and indeed of a higher order—namely, simplicity and greatness of material and of execution, which conveys such a sense of the mechanical power of the people who produced them.

The next period of art—namely, the Greek—may be said to embrace, if not the birth, at least the first forward step, the progress and perfection, the decline and extinction of Classical taste.

It is in the Greek works that we find the first germs of that taste which reached its culminating point in the age of Pericles; and the art of the Romans, however debased, is still formed upon the Greek traditions, which were handed down till the deluge of barbarism swept away what little of good remained, and sowed the seeds of another style, which, faithfully following nature, as the Greeks had done before, ran a course not less glorious than them.

We have mention in history of periods of whose art no vestiges remain. Traditions, repeated by Diodorus and other authors, speak of the works of the first Dædalus (for three are mentioned at various times). Some antiquaries have endeavoured to give a reality to this mythic father of Greek art, and have supposed him to be a contemporary of Theseus, and placed his existence in the fourteenth century before our era. Probably he is simply an ideal impersonation of art, as Theseus no doubt may be of the heroic character. But this is mere curious antiquarian speculation, and has no bearing upon the history of art.

Of the earliest Greek works known to us, perhaps the most important are the temples of Selimentum, in the south of Sicily, This great and flourishing Greek colony was founded about the year 650 before our era, and was destroyed in 409 B.C. There are seven temples remaining, and the best authorities consider that the first and the last of them are about parallel with the commencement and end of its existence.

I cannot speak positively of any remains of colour in the architecture of the earliest of them, but there can be no doubt that there was colour, from the fact that the metopes are painted.

There are very distinct remains of colour in the other temples. The Duke of Serradifalco, in his work upon the temple of Selimentum, says,—"The excavations carried out in the temple E, and the œdicule B of the Acropolis (see his work, plate 2) gave new and more evident testimony of this sort of ornament. There remains of the first many trunks or columns coated with the finest white plaster, and one of them still retains three horizontal zones, each of which is successively painted with red, white, and blue. The listel of the architrave is red, that of the guttæ blue.

Digitized by Google

The triglyphs painted blue upon the face with black channels. The astragal (?) of the capitals red; and to the posticum of this temple belong certain mouldings in terra-cotta of a yellowish colour, with frets and other ornaments painted in red and dark grey. From various fragments we learn that, as in the Parthenon, the ground of the metopes is blue; and upon the arm of the female figure (plate 32 of the work) one discovers some traces of red, which colour as well as blue is much more clearly discoverable in a fragment of drapery found in the posticum of this temple. Nor should we here omit to mention the very singular circumstance that we find the cap of one of the triglyphs first painted red upon the stone, afterwards coated with stucco, and at last repainted with the same colour. We have more important remains of the œdicule B, namely,—the trabeation of the south-west angle, one of the lions' heads of the cymatium, in which there remains still the sinking prepared to receive it; one angle and various fragments of the pediment, the whole cap of the ante, the lower portion of the shaft of a fluted column, with part of its Doric cap, and several fragments of minor importance. From the observations made upon these remains we find that the whole fabric was coated with a very fine stucco of a pale yellowish colour, the listels of the architrave, of the bed-mould, of the corona, and of the mutules; the last blue with white guttæ, blue also are the triglyphs and their fascia, which is divided into two by a very fine line. The capital and what remains of the ante is of a yellowish tint, and all the sunk lines are marked with a fine black line, so as to give more effect to the other mouldings."

M. Hittorff, a received authority upon the antiquities of Sicily and author of the ingenious work 'L'Architecture Polychrome chez les Grecs,' goes much further, and launches very far into the ideal. Indeed he does not pretend to confine himself to the facts found in the ruins of this temple, but unites fragments and authorities from other temples in Sicily and elsewhere to produce his ideal of the Greek system of Polychromy. Perhaps his enthusiasm may have carried him somewhat beyond the bounds of probability in his opinions. A reference to this work, and to that of Serradifalco, will enable those who are interested to judge how far his opinions are borne out by reason and by facts.

The temple of Jupiter, in the island of Egina, supposed to be about forty years earlier than the last of the temples of Selimes, which in architectural proportion and refinement is a step in advance of those of Selimentum, still show very clear traces of colour.

The best authorities have established that the triglyphs were painted blue, the tœnia red, the mutules blue; their fillet and the rest of the soffit of coronæ red; the cymatium enriched with a honeysuckle in gold; several mouldings and the soffit of portico painted, &c. There is no evidence, nor do the best authorities conjecture that the broad surface, the shaft and caps of columns, or the wall of cella, were painted.

The large patches of blue presented by the triglyphs appear crude and unhappy, and little in accordance with the refined taste of the artists of Egina, but we find an explanation of this in Vitruvius, where he tells us that in the early wooded constructions the ends of the beams (the triglyphs) were covered with a board painted with blue wax to preserve it from the action of the weather; and, as we find in other temples where there are traces of colour, that the triglyphs were likewise blue, it is clear that this ancient practice was carried into later times, as a tradition which popular prejudice and a religious reverence for antiquity insisted upon preserving. In the sculptured parts there are undoubted evidences of colour; the shields and the crests of the warriors were painted red, parts of their arms and armour gilt, while the tympanum of the pediment was blue.

The frieze of the mausoleum of Halicarnassus, though of a date about 180 years later, is treated in the same way; and the last discoveries show that the lions' mouths were picked out with red.

No one can doubt the value, and indeed the necessity, of such a distribution of brilliant colour to give relief and interest to the otherwise monotonous blaze of white standing out in strong relief against the deep blue sky, and having no interest of colour to bring into harmony with the brilliant scenery.

But at this period in the progress of art, the refinement of study being directed to the perfecting of form, we may fairly suppose that where so much love and study as were required to produce the Egina marbles had been expended, the result would be considered of higher importance than colour, which, from being so constantly repeated, could scarcely have ranked with the other branches of architecture, and must have been treated as a matter of mere traditional practice, as was no doubt the case in the painting and sculpture of Egypt.

It is important to observe that in the cases of Egina and Halicarnassus the colours are made entirely subservient to the sculpture, and so distributed as to assist materially in giving relief to its forms. There is no painted detail (in the sculpture), no ornament or variety of colour to arrest and give occupation to the eye. It is the inferior and less interesting portions which are coloured, and that with uniform tints, producing that sparkle which is so essential to pictorial effect, and leaving the nobler portions—the human form divine—untouched, and indeed assisting and giving expression to them by contrast.

And here it is desirable to observe that some picking out is more an optical necessity under a southern sun than we can imagine in our tame light. Those who have studied in those countries will have found over and over again a difficulty in distinguishing forms upon a background of the same colour, from the violent contrast of intense blazing light and black sparkling shadows, which dazzles the eyes and causes the half tints to disappear. In the tangled intricacy of the frieze of Halicarnassus, being as it was at a considerable distance from the eye, this would be particularly the case.

In this principle of aiding form by colour we may find an analogy with nature in most of her works. For instance, in flowers the sinking of the calix is marked by getting darker or lighter, and the forms of shells are constantly marked in the same way. The eyebrow seems to have no other purpose than to give expression to the form of the brow, &c.

But in our own convenient works of architecture nature's working in this respect teaches a lesson in the plainest terms and in no parable. Soffits take a rich warm tint, and upper surfaces of salient parts a cold and pale grey, which comes out in strong relief against the varied tints of the vertical surfaces.

(To be concluded in our next.)

THE GREAT EASTERN.

THE preparations necessary for fitting this noble vessel for sea have at last been decided on, and will be immediately carried out. To one contractor will be entrusted the iron work still requisite in the hull and in the construction of the poop and masts, while separate contracts will provide for the rigging and sails and the cabin fittings and joiners' work. No money will be wasted in the mere frippery of decoration, though at the same time all the fittings will be of the best and most substantial kind. The design for the poop is complete in all its details. All of it will be constructed of iron, and some idea of its size may be gathered from the fact that the chief dining saloon, 120 feet long by 47 feet wide and 9 feet high under the beams, will be in that part of the vessel. There is to be a large number of bath-rooms allotted to each class of passengers, all of which will be kept supplied with hot and cold fresh and sea water. The contractors are to commence their work on the 15th instant, and are bound under penalties to complete all in five months from that date. The long-expected first trial trip will therefore take place about the middle of July, when it is intended to run out from Weymouth to the middle of the Atlantic and try the ship under all possible conditions of sail and steam. This short voyage will probably occupy about six days, for the lowest estimate yet made of her speed allows her 17 knots, or about 18½ statute miles an hour, the speed of a parliamentary train. The commencement of the work of fitting will be made by which the large iron floating Derrick launched last autumn will be used for the purpose of hoisting in the main shaft of the paddle engines and the rudder. The former weighs 40 tons, the latter 13, and each of these ponderous masses of iron work have been finished off with as much care and even neatness as if they were intended for the works of a clock. Both these will be deposited in the fore part of the vessel in order to assist in bringing her more down by the head when the blades of the screw are being fixed. The latter have not been attached to the screw bars, as in case of ice during the winter enough might have formed round them to have held such a mass of the loose pack as with the flow of the tide might have seriously endangered the ship. Trotman's anchors, by which she is now moored, would never have given way; but the chains unquestionably might.

A MODE OF CONSTRUCTING CANNON, WHEREBY THE STRAIN PRODUCED BY FIRING IS DISTRIBUTED THROUGHOUT THE MASS OF METAL.

By Capt. T. A. Blakely, R.A., M.R.I.A.*

It has long been known that increasing the thickness of metal in the cylinder of a Bramah press does not increase its strength beyond a certain point. The failure one after another of the huge presses used in launching the Leviathan, under a pressure of less than five tons to the inch, must be fresh in the memory of all; yet the thickness of metal in some of these was as much as 7½ inches, the diameter of the piston or ram being only 10 inches: the tensile force of 15 inches, two thicknesses each 7½ inches, being thus opposed to a pressure on only 10 inches. This small proportion of pressure has always been found sufficient to burst a cylinder.

The cause of this weakness, which equally affects cannon, is even now but very little known, although it was distinctly pointed out by Prof. Peter Barlow in a paper read to the Institution of Civil Engineers many years ago, and published in the first volume of their 'Transactions.' As that paper is in the library of this Institution, I need only refer to it very briefly.

Prof. Barlow proves that the outer portions of a cylinder have comparatively little strain transmitted to them, and therefore add little to its strength. He bases his argument on the well-known law,—that metal subjected to a moderate tensile strain stretches in the direction of the strain, and very nearly in proportion to it; that is to say, if 1 ton will stretch a bar of a certain length 1 inch, 2 tons will stretch it 2 inches, or 6 tons 6 inches. This is generally known as "Hooke's law" *ut tensio sic vis*, and has been found by experiment to be very nearly correct. Prof. Barlow argues that fluid pressure from within a cylinder must stretch it. That it really does so in a gun or rifle is easily proved by placing a leaden ring round one: if it fit tight before the piece is fired, it will be loose afterwards.

No known material is capable of exerting a tensile force without stretching. The amount of stretching in many materials is so well known that it can be used as a measure of the tensile force; this is the case with iron.

Now a moment's reflection must convince any one that the outside of a thick cylinder cannot stretch as much as the inside. If it did the mass of metal or other material must be increased during the strain. Let us consider, as an example, a cylinder the size and thickness of the strong part of a 10-inch gun, 10-inch bore and 10 inches metal round it; and let us imagine this cylinder to be made of homogeneous india-rubber. In this case the inner diameter might easily be stretched to double its size, becoming 20 inches instead of 10.

Now it is evident that the outside circumference and diameter cannot be doubled at the same time, or else the latter must become twice 30 or 60 inches, which would give a thickness of 20 inches, quadrupling the mass of material,—which is impossible.

A moment's reflection shows that the thickness must diminish as the circumference is increased by pressure from within; for, if the thickness remain 10 inches when the internal diameter has become 20, the external diameter must be 20 plus twice 10, or 40 inches.

This could not be, unless we imagine what seems impossible, viz., that the bulk of the material is considerably enlarged, as each inch in length of the cylinder would now contain 1200 cylindrical inches, (the difference between the squares of 40 and 20, the external and internal diameters), whereas, originally it only contained 800 inches, the difference between the squares of 30 and 10.

Yet, even if the thickness could remain the same, notwithstanding the increase of circumference, the outside layer could only be strained one-third as much as the inside one, because three times as long. The same elongation which would cause a strain of 1 ounce or 1 pound in the longer circumference would cause a strain of 3 ounces or 3 pounds in the shorter one; and the elongation which would but moderately strain the one would break the other.

This reasoning is equally applicable to the minute extension of iron; the increase of $\frac{1}{10}$ of an inch in the outer circumference of a 10-inch gun being possible without fracturing that part, being an elongation of but 1 in 940; whereas the same extension must crack the inside, as no iron could stand an elongation of $\frac{1}{10}$ in 31½, or 1 in 314.

Even on this showing, then, the outside of a thick tube cannot do its share of work; a closer examination, however, must convince us that it cannot even do thus much, for the thickness of material must diminish as the circumference is increased.

When the inner diameter of the 10-inch cylinder becomes 20 inches the thickness must diminish from 10 to 7·32 inches; the mass of material in the cylinder, and therefore its cross-section, remaining the same.

The cross-section was originally 800 circular inches, 800 being the difference between the squares of 30 inches, the outer diameter, and 10 inches, the inner; or 900 minus 100. When stretched the area of the cross-section must continue to be 800 round inches.

Now the thickness of 7·32 inches gives us an external diameter of twice 7·32 or 14·64 added to 20, the internal diameter; in all 34·64 inches, the square of which is 1200. Subtracting 400, the square of 20, leaves 800 round inches as before.

In this case the outside of the cylinder is stretched but 4·64 in 30, about 1 in 7, when the inside is stretched to double its original size.

If the inner diameter be only stretched to 11 inches the thickness must be diminished from 10 to 9·674 inches, the outer diameter becoming 30·348 inches, the cross-section remaining 800 round inches as before, the difference between the squares of 30·348 and 11. Here the outer layer is elongated ·348 in 30, or 1 in 86; whereas the inner is extended 1 in 10, showing a strain or an exertion of power 8½ times greater.

In the minute extension of metals the disproportion is still more striking. Thus in cast-iron the 10-inch inner diameter may become $10\frac{1}{10}$, which would extend the outer diameter only from 30 to $30\frac{1}{300}$, the cross-section remaining 800 inches, and the thickness diminishing from 10 inches to $9\frac{9}{10}\frac{8}{00}$ (see fig. 1). Here the outside would only be stretched $\frac{1}{300}$ in 30, or 1 in 9000; the inside being stretched $\frac{1}{100}$ in 10, or 1 in 1000, exerting therefore nine times as much power as the outside.

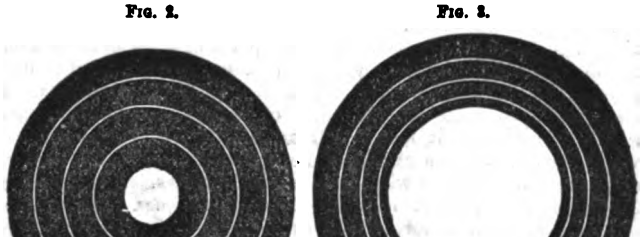

Fig. 1.

It is evident that a slight increase of pressure from within would break the inside, while the outside could help but little in restraining the disruptive force.

If we make equidistant circular marks on the end of an india-rubber cylinder (fig. 2), and stretch it, we can see plainly how much more the inside is strained than the outside or even the intermediate parts. The spaces between the marks will become thinner, each space becoming less thin than that inside of it, and the inner space *much* thinner than the others (fig. 3), showing that when the inside is strained almost to breaking the intermediate parts are doing much less work, and those far removed almost none.

Fig. 2. Fig. 3.

The law (see Note A, p. 48) deduced by Prof. Peter Barlow in the paper referred to, is that in cylinders of metal the power exerted by different parts varies inversely as the squares of the distances of the parts from the axis. The following table shows the elasticity exerted according to this law by the different concentric layers of metal in a gun where the thickness is one calibre and divided into ten imaginary equidistant portions, E being that of the inner part of all, E_1 that of the part one-tenth of a calibre from the inner surface, E_2 two-tenths, &c.

$$E = E \qquad = 1{\cdot}0000\,E$$

$$E_1 = E\frac{c^2}{c^2(1+\frac{2}{10})^2} = E\frac{100}{144} = 100\,E \times = \frac{1}{144} = {\cdot}6944\,E$$

$$E_2 = E\frac{c^2}{c^2(1+\frac{2}{10})^2} = \qquad 100\,E \times \quad \frac{1}{14^2} = {\cdot}5102\,E$$

$$E_3 = 100E \times \frac{1}{16^2} \qquad = {\cdot}3906\,E$$

$$E_4 = 100E \times \frac{1}{18^2} \qquad = {\cdot}3087\,E$$

$$E_5 = 100E \times \frac{1}{20^2} \qquad = {\cdot}2500\,E$$

$$E_6 = 100E \times \frac{1}{22^2} \qquad = {\cdot}2066\,E$$

$$E_7 = 100E \times \frac{1}{24^2} \qquad = {\cdot}1736\,E$$

$$E_8 = 100E \times \frac{1}{26^2} \qquad = {\cdot}1479\,E$$

$$E_9 = 100E \times \frac{1}{28^2} \qquad = {\cdot}1275\,E$$

$$E_{10} = \frac{1}{9}E = 100E\frac{1}{30^2} \qquad = {\cdot}1111\,E$$

Thus we see that in a 10-inch gun, when the inside—which is 5 inches from the axis—is fully strained, the metal 2 inches from the inside, or 7 inches from the axis, can only exert a force $\frac{25}{144}$ or little more than half as much; 3 inches further, 10 inches from the axis, the force exerted diminishes to $\frac{25}{100}$, or but a quarter of that exerted by the inside; and if the gun be 12 inches thick the outside, which is 17 inches from the axis, can exert but $\frac{25}{289}$, or about $\frac{1}{12}$ as much power as the inside. Of course casting the gun still thicker would add but very little to its strength; we cannot therefore be astonished that it has been found in practice that cylinders for hydraulic presses with a thickness equal to about half the diameter of the piston are very nearly as strong as if ten times as thick.

In 1855 Dr. Hart, of Trinity College, Dublin, investigated the problem. His calculations (see note W, p. 259, of Mr. R. Mallet's work on the Construction of Artillery) gave greater strength to the inner parts, but still less to the outer, than those of Prof. Barlow. Both these gentlemen (see Note B), as well as General Morin and Dr. Robinson, the astronomer, who have also studied the question, agree that no possible thickness can enable a cylinder to bear a pressure from within greater on each square inch than the tensile strength of a square inch bar of the material; that is to say, if the tensile strength of cast-iron be 6 tons per inch a cylinder of that metal, however thick, cannot bear a pressure from within of 6 tons per inch. This has been found practically true with hydraulic presses, and indeed with guns also, a 32-pounder being the largest which can with safety be fired with a full charge of powder.

It may perhaps aid in impressing the truth of the theory of the almost perfect uselessness of the outer parts of thick cylinders on the minds of some of my audience, if I describe how it was discovered by myself, and how before me by Sir Charles Fox. I was seeking to evade the difficulty of casting very large masses sound and strong; it being well known that iron when cooled very slowly (as when cast in large masses) crystalises coarsely, and is not so strong as when cast in smaller sizes. I wished also to be able to transport monster mortars in pieces. With these objects I planned a mortar consisting of several concentric mortars, not fitting closely throughout, but only at their mouths or open ends. The spaces between them I intended to fill simply with water or oil, which (all apertures being closed hermetically) could transmit the strain quite as well as metal, being perhaps even more incompressible. In considering the manner of this transmission of strain by the film of water, it seemed evident to me that it could only receive the pressure from the interior by the inside metal being pushed against it,—that is to say, by the particles of the inner cylinder changing their position, and some of them occupying (during the continuance of the strain) a portion of the space before occupied by the water; the film of water changing its position and pushing outwards some portions of the outer cylinder, these again pushing away portions outside of them. I can conceive no other way by which transmission of pressure can take place but by such "pushing." It at once occurred to me that the cylindrical film of water in the necessary change of position would be enlarged in diameter very sensibly; for instance, in a 40-inch mortar, with the sides of the inner cylinder 5 inches thick, the film of water around it would be about 50 inches in diameter, and, fully to strain the metal outside of it, must acquire a diameter of $50+\frac{50}{1000}$, or $50\frac{1}{20}$ inches. Without such an enlargement the outer metal could not be fully strained, strain without proportionate stretching being impossible, and $\frac{1}{20}$ of an inch being the elongation necessary in a 50-inch bar when exerting its greatest power consistent with safety. Now, it is evident that a film of water increasing in circumference three-twentieths of an inch must decrease in thickness, the quantity of water remaining the same. Exactly the same increase of circumference and decrease of thickness must take place in the metal of a press or cannon, but this had never occurred to me till I thought of the water transmitting the strain. A calculation in the difference of the amount of work done by the outside and inside of a thick cylinder was easily made, and certainly the result astonished me. It seemed so improbable that such a thing should have remained unknown. Much greater was my astonishment when I heard that Prof. Peter Barlow had made the cause of the weakness in cylinders public many years ago, but that his paper on the subject was utterly neglected.

Sir Charles Fox made the discovery by a process exactly the reverse of mine. He observed the effect first, I the cause. Many years ago he was making a suspension bridge to be sent to Russia. The chain was to be formed of bars of iron bolted together through holes at their extremities. The size of the bolts had to be determined by experiment. The first bars were made 4 inches wide, the holes (and bolts) being only 3 inches, and the metal round them 5 inches, seeming the strongest part.

Fig. 4

This thickness was given to admit of being reduced if the 3-inch bolt proved to be too weak. Three bars were bolted together, two in one direction, the third between them and in the other direction. They were then strained, and, instead of the thin bolt breaking, the bars gave way at the part where they seemingly had 10 inches to resist rupture. This always took place in the same manner, viz., from the inside of the eye or bolt hole (fig. 4). Thoroughly to investigate this strange phenomenon, Sir Charles had straight lines cut in two directions at short intervals across the face of the bars near the bolt. He took an impression of these on a sheet of paper by rubbing a soft lead-pencil over it, as one copies monumental brasses. The bar was stretched a little and another copy taken, a little more and another copy; and so on, till a complete history of the motion of each particle was before the ingenious investigator. This history showed that the inner (and therefore the shorter) fibre broke before the outer one sensibly stretched at all. Until Sir Charles Fox with great kindness told me of this practical investigation, I confess I almost doubted the truth of the merely geometrical solution of the problem. I trust I have been able to convince others that in a thick cylinder (like a cannon) the outside can take only—I will not say one-twelfth, as I myself believe, but—one-sixth of its share of work, an amount which could not be transmitted to it without an increase of $\frac{1}{2000}$ in the bulk of the cylinder, or a diminution to that extent in its length.

If this be the case with long-continued pressure (which we have been considering), what must it be when the pressure is applied and removed almost instantaneously, as in a gun? If the gun were thick enough and very short, the pressure might have absolutely passed from the inside before it reached the outside at all. In estimating the value of the present system of constructing guns we must bear in mind also that the outer half-inch weighs about three times as much as the inner. One-sixth

Digitized by Google

its share of work by thickness is therefore only one-eighteenth by weight. One ounce of metal at one part does more than seventeen ounces at another.

My arguments have often been met by the query,—How is it that guns and Bramah presses stand so well as they do? To this I answer that Bramah presses do not stand, and the work performed by guns has always been much over-estimated. For instance, in a smooth-bored musket the annexed table shows that the pressure can never have been 300 atmospheres, or 2 tons to the square inch.

Table of Experiments made by Mr. Piobert to determine the Initial Velocity of Shot fired from Guns of different Lengths, and deductions from them by the Author.

1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
Length of Gun.		Space passed through by the shot.	Total velocity acquired	Velocity added.	Space in which the latter velocities are added.	Times in which the latter velocities are added (in millionths of a second).	Total time in millionths of a second.	Pressure, if uniform, on shot from behind necessary to add the Velocities in col. 5, during the Times in col. 7.	Pressure of the gas on a surface the size of the section of shot necessary to move the gas itself with the velocities in column 4.	Mean resistance from the air in front, and friction.	Total pressure per sq. inch in atmospheres.	Number of times the size of the cartridge occupied by the gas.	Pressure in atmospheres which would result from compressing the gas into the space occupied by the cartridge.	Supposing the gas at the heat of ignition to fill 3000 times the space of the cartridge, proportion of powder burnt.

The bullet weighed 15 drachms = ·06 lb. The powder occupied about 1·4 inch in length.

The first four columns are the data obtained by actual experiments with muskets of various lengths. The 4th column shows the velocity acquired by the bullet in passing through the spaces recorded in the 3rd column. Now, these quantities and the weight and size of the bullet being known, it is easy to calculate the pressure, &c. (Note C.) Column 12 gives the pressure in atmospheres for the different portions of a long musket, 257 being the maximum.

The simplest way of verifying my calculations will be to assume a pressure of 300 atmospheres, or two tons per inch, and find the velocity this would produce in bullets from muskets of the different lengths. The velocities thus found will much exceed those found by experiments, proving that the pressure, as I said, never reaches that amount. As the size of the gun increases, however, the pressure of the gas of the powder increases; for whereas the musket-ball in moving, say 4 inches, has left a space for the powder seven times its original size (if the cartridge be about the size of the bullet), a 9 lb. shot in moving 4 inches only leaves a space of double the size of the cartridge.

Thus a shot of extremely large dimensions would move so slowly that the powder could all be turned to gas, while the space left free for it would scarcely exceed its original dimensions. According to the most reliable theory, that of Capt. Boxer, the pressure then would be 3000 atmospheres, or 20 tons to the square inch.

We do not know the exact time required for powder to burn. In a musket (see table) it took $\frac{1}{100}$ of a second, during which time the bullet moved 30 inches, but what the time required in large guns is we do not know.

We do know, however, that a 32-pounder is the largest English cast-iron gun which can fire double shot with full charges. We may therefore assume that in it the pressure acting during the short time has about the same straining effect as the continued pressure of between 4 and 5 tons to the square inch, which we found to be the maximum a cast-iron cylinder could bear. We may also assume that in a 68-pounder the strain exceeds that amount.

Before proceeding further it is necessary to show what effect a pressure of 4 tons per square inch would have on different sized shot, for if the known effects exceed those which that pressure can produce, my theory must be abandoned.

The well-known formula

$$V^2W=2PGS$$

gives us the information that a pressure of 4 tons per inch on a 9-pound shot would produce a velocity of 1600 feet per second in a space of about 40 inches, less than half the length of a gun; that the same pressure would produce the same velocity in a 32-pound shot in a space of about 60 inches (the naval 32-pounder being 120 inches long), and in a 68-pound shot in 80 inches. This proportion in the 68-pounders would lead us to the correct conclusion, either that the guns must be made stronger or the velocity of 1600 feet must be sacrificed. The latter is the course adopted, a smaller proportion of powder being used in a 68-pounder than in a smaller cannon. The velocity of 1200 feet per second, which is actually attained, could be produced by a pressure of 4 tons in a space of 45 inches.

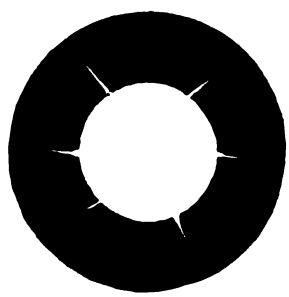
Having thus shown that a pressure of 4 tons per inch can produce greater results than we know are produced, and having proved that cast-iron cylinders (Note D) cannot bear a greater pressure, I think it remains with those who maintain that the pressure is greater to prove that it is so, and to account for the velocity of the shot not being in proportion to such great pressure as they assert to be developed.

We much want a stronger 68-pounder and 10-inch gun, and must therefore seek some other method of construction than casting them of iron. Steel guns have not yet succeeded on a large scale, and, if they did, it would be a pity to use so valuable a material so unscientifically that one part shall be strained to breaking while another is idle. The same may be said of wrought-iron.

The remedy I would venture to suggest for the equal strain on different parts of the thickness of a gun is extremely simple. Several parts should be made to take a moderate share of the strain, instead of the inside having too much and the rest of the gun too little, as in the cast gun; or the inside none and the middle too much, as in the old mode of manufacture with hoops and staves of iron. One glance at a section of a gun (fig. 5) of the latter construction will suffice to convince us of the futility of the attempt lately made to reintroduce it. It has nearly all the defects of a cast gun, particularly that of the unequal straining of its parts, besides others peculiar to itself,—the penetration of the gas between the staves for instance.

Fig. 5.

A more equal distribution of strain can only, I think, be secured by building guns of concentric tubes, each slightly too small to be placed over the one below it without force. The difference of size necessary is easily calculated with sufficient exactness for practical purposes. The greater the number of layers the greater the strength; as, by a minute subdivision, all parts doing but one-half their share of work or less can be replaced by metal capable of exerting nearly its whole force with so small an additional extension as not to render an undue extension of any other part necessary.



Digitized by Google

A very simple way of making a great number of parts each exert an equal amount of power, is to wind wire around an inner tube, with a tension increasing with each layer.

Very shortly after I took out my patent for this mode of constructing cannon, Mr. James Longridge, an eminent civil engineer, took out one for manufacturing hydraulic presses in the same way. He made several experimental cylinders, and some, with sides but one-third as thick in proportion as those of a gun, were filled with gunpowder, closed hermetically with the exception of a small vent, and without injury bore the shock of the explosion of the contained powder.

The pressure cannot have been less than 15 tons per inch, an amount which certainly the tubes could not have borne for a much longer period. These cylinders had flanges to keep the wire on. Some of these gave way, as shown in fig. 6, the cracks being much more open at the inside, and some not extending to the outside; thus proving how comparatively little the latter was strained, and fully corroborating Sir C. Fox's experiments.

Fig. 6.

Mr. Longridge has lately made a 6-inch cylinder for a Bramah press, which, with sides of $\frac{3}{4}$ of an inch of cast-iron, covered with $\frac{1}{2}$ inch of wire (ten coils of one-sixteenth inch wire), has borne a pressure of 7 tons to the inch,—a much greater proof than ordinary cylinders of treble thickness are subjected to.*

Although a greater number of layers of tubes gives greater strength, still much benefit arises from the division of the metal even into two. I made a 9-pounder gun of two layers—the inner one 4 inches in bore and $10\frac{1}{2}$ inches in outer diameter—cylindrical from the breach to the trunnions. Over this I put another layer, about one-hundredth of an inch less than $10\frac{1}{2}$ inches in inner diameter, so that it had to be heated to make it pass over the other part. The outer tube I made of wrought-iron, and for convenience of four pieces. When finished the gun had exactly the appearance of an ordinary one, and was about the same weight as the service cast-iron gun; against one of which, as well as a brass service gun, and one made by Mr. Dundas, of Dundas (of wrought-iron staves hooped together), mine was tried at Shoeburyness, by order of the Ordnance Select Committee, in 1855 and 1856. The four guns were fired as follows :—

2	rounds	with 8 lb.	of powder	and 2	shot.
86	,,	3	,,	1	,,
26	,,	4	,,	1	,,
5	,,	5	,,	1	,,
5	,,	5	,,	2	,,

So far all four remained serviceable. The charge was increased to 6 lb. of powder and two shot, with which Mr. Dundas's gun burst at the third round; the service cast-iron gun burst at the 110th round; the service brass gun became unserviceable after 174 rounds; but my gun was so sound after 318 rounds, that the charge was increased by one shot at a time till the gun was loaded to the *muzzle*, in which state it was fired 158 times before it burst!

This astonishing endurance must not be attributed to the mere substitution of wrought for cast iron in the outer inch-and-a-quarter. The mere change of material added but $\frac{1}{7}$ as much strength as the change in the *size* of the outer layer; for without this adjustment of size the wrought-iron could not have exerted its power,—as when the inner metal was fully strained, and the diameter of the bore increased from 4 to $4\frac{1}{100}$ inches, the diameter of the outside of the inner layer could be extended only from $10\frac{1}{2}$ inches to $10\frac{1}{2}+\frac{1}{666}$ inches,—1 in 7000. With such a slight enlargement, the outer layer could not be pressed against enough to enable it to exert its full force,—good wrought-iron extending 1 in 7000 with a tension of $1\frac{1}{2}$ ton per inch. By making the outer layer $\frac{1}{100}$-inch less in diameter originally, I secure, that when the outside of the inner tube stretches $\frac{1}{700}$-inch, the outer tube shall be extended $\frac{1}{100}$ added to $\frac{1}{700}$, or $\frac{1}{87}$-inch, being 1 in 900, the elongation due to an exertion of power equal to $10\frac{1}{2}$ tons, seven times greater than the mere substitution of wrought-iron could give. (See note E.)

In a 68-pounder the strength of two layers will probably suffice, but for larger guns more of the metal must be made to take a fair share of work, and therefore more concentric tubes used. Care must be taken to have sufficient longitudinal strength. For this purpose some circumferential strength may well be sacrificed, by casting one part the length of the entire gun and of adequate thickness.

For various reasons it seems better that this single large piece should be the inside, cast-iron being admirably suited for the bore of a gun, whereas wrought-iron generally has some defect in the welding which would certainly be penetrated by the gas of the powder. In some cases—for instance, in breech-loading guns—it may however be preferable to have the longitudinal strength outside. The latter construction has the advantage of giving greater circumferential strength; for (strange though it may seem) an ordinary cast gun, whether of iron or brass, would be strengthened at the breech by removing one-quarter of the thickness from the inside, and replacing the metal with even lead or pewter. The reason of this apparently paradoxical increase of strength is, that each remaining portion could do more work without any part giving way, in the proportion of 9 to 4, when the inner part (which must yield first) is larger than as at present in the ratio of 3 to 2 (Note F). The gain of power by thus permitting the outside to exert more of its force is greater than the loss by removing the inner parts, which must have cracked before the outer could be moderately strained. A brass lining near the breach of a gun would evidently add much to its strength. This would also be a convenient way of strengthening mortars already cast.

With the exception of the single large piece for longitudinal strength, the gun may with advantage be formed of a number of small tubes accurately put together. Mortars, which are seldom subject to the fire of an enemy, cannot be more easily and strongly made than of wire wound with proper tension round an inner tube of brass, steel, or iron.

Mr. Longridge made a wire gun weighing but 3 cwt., from which he obtained ranges of 1500 yards with a 9 lb. shot. The service brass 9-pounder weighs 13 cwt.

A wire-strengthened gun made with these proportions could bear any strain gunpowder could directly cause. I can therefore see no reason why a solid shot weighing a ton should not be thrown eight miles from such a gun.

A gun formed principally of cast-iron, and reinforced near the breech with three layers of tubes forced on (I should prefer wrought-iron or tough steel for the latter), may seem stronger than necessary near the breech, but it must be borne in mind that it is only there that the largest guns are more strained than the smallest.

In various other obvious ways my object can be effected. This object is—So to construct guns that at the moment of firing the greatest possible proportion of the thickness of metal shall be nearly equally strained.

In consequence of the wonderful endurance of my 9-pounder, the British government is now trying experiments with an 8 and a 10 inch gun of the same construction. It is expected that an 87 cwt. 10-inch gun can be made capable of firing solid shot of about 130 lb. For this purpose the metal should have been distributed differently, a greater thickness being given to the breech end: however, I anticipate a successful result even from the gun now at Woolwich on the pattern of the ordinary shell gun.

(To be concluded in our next.)

* This press was exhibited and explained after the lecture by Mr. James Longridge.

Note A.

The following are the Professor's own words:—"It would appear at first that, having found the strain at D and C, it would only be necessary to ascertain the thickness of metal necessary to resist this strain when applied directly to its length. This however is by no means the case, for if we imagine, as we must do, that the iron in consequence of the internal pressure suffers a certain degree of extension, we shall find that the external circumference participates much less in this extension than the interior, and as the resistance is proportional to the extension divided by the length, according to the law *ut tensio sic vis*, it follows that the

Digitized by Google

external circumference, and every successive circular lamina from the interior to the exterior surface, offers a less and less resistance to the interior strain;—the law of which decrease of resistance it is our present object to investigate.

"In the first place it is obvious that, whatever extension the cylinder or ring may undergo, there will be still in it the same quantity of metal; or, which is the same, the area of the circular ring formed by a section through it will remain the same, which area is proportional to the difference of the squares of the two diameters.

"Let D be the interior diameter before the pressure is exerted, and $D+d$ its diameter when extended by the pressure. Let also D′ be the external diameter before, and $D'+d'$ the diameter after, the pressure is exerted. Then from what is stated above it follows that we shall have

$$D'^2-D^2=(D'+d')^2-(D+d)^2, \text{ or,}$$
$$2D'd'+d'^2=Dd+d^2, \text{ or,}$$
$$2D'+d' : 2D+d :: d : d';$$

or, since d' and d are very small in comparison with D′ and D, this analogy becomes $D' : D :: d : d'$. That is, the extension of the exterior surface is to that of the interior as the interior diameter to the exterior.

"But the resistance is as the extension divided by the length, therefore the resistance of the exterior surface is to that of the interior as $\frac{D}{D'} : \frac{D'}{D}$ or as $D^2 : D'^2$. That is, the resistance offered by each successive lamina is inversely as the square of the diameter, or inversely as the square of its distance from the centre; by means of which law the actual resistance due to any thickness is readily ascertained.

"Let r be the interior radius of any cylinder, p the pressure per square inch on the fluid, t the whole thickness of the metal, and x any variable distance from the interior surface. Let also $rp=s$ represent the strain exerted at the interior surface, according to the principles explained in the preceding part of this paper. Then by the law last illustrated we shall have

$$(r+x)^2 : r^2 :: s : \frac{r^2 s}{(r+x)^2}$$

for the strain at the distance x from the interior surface, and consequently

$$\int \frac{r^2 s\,dx}{(r+x)^2} + \text{Cor.}$$

=the sum of all the strains, or the sum of all the resistance. This becomes, when $x=t$,

$$R=r^2 s\left(\frac{1}{r}-\frac{1}{r+t}\right)=s\frac{rt}{r+t}$$

That is, the sum of all the variable resistances due to the whole thickness t is equal to the resistance that would be due to the thickness $\frac{rt}{r+t}$ acting uniformly with a resistance s, or rp.

"*Application of this Rule for computing the proper thickness of metal in a Cylindric Hydraulic Press of given power and dimensions.*

"Let r be the radius of the proposed cylinder, p the pressure per square inch on the fluid, and x the required thickness. Let also c represent the cohesive strength of a square inch rod of the metal. Then, from what has preceded it appears that the whole strain due to the interior pressure will be expressed by pr, and that the greatest resistance to which the cylinder can be safely opposed is $c\times\frac{rx}{r+x}$: hence, when the strain and resistance are in equilibrio, we shall have

$$rp=\frac{rx}{r+x}\times c \quad \ldots \quad \ldots \quad \ldots \quad (1)$$

or $pr+px=cx$, whence $x=\frac{pr}{c-p}$, the thickness sought."

NOTE B.

Dr. Hart's formula for the pressure a cylinder can bear is

$$p=t\frac{R^2-r^2}{R^2+r^2} \quad \ldots \quad \ldots \quad \ldots \quad (2)$$

where p is the pressure on each square inch of interior surface, t the tensile force of a square inch bar of the material, R the radius of the outer surface of the cylinder, and r that of the inner surface or bore. Using this notation, Prof. Barlow's formula (1) is

$$p=t\frac{R-r}{R} \quad \ldots \quad \ldots \quad \ldots \quad (3)$$

These equations become identical when R is indefinitely large compared with r, then $p=t$; which means that an *infinite thickness* of metal is requisite to bear a pressure on each inch of the bore equal to the tensile force of a square inch bar of the metal; yet a thickness equal to the radius of the bore would suffice if each particle were equally strained.

NOTE C.

The experiments were made with guns of $\frac{3}{4}$-inch bore and different lengths, firing a bullet of 15 drachms=·06 lb., the powder occupying about 1·4 inch of the bore. The object was to find the effect of the length of the gun.

The first four columns are the data from which I have calculated the rest.

The 5th column is simply the difference between the velocities at the beginning and end of the spaces mentioned in the 6th column, which is deduced from the 3rd by subtracting from each line that preceding.

The times in the 7th column are found on the supposition that the pressure during each short interval is constant (which it is very nearly), by the following formula: $t=\frac{s}{u+\frac{1}{2}v}$ when s=the space in which the velocity v is added (columns 6 and 5), and u=the velocity at the commencement of the period (column 4).

The pressures in the 9th column are found by the formula $p=\frac{vw}{tg}$ when v=velocity added in time t, and w=·06 lb. the weight of the shot, g being 32, the force of gravity.

Those in the 10th column are found by using the formula

$$v=\sqrt{2g\frac{p-p^1}{\pi}}$$

as given by Charles Austin, Esq., C.E., for the velocity of gas issuing through an orifice; when p=pressure of gas on square foot, p^1 that of the atmosphere; π=weight of a cubic foot of gas.

$$v^2=2g\frac{p-p^1}{\pi}$$

neglecting p^1 as being accounted for in the next column, and assuming π=1 lb., we have $v^2=2gp$ ∴ $p=\frac{v^2}{2g}$= pressure per square foot. The pressure on $\frac{1}{3}$-inch $=\frac{p}{3\times144}=\frac{v^2}{26,208}$ lb. $=(\frac{1}{10}v)^2\times$ ·004.

The resistances in column 11 are obtained from Hutton's formula for spheres moving through the air, $R=\frac{(\cdot7565v^2-17\cdot5v)d^2}{10,000}$, d being the diameter of the sphere in inches. I assume the resistance in a confined space like the barrel of a gun, and the friction against the sides, at four times the above, in round numbers $\frac{12v^2-280v}{90,000}$ lb., and the numbers in column 11 give the mean between that at the beginning and end of the short periods.

The 12th column is the sum of all the three preceding, multiplied by 3 (the area of the section of the bullet being only $\frac{1}{3}$ square inch) and divided by 15.

The manner of obtaining the next three columns is evident.

NOTE D.

A gun could of course bear a greater strain near the breech than an open cylinder, on account of the metal closing the breech assisting what we may call the sides in opposing the pressure. A gun possesses another element of strength in the pressure not coming at once on the whole bore. Thus, during the infinitesimal period that the pressure is only on, say 12 inches from the breech, it is evident that also the 13th, 14th, and in a large cannon many more inches, assist in resisting the pressure.

NOTE E.

It may perhaps make this more evident if we consider the case of india-rubber. We found that a tube of this material 10 inches bore and 10 inches thick, when stretched till the diameter of the inside is doubled, diminishes in thickness from 10 to 7$\frac{1}{2}$ inches. (See figs. 2 and 3.)

Now if we attempt materially to strengthen this tube, by merely fitting another accurately over it, we must fail, because so little of the strain will be communicated to the outside, the inner diameter of which can at most be stretched from 30 inches (its original size) to 34$\frac{2}{7}$, the size of the outer diameter of the inner tube when stretched. Even this amount we should lessen, on account of the pressure on the inner tube, which would make it slightly thinner and longer.

If however we put a tube whose inner diameter is only 17$\frac{1}{2}$ inches over the inner one (for which purpose the former must be temporarily stretched, as the outer diameter of the inner tube is 30 inches), then both tubes will be nearly equally strained when the inner diameter of the inner tube is doubled, as the inner diameter of the outer tube will also be doubled, becoming 34$\frac{2}{7}$, having originally been but 17$\frac{1}{2}$.

Any number of layers of tubes can be made each to do a fair share of work, by regulating their original size, so that when the inner tube is extended to a certain amount, each shall be extended to the same amount. Should this amount be exceeded, however, the inside will again have an undue share of strain. On the other hand, a small strain will affect only the outer layer.

NOTE F.

Prof. Barlow's expression (1) for the strength of cylinders (Note A) $\frac{crx}{r+x}$ gives us $c \times \frac{4 \times 8}{12} = c \times \frac{32}{12}$ as the strength of an 8-inch gun with sides 8 inches thick, and $c \frac{6 \times 6}{12} = c \times \frac{36}{12}$ as that when the bore is increased to 12 inches;—the thickness being *diminished* from 8 to 6 inches, yet the strength increased. This is interesting, as it proves that hydraulic presses would be much stronger if cast thinner. Dr. Hart's formulæ give the same result, and experiment has confirmed it.

ON THE COMMON SENSE OF ART.*

By A. J. BERESFORD-HOPE, Esq., M.P.

THE lecturer said, he often found that what they might call the prose of art was handled with great ability, and at considerable length, by writers of various technical and scientific treatises. He also found some treatises on what they might describe as the poetry of art, the subject being treated in a more or less imaginative manner. But there was one phase of art which had never, by that term, been treated specifically. It was something that should seem superior to prose, and something that should seem superior to poetry,—that thing that was not so common, and which the French proverb said was by no means common,—he meant common sense. By "the Common Sense of Art" he hoped they would allow him to say, that he did not mean to imply that he wished to lay any particular claim to his own common sense upon the subject; but to give them some idea as to what, in his mind, constituted the common sense of art. And, if he were to define common sense, he should say it stood in an ascending ratio —that it was something beyond prose, and something above poetry. Prose, we were told, was the best language in which to describe any particular thing; poetry was the best language, having the best words in the best places; common sense was the best thing in the best place, and, therefore, above prose or poetry. With this preface or definition of common sense, he would, with their permission, at once plunge into the subject.

This being an Architectural Museum, they might ask why he called upon them to consider not merely the common sense of Architecture, but the common sense of Art. His answer was this,—that Architecture, whether it were an art that involved and included all others, was at all events the art that busied itself and was concerned with all others. Painting stood by itself, as did sculpture; painting required no assistance from sculpture, neither did sculpture require assistance from painting. But architecture, though it had an existence of its own,—though the doctrine that architecture was merely the machinery to convey ornamentation was one that he must denounce as a heresy,—architecture, he said, though an art of its own, was intimately blended with all other arts. Therefore, in looking at the common sense of architecture, they would see what was the common sense of all art, and they would have to consider all art in its relation to architecture. In laying down some canon of architectural common sense, what first principle should they start with? He believed that he should most safely start upon the broadest grounds,—upon the enunciation, which he ventured thus to make, that with all the varieties of style, with all the different conditions, with all the merits, and with all the demerits of different lands, yet, considered implicitly in itself, the object of all architecture was one and the same—the means by which to attain the end in view, however imperfectly that might be realised. What was architecture? It was the struggle of the human intellect to assimilate the great physical wants of man,—the want of man which he felt for covering,—covering for his daily life, covering for his public duties, covering for his religious observances, and to carry out and realise the great architectural ideas of beauty which existed in every human mind. That was the first of architecture, —that was architecture pure and simple,—the architecture, that was to say, of construction. But next to the architecture of construction, and treading closely on its heels, came the ornamentation of all construction. That ornamentation no longer referred itself directly to the archetypal idea,—indirectly no doubt it did so;—but directly, and in the first instance, it dealt with the glorified reproductions of the visible things of human nature,—the reproduction of crystallised organisation, the reproduction of vegetable life, the reproduction of animal existence, and, above all, the reproduction of that purest and noblest exemplification of beauty vouchsafed to us—the noble and Godlike image of the human form. Thus, with these various relations of ornamentation to painting and to sculpture, architecture did, as he said, concern them above and in all art, and therefore it ought to be considered in connexion with all that art.

Now, thus having made these prefaces, and realised to themselves that architecture was the study of the archetype, as he attempted to word it, where could they begin their progress?—Where could they, as pilgrims in this land of England in the year 1858, begin their journey?—where could they take their start in their voyage of discovery in search of the ideal?—where, to make use of a beautiful mediæval myth, could they look for the Temple of Sangraal, a building which was imagined to be the embodiment of all that was beautiful and hallowed in all the buildings of creation? Whence could they take their journey towards this ideal?—where could they find the clue that was to lead them up the thorny mountain-path that would bring them to the green valley that encircled in its woods the crystalline pool, where dwelt reflected in the waves the image of the temple built above?

> "——— Windless and crystalline pool,
> Where ever dwells in unerasing waves
> The image of the temple built above,
> Distinct with column, arch, and architrave,
> And palm-like capital far overwrought,
> And populous most with living imagery;
> Praxitelean shapes, whose marble smiles
> Fill the hush'd air with enchanting love.
> It is deserted now; but once it bore
> Thy name, Prometheus!"

Prometheus in learned tongue meant the man of forethought,—the man of common sense. Taking this common sense as their guide, where should they Englishmen, in this waning age, where should they work up for their idea, and where should they find a clue that would lead them to this temple? He said that for them, being Englishmen, being Teutons, being Europeans, being members of the great civilised and great Christian fraternity of nations,—a strong, a very strong antecedent probability was that they should find their starting point in their pilgrimage for a style of architecture in what should suit them as Englishmen, suit them as Teutons, suit them as Europeans, and a portion of the civilised and Christian fraternity of nations. He said there was a strong probability that in such an antecedent they should have a starting point to gain a style. He would base the rest of his discussion upon that probability. Of course, whether their search were successful, or whether it were not so, was not the point for them to set forth. What they had to do was to labour onwards, and to trust to events for success. It might be that art was waning in the land, and going to its fall; or it might be that art was rising to a noble future. But their task was one and the same. If the world of art was still in the diminutive morning of its growth, then let them toil for the bright and sublime noonday; if, on the contrary, it was drawing to its eventide, then let them anticipate a glorious sun-down. Then, with these prefaces, dwelling on this antecedent probability, where should they take their stand? Should that architecture of the future, to which they looked, be an architecture that was progressive, or should it be an architecture that was stationary? Upon this matter he would have to offer to them two reasons: the first reason was a positive one—that it ought to be progressive; the second reason was a negative one—that it could not be stationary. As to the first reason—that art ought to be progressive—he would not argue, for it was an argument which they must have heard thousands and thousands of times in lectures, in books, and in journals,—it was an argument that was drawn from our history and literary achievements, and from the fact that all art had been progressive in every age of the world. With that brief sketch he must leave his audience to fill up the outline upon that point. He must, however, speak more at length upon the second part,—why architecture could not be stationary. He would narrow the question by appealing to their own consideration as Englishmen, and to their own particular phase of art, to which he had directed their attention. He assumed as a certainty that their art for the future was to be founded on the Gothic. Well then, granting that, could their Gothic for the future be stationary? If so, it could not be stationary without standing somewhere? Where then should it stand? They knew there were the Gothic of England, the Gothic of France, the Gothic of the Low Countries, the Gothic of Italy, the Gothic of Spain, and the Gothic of Germany. And they knew that all these Gothics had an early and a late

* Lecture delivered at the Architectural Museum.

Digitized by Google

phase, and many of them a middle one. On which should they make their stand? He said the English stand-point must be somewhere within the Gothic of England. As to the stationary view of the matter, there could not be advancement, nor could there be retrogression,—advancement and retrogression were equally contradictory to the idea of being stationary. Well, Gothic, as they knew, after many centuries, was put to the bar of public opinion. It was thought that it had died, but it came to life again. But if it had come to life again it must be with its age upon it, like the statue-queen Hermione, with years of sorrow and exile on her brow. If architecture was to be stationary, it could not have advanced, neither could it have retrograded. By logic, which he defied any one to controvert, the stationary Gothic (if such there could be) must be the later and corrupted Tudor of Henry the Eighth in England; and in France it must be the Flamboyant of the House of Valois. But no stationary antiquarian would accept such a proposition; he would choose some style for himself of an antecedent date. Well, he said, that though he did carry out that style of an antecedent date with the most stationary accuracy, he did not for all that belong to the stationary school. Such a one was in short not stationary, but eclectic, and there was no such thing as a stationary school of Gothic. There might be an eclectic one; there must be a progressive one; and progress must select where it should progress. In short, the only theory of architecture which rested on common sense, which he set up as their supreme tribunal,—the only style of architecture for the future of England, was the Gothic architecture, cultivated progressively, and that progress founded upon eclecticism. But here they only got into their difficulties; if they were eclectic what had they to choose from? Where should they make their starting point? And, having made that, how far should they expand their diverging process, in bringing it to that centre which they should make for themselves? No doubt, whether they eclected in or out of our own land, their starting point must be within that land.

It would be in the recollection of many of those present that some fifteen or twenty years ago, when the new Gothic school first began to consolidate itself, a brisk controversy arose as to the development and perfecting of English Gothic. There was a strong party in favour of the Early English or First Pointed style; there was another party who were for the Decorated or Middle style; while there were a few outsiders who were in favour of the Norman, or the Perpendicular. After some time the victory declared itself in favour of the Middle or Decorated style, as the golden mean of English Gothic; for it seemed to be the apex of the triangle,—it seemed to be the holy ground from which they could survey the landscape around them. And so for some time they enjoyed that state,—they were in a state of insular pride—they believed themselves to be the best men in the world, and that nobody could beat their style. But very soon knocks were heard at the door from many a quarter; they found out, they learned, they realised at the bottom of their souls that there was such a thing as Foreign Gothic, that it was a noble and a multiform thing, and that it had many claims on their admiration. First of all came the Gothic of France,—of free France—with its unrivalled churches, and its enthusiastic band of eloquent young art-writers, headed by the young, intrepid, and noble-minded Montalembert. These buildings and these writers arrested our respect, and went far to divert us from the admiration of the Middle style to that stern and severe style which was the ideal of the Early French Gothic, and which had been impressed on their minds more recently in consequence of the Lille competition. Then came a voice from Germany, by several monuments in that country, all of which had claims on their attention,—in the completion of the Cathedral of Cologne, the rebuilding of St. Nicholas at Hamburg, and the Art-monument at Munich. The Low Countries, too, opened themselves to our investigation. Perhaps, a little later, English architects and tourists crossing the Alps found that they and their fathers had long been blind, and found that in the very plains of Italy, in the Campagna of Rome, there were to be found Gothic structures full of grace and beauty. These impressions were deepened by a sense of wrong, and thus they were led to recognise that Italy had also yielded its contributions to their first style. Here, then, was what he might say was the present attitude of what he might call the Gothic party in England. There was a strong feeling in favour of the various phases of the Middle style; another party, smaller and humbler, had supporters in favour of the Early style; and then there were supporters of the French or of the Italian specimens. How, then, were they to deal with these? and how were they to meet this difficulty? Was any English style in itself sufficient for our wants?—assuredly not. Was the French sufficient for their wants?—he would not say it was. Was the Italian?—certainly not. Were all these three collected and taken together sufficient,—the Early and Middle English, he meant, the French, and the Italian?—not even so. They must have something more broad and more comprehensive even than these for their starting point. They must have peace; but peace in this case could not be got by comprehensiveness. And if they were to have eclecticism, eclecticism must eclect out of everything that could be collected. The English school were very logical in choosing the Middle style of English architecture. They must do the same thing, and bring together for themselves some middle form out of the Gothic architecture in all and every age. In doing so they only did half the work that might be in store for their successors after them. That eclecticism of which he had spoken so often was the eclecticism of the past; there might be, and there would be, he imagined, an eclecticism of the future. That progress of manufactures which produced materials of singular beauty of colour, of singular durability, out of the earth; that literal fulfilment of the prophecy—that for stones we shall have iron; the increased means by which the vegetable and mineral productions of every land are laid at our feet,—all these might in time revolutionise architecture; but he thought it would be a pacific and not a destructive revolution, and that all the changes would not supplant, but only supplement the architectural traditions of the past. For himself he would only endeavour to grapple with the eclecticism of the past, and to contribute one stone to the structure of the eclecticism of the future.

Here then again to revert to first principles; they had to perform their task of progression through eclecticism, they had to eclect out of the past; they had to select out of the Gothic of their ancestors. All would agree that they must select from the past of France, from the past of Italy, and from the Early and from the Middle days of England. But were they to stop there?—was there nothing else to select from? He was going to refer to a selection that might seem to run counter to a great deal said by those of high authority in architectural matters in latter days. He said there was much they might select from in both the Later Gothic of England and of the Continent. It was easy to talk of the germs of corruption of the Later and Middle Gothic of the Flamboyant and of the Early of England. But easy as that might be, it was a truth that was only half a truth; for, distorted, perverted, and corrupted as the Gothic of that period might be, it yet unfolded vestiges of vitality destined under more favourable circumstances to be brought into life hereafter.

If there was one axiom more undeniable than another, it was that,—without attempting for one minute to strike the balance of merit between the two, but merely to make a naked statement of fact,—if there was one axiom more undeniable than another it was, that Classic architecture was the architecture of the horizontal line, and that Gothic or Pointed was the architecture of the vertical. And Classic was the architecture of superposition, while Gothic was the architecture of germination and continuity. Well, taking that—the germination and continuity of Gothic,—let them look at the Early English just emancipated out of Norman, and let them look at the Early French building. What did they see then? They saw a pillar surrounded by a capital with a very broad abacus, which in the French was absolutely square; they saw the mouldings very different in their sections from the shafts placed under them; they saw strings of horizontal lines of very dark shadow; they saw square lintels; they saw low-framed pediments; they saw strings of windows arranged in horizontal strips; they saw spires growing out of towers with strong horizontal indications, and pyramidical turrets at the corners,—they saw such indications, all of them strongly flavoured with the horizontal principle. They saw that the Early Gothic had inserted that horizontality which came from the Renaissance, which was drawn from Roman, and which was taken directly as a free gift from Ephesus and Athens. He did not deny that there was a great massiveness and beauty in horizontality. So, too, in the second style of Gothic. In the form in which tracery was put in, in the way in which windows and geometrical forms were put together, in the way in which circles and so on were put together, they saw something that a great deal more resembled superposition than it resembled continuity. Now change the scene, and come to the late Gothic. Take one of the Flamboyant cathedrals of the Low Countries; they saw there that

Digitized by Google

there was a great deal of perversity, a great deal of scrambling grotesqueness for effect, and a certain vulgarity of sentiment; yet they saw that under that vulgarity there were the germs of continuity, the differential characteristic of Gothic.

Having pointed out some of such indications as were manifested in Early Gothic, as shown in the Cathedral at Antwerp, and in specimens at the Crystal Palace, the lecturer proceeded to make some remarks in reference to the Flamboyant and Perpendicular. He said, that in their Gothic of the future, while they repudiated the shabbiness and feebleness of the Flamboyant and Perpendicular ornamentation, they must not deny that they were the first principles which they saw in ornamentation. When he saw the Flamboyant style he was reminded of the German tale of the giant, who was so weak that a child might throw him down, but whose shadow was so strong as to knock down trees and men;—or he was reminded of a story he once read in a foolish railway story-book, of an artist who wooed and won a lady, and under her face discovered the distorted lineaments of another face which she ought to have had, but did not have. The later phase of English Middle Pointed, the flowing Decorated, had never had justice done to it; it carried its death-warrant with it from the first; in spite of its beauty the hectic flush of dissolution was along with it. The students of Rickman were well acquainted with that. Here, then, were some arguments, he said, for which he might dare to challenge contradiction,—that the Later as well as the Earlier styles of the Gothic of England, as well as of the Continent, shall contribute to future eclectic art. But he might be met by the argument on the other side,—that this Early Gothic of England (especially the Early Gothic after it had emancipated itself of Romanesque) and that the Early Gothic of France, were pre-eminently masculine. He fully granted that, and confessed that he pitied the soul of the man who could step for the first time under the choir of Shoreham or Canterbury, or other of the buildings of that period, without feelings of emotion and admiration. This style was overpowering,—it was noble, it was masculine. But, while they gave it the praise of being masculine, did they give it all praise? Was all the world masculine? Were there not graces which were attributable to the other half of creation?—Norman and Early Pointed architecture, which were the mirror as it were, shadowed out only half of that creation. To have done so might be a great thing for their forefathers to have accomplished; but they, the disciples of common sense, the advocates of eclecticism through progression, scorned to be contented with half measures. Nature was great and varied; and, while he recommended them to avoid luxuriance of ornamentation, he would also recommend them to take care that they did not fall into the opposite extreme of stiffness and angularity. They might admire the purity and grace of the semicircle and the lancet; but in nature they were rare forms; while they would find multitudinous in nature, the beautiful form of the ogee. Honour, then, to the man who introduced that ogee into architecture,—who first enlisted it in the troop of the servitors of architectural glory! It had been toyed and dallied with until it had been weakened and deprived of much of its beauty; but, in its proper place, and in due subordination, as it was to be found in the Archway at Bury St. Edmund's, it might be regarded as a splendid contribution to the resources of architecture. And the ogee was only of the Later style of architecture. He said, then, that they should take up the Early and Late styles of English Gothic as well as that of the Continent.

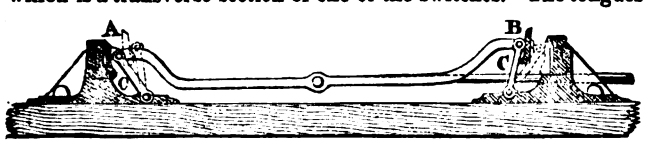
They knew that the progress of modern discovery had yielded to them great advantages in ornamentation,—such as the serpentine, the red and white granite of Scotland, and the many accessories to art afforded by the Staffordshire kilns. As to the Italian, surface colour and ornamentation were to be found more in the Italian than in other Gothic. In street architecture, too, we had a lesson from the Italian; the system of street architecture followed called for a cornice where our ancestors would have put up a gateway. And so, he said, that the Italian Gothic ought to yield its share in the construction of their eclectic and progressive style of the future. If they held fast to these principles, and if they gave to their architecture of the future the distinctive characteristics of each style,—making it masculine as the Early French, and effeminate as the Flamboyant, as they might wish to make it so,—what a boundless field of imagination opened itself before them! For instance, they might want a building in which should be given to the lower story a rustication; the lower story should be of the Early style, and the upper stories should be of the continuous. Or they might wish to produce the artistic effect of the overhanging cornice; then they would borrow that from an early date. Again, the windows, instead of being ranged in horizontal arcades, might assume the vertical strip, with columns, instead of the flimsy mullions of the later days. Let them have sometimes mullions, sometimes pillars,—everything just where it was wanted. Even as to the latest manifestations of circular windows of Henry VII.'s time, why should not these be pressed into their service as they became wanted? But it might be asked, "Where will you stop,—what is there you will not absorb?" To this he would answer, that he would stop where common sense told him to stop, and that he would not absorb anything that common sense forbade him to absorb. But onward he would go, until common sense checked him; he would take all on which common sense had not laid its brand. He would ask the architects of the future to employ the Renaissance; and he did not see why the stout-hearted men of the future should not appropriate and make their own the treasures they might find in the palaces of Rome, of Athens, and of Florence.

So much for architecture; but, as he had promised to speak of the Common Sense of Art, he would now address himself very briefly to the common sense both of Painting and Sculpture. In painting they must all acknowledge—however much we might like to see some particular phases of practical art,—they must acknowledge that the broad distinction between what was Classical and what was Gothic in architecture did not exist in painting. There were painters whose Christian tone delighted us, and there were others whose Pagan tone pleased us; but, generally speaking, there was not that thorough distiction in painting which was found in architecture. Therefore, in painting, common sense taught them that eclecticism might be more easily accomplished; there were less surface difficulties in making good its claim than they would find in the sister, or rather the mother art of architecture. He honoured those men who wished to strike out for themselves a new school,—who looked to purity, and relied upon tradition and nature for the canons of their art; but he could not honour the study of rudeness for rudeness' own sake. He agreed, then, thoroughly in repudiating with disgust the vulgar, the trite common-places of academic models; he repudiated academic models, because their beauty, if beauty they had, was of the vulgar and of the inferior sort. But their beauty being of the vulgar and inferior sort, the best protest against it was not to represent with startling accuracy the vulgar, but to raise the standard of an ideal beauty. No doubt second and third rate painters had been neglectful of their outlines, and atmospheric effects were juggled in a manner wholly at variance with the designs of the Great Architect of the Universe. The same Creator who made the mountains and the fields made also the air and the mist, and never intended that all nature should appear without atmosphere and under the bright noonday sun, or that it should have a literal dry distinctness. They must not be led away by new school doctrines any more than by old; they must look at the matter in a common sense view. If they took a mythical subject, or a scriptural subject, they must try to be not too vulgar, but to be ideal. And if they wish to be real, they must imitate nature. In painting nature in her various aspects artists should take care not to be deluded by a longing after effects that were irreconcilable with common sense. For that reason, he confessed, he did not wish to see leaves and flowers appear in pictures with the literal dry distinctness which some people admire, and which could only be seen by persons who, unlike himself, were not short-sighted.

It would be found that artists who were the most literal, not only in mass, but in every line and fold, were not always the most pleasing. Amongst the most literal of the Dutch school might be named Vanderveldt; and in the English school the clever caricaturist, our over-praised Hogarth, whose works, however, he should not set up as models. Such was not the mode in which our fathers worked, or in which Praxilites worked, or the method adopted by the men who sculptured the figures at Wells or Chartres; and such a mode of working would have been repudiated by the time-honoured Flaxman. Whatever defects, however, there might be in art, there was, he believed, in our painting and sculpture of later years a spirit of reality such as we never knew before, and that showed that they were on an onward march. And so it was in architecture; how long it might be on that march they could not tell. They knew that perfection in this nether world was, of all things, most uncertain. They knew that the brightest flowers were the first that faded, and the noblest aspirations were often nipped into despair, or soured

Digitized by Google

into cynicism. But it was not for them to indulge in such a thought. Let them, then, toil and labour on in search of truth, in search of progress, in search of the ideal, in search of common sense, as if on each of them singly depended this ideal of success. And then the crown, the satisfaction would be all the more most legitimate, whatever the broad result might be. For to toil, suffer, and labour for the truth, and, if need be, to die for the truth, was the Common Sense not only of art, but of all human life.



IMPROVED RAILWAY SWITCH.*

By J. A. Haswell.

In the various kinds of switches now used on railways the moving tongue slides upon the chairs, rubbing upon them throughout the extent of its motion; and the switches are made self-acting by a balance weight hanging from the lever and constantly pressing the tongue home to the side of the main rail. But in practice this plan is found defective; for, although a weight is employed as heavy as can be conveniently worked, its action is uncertain, being frequently impeded by the friction of the sliding tongue from the chairs having become dry or the oil becoming adhesive or mixed with sand and ashes; the tongue rails are then liable to remain on the wrong side, or only partially reversed, thus presenting both tongues open, and causing danger of accident from wheels running off the rails by the flanges entering between the tongues and main rails at both sides. To lessen this defect a raised strip has been used upon the rubbing part of the chairs, which reduces the surface for holding sand; but this plan involves the objection of the oil being sooner rubbed off by the motion of the tongue from the increased pressure between the rubbing surfaces. The large consumption of oil that takes place with the ordinary switches forms a serious item of expense, most of the oil that is applied being unavoidably wasted.

The new construction of switches described in the following paper, which is invented by Mr. Edwin Thompson and Mr. William Nicholson, of York, is designed to remove this difficulty by avoiding the sliding of the tongue-rails upon the chairs, and so dispensing entirely with the use of lubrication.

The construction of these switches is shown in the annexed, which is a transverse section of one of the switches. The tongues

A B are of the ordinary form, but a short iron strut or link CC is jointed to the thin end of each tongue-rail and to the end chair, so that when the tongue-rail is opening this strut causes the end of the tongue to rise off the chairs, and the other tongue at the same time descends upon the chairs, the short strut acting as a radius link. The elevation of the tongue-rail when open is 2 inches above the level of the main rails, which is found to ensure the tongue-rail being properly put down upon the chairs and closed to the main rail, and being also entirely clear from any low portions of the engines, &c.

In this construction of switches, on account of the sliding motion and friction of the tongue-rails being entirely avoided, oil is not required, and no danger can arise from sand or ashes lodging on the chairs: also the removal of any larger fragments of coke or ballast is to a certain extent provided for by the altered form of the chairs, which this manner of opening the tongue-rails admits of. As the tongue-rails require no larger surface to rest upon than is actually in contact with the chairs when they are closed to the main rail, advantage is taken of this by increasing the thickness of the chairs at the particular part upon which the rails rest, forming a raised step which is completely covered when the tongue-rail is closed; and on the open side the width of the tongue-rail only is exposed to the reception of rubbish, the larger pieces thus falling off and the smaller ones being crushed or removed by the descent of the tongue. The accomplishment of this object has been satisfactorily shown by the working of one of these switches, which has been put down in a situation where sand was constantly used for the engine wheels, and has continued to work well although sometimes nearly buried by the accumulation of sand.

In these switches the ends of the tongue-rails are extended a foot beyond the sharp edge that fits against the top of the main rail, and the extended ends are curved inwards like a check rail end, and reduced in height 1¼ inch to allow the wheel flanges to pass over the top when the tongue-rail is closed to the main rail; and in any case of the tongue not being properly closed the pressure of the wheel flange will tend to crush any obstructing substance upon the chairs. This action is aided by the check-rail end of the tongue on the opposite side, which in such a case will not be opened to the full extent but sufficiently so to guide the wheel flanges in the proper course, and by drawing them from the other imperfectly closed side prevent the wheels from taking both lines.

The advantages aimed at in these switches are safety and economy in use, on account of their working as well without oil as the ordinary ones do when clean and perfectly oiled, saving by this means a cost of at least 20*s.* per annum for each switch; the safety from risk of the switches being reversed when the train is passing over, either by a bent axle or other unusual strain, in consequence of the closed point being kept down by the weight of the train itself; and the convenience of these switches for shunting, for which no balance weight is required, the tongues being perfectly safe when standing on either side, thus requiring less attention from the men engaged with the trains. The application of this plan does not require any alteration in the dimensions or form of the ordinary switches in general use, and it can be applied easily and at trifling cost to those already fixed and in use.

Some of these switches are now in constant use at the York and Newcastle stations, where they can be seen in operation.

In the discussion which followed, Mr. J. Bourne said that he had had one of the switches in operation at the Newcastle station for a month, and some others had been tried for about six months at the York station; these had been working very satisfactorily, and were found to have a decided advantage over the other switches in use. The others required constant oiling and attention to keep them in working order, and the oil collecting the dust and grit caused frequent cleaning to be necessary to prevent risk of accident from the switch sticking partly open. In winter great difficulty was experienced with ordinary switches from the snow, which partially melted in the day-time and then froze again in the evening, causing the switch tongue to be choked up by ice and prevented from shutting close, and the men had to be continually using salt to thaw the ice and keep the switches working. But these new switches were completely free from those defects, and appeared very successful in meeting the requirements of self-acting switches; no oil was used, and this effected an important saving in annual expense; and from the switch tongues not having any sliding motion on the chairs no inconvenience was experienced from sand and dust, and the risk of their sticking partly open was effectually prevented, as they must fall on one side or the other. In reply to a question,—whether any special provision was required in boxing up the switches to protect them from injury, Mr. Bourne said that the switches were all boxed up in the station yards to protect the connecting rods from the risk of being caught by the waggon coupling-hooks; no other protection had been required for the new switches, and they had kept in complete order.

In reply to an inquiry, whether an engine passing over the switch backwards opened the tongue as readily as in the ordinary switches, Mr. J. A. Haswell replied that no difficulty was found in this respect, and the small-sized chaldron coal-waggon readily opened the tongues.

Mr. E. A. Cowper thought the new switch accomplished in a very neat and effective manner an object that had been much aimed at, and had been the subject of many ingenious schemes. One plan that had been proposed was to have inclined surfaces upon the chairs for the switch tongue to slide down; but there was an objection to an inclined plane in the risk of bending the tongue from the friction when the weight came upon it; and it was undoubtedly a favourable point if the use of oil and the sliding motion could be entirely dispensed with, as in the plan now described. The new switch would have a tendency to crush

* Paper read at the Institution of Mechanical Engineers.

Digitized by Google

any stones by dropping down upon them in closing, and it would certainly be less likely that anything would remain on the chairs than in the case of the ordinary switches, where the action in removing stones was by pushing them along, and there was the risk of some getting jammed in between the tongue and the main rail, and preventing the tongue from fully closing.

Mr. J. Tomlinson remarked cases were frequent of engines getting off the rails from a switch remaining half open, so that both tongues caught the wheel flanges; and thought it would be a useful improvement if this switch prevented the risk of sticking half open, by the tongues being sure to fall on one side or the other.

THE PEEL INSTITUTION, ACCRINGTON.

The new building for this institution was opened on the 24th December last. It is built in the Modern Italian style, the principal front having a bold projecting arcade under cover of which carriages can put down or take up for the principal entrance. The arcade has deeply recessed and moulded semicircular arches with rusticated quoins and voussoirs; the central archway having a finely executed head of Minerva on the keystone. The arcade forms the base of a portico of ten Corinthian columns, surmounted by medallion cornice and pediment. The wings are lighted by windows on the ground story, having rusticated arches and quoins, and on the second story by handsome moulded windows having carved trusses and segmental cornices; the whole being surmounted by a bold cornice and balustrade.

The ground story is approached by a spacious entrance hall, 24 feet square, from which is the principal staircase to the second story. It also comprises rooms for the accommodation of the mechanics' institution, consisting of reading room 32 by 25 feet, class rooms, &c.; a meeting room 45 by 26 feet, and other rooms intended to be used as town's offices, &c. The second or principal story is devoted entirely to a large public hall or assembly room, 120 feet long, 45 feet wide, and 30 feet high, having ante and retiring rooms, with gallery over.

The interior decorations of the assembly room are of considerable richness, and fully carry out the style of the exterior. The walls have panelled pilasters, filled in with festoons and wreaths of fruits and flowers, from which spring brackets for side gaslights; a bold medallion cornice and enriched frieze runs round the entire room, from which springs a coved and panelled ceiling, having the central panel enriched with highly decorative perforated flowers. The room is lighted by three handsome bronzed chandeliers, supplied by Massinger, of Birmingham, and is ventilated through the ceiling and roof. The entire building is heated by Hadens' system of hot air and water combined, and is very effectual in its operation. The entire cost of the building, exclusive of land, will be when completed about 9000*l*.

The architect from whose designs and under whose superintendence the building has been erected is Mr. J. Green, Portsmouth-house, Todmorden.

EXHIBITION OF THE PHOTOGRAPHIC SOCIETY, SUFFOLK STREET, PALL MALL.

On a careful examination of the pictures on view in this the sixth year of the existence of the above institution, we are disposed, while acknowledging the rapid strides which the art has made, to believe that some of its happiest productions, and those which tend most to exemplify its capabilities, will be found wanting on the walls. Consequently, although the collection is a large one, and possesses attractions of varied interest, that peculiar element seems lacking which would enable us to pronounce the present exhibition to be not merely superior in the number of meritorious works to any of its predecessors, but as illustrating one or more of every phase of application which photography has assumed. It is to be regretted also that so many duplicates have been admitted; we do not mean such as show a study in its crude and then in a coloured state, but *bonâ fide* reproductions in different frames; and this is more especially observable among the portraits, a class which, as in exhibitions generally, constitutes a prominent feature here. In the catalogue we read interminable records of "portrait of a lady," or "of a gentleman," which, under those titles, have not the slightest interest for the public; but some of these, again, meet our eye in which the vagueness of description has vanished, and the real name of the individual more properly takes its place. There are few things more truly interesting to a reflective mind than a leisurely comparison of what phrenologists call the "developments" of the heads of different individuals, and this interest is vastly heightened if one is enabled to identify well-known features, and to feel assured that every lineament we behold has been depicted with truth's unerring hand. By all means, therefore, if a revision of the catalogue should be called for, let the shortcomings of the present one be as far as possible made good.

The collection this year is a large one, numbering 643 subjects, but many of them having become previously familiar through the medium of the print-shops, such will not invite, in a general way, a renewed inspection. We allude to this for the purpose of suggesting whether, with such means of forming an annual exhibition as they ought to possess at command, the Photographic Society should not confine its selection (except in very special cases) to entirely new or unpublished works. The field of art now embraced is emphatically an ample one, and hosts of skilful practitioners are contributing the fruits of their labours from every portion of the globe. One most valuable series of photographs in the present gallery is that forwarded from Egypt by Mr. F. Frith, whose "Panorama of Cairo" (553), on a most extensive scale, is alone worth a visit to see. Such curious forms, yet elegant in combination, as are offered in Mr. Frith's views of "Mosques in Cairo," and "Tombs of the Mameluke Kings," are eminently suggestive to our adventurous architects, while to those who are attracted by the grandeur of nature, such views as his "Mount Serbal, Sinai" (547), and "the Sphinx" (549), "the Pyramids" (548, 551), and "Jerusalem" (558), will not pass unnoticed.

By far the largest wall space, however, is occupied by the wonderful reproductions of Raphael's Cartoons, by Messrs. Caldesi and Montechi, the most recent and one of the most useful achievements in the art. These photographs are of the largest available size, and must necessarily supplant even the most elaborate hand-transcripts of the masterly originals. Parts at large of each have also been taken as additional studies for artists, by whom they will be prized as a long-coveted treasure.

The names of Roger Fenton and Francis Bedford hold a prominent place in the catalogue, but not more so than their productions deserve. In every case we discern the operations of science commingled with the fascinations of artistic power. Mr. Fenton has done noble service to architects in his exquisite series of studies from our venerable cathedrals; nor, perhaps, are Mr. Bedford's contributions from our ruined castles and abbeys less valuable, as certainly they are not less picturesque and attractive. Those of our readers who have scanned the neighbouring "Architectural Photographic Exhibition" will have noticed the beautiful series of views from Tintern, Raglan, Chepstow, &c., which the latter gentleman has produced: some of these are again visible in the collection we are now surveying, while the additional photographs before us, which are of the same choice kind, may be said almost to have left no peep unexplored, or delicate fragment not brought to view. Mr. Bedford has also nine delightful views (108) of Gotha and its vicinity, photographed by command of Her Majesty the Queen; and, in conjunction with Mr. Cundall, (125) some pretty glimpses of Hever Castle, the Moat at Ightham, Charlton, Kent, and part of Rochester Cathedral. Nearly all of the photographs we have alluded to were produced by the collodion process. Others may be seen in which the collodio-albumen has been employed, while again for others we are indebted to waxed and plain paper, oxymel, the original Talbotype, and Taupenot's process. The cartoons are wholly by collodion. Two subjects (592, 613) have been worked by the "honey" process; and one, (603)—a photograph from an oil painting—has been transferred by photo-galvanography.

To the visitor who desires more closely to investigate the results of these several methods we would recommend for study, as among the gems of the exhibition, besides those already named, Mr. Edwards' "Study of Clouds" (4),—Mr. Morgan's "Study in Hambrook Glen" (15)—a charming specimen;—Mr. Fenton's "Views at Haddon Hall" (33, 61)—that favorite haunt of all artists;—the magnificent scene in "Dovedale Lower Valley" (51), by the same gentleman, and the stately majesty of his "Cheddar Cliffs" (55);—Mr. F. G. Eliot's four views from the lakes of Cumberland (89);—the splendid large photograph, by Mr. Philip H. Delamotte (169), of the "Crystal Palace, Sydenham"

Digitized by Google

(interior);—and the series of pictures, from (384) to (392), by Mr. C. J. Burnet, exhibited to show chemical actions. (See *Photographic Journal*, Jan. 21, 1858.)

Those who may be interested in architectural pursuits will find an agreeable, if not an extensive variety. The works of Fenton and Bedford already alluded to are by far the most finished and perfect of their kind, nor ought we to forget the views of Eltham, Penshurst Castle, Hever Castle, &c. in (580, 585), with which Mr. Cundall's name is also associated. Besides these we have "Sparrow's Ancient House, Ipswich" (72), by Mr. Dixon Piper;—a last century Roadside Inn, at Wansford, Northamptonshire (92), by Cundall and Downes, which has a truly sensible and comfortable look;—some clever studies, chiefly in Kent, by Mr. Cruttenden, such as (97), "the Baptistery, Canterbury Cathedral,"—and the "Christ Church Gate," near the same spot (110),—High Street, Maidstone (567),—"Boughton Monchelsea Church" (593)—a beautiful specimen; and Viscount Falmouth's seat at Mereworth Castle (631). There are several continental subjects which are exclusively architectural and good, such as those from the Palais de Justice, Rouen (178), by Mr. Howlett,—the "Porch at Rheims Cathedral" (271),—"Ruins of Heidelberg Castle" (485, 486), by Mr. G. C. Backes, &c. &c.; while, among English ruins, may be seen views of St. Osyth's Priory, Essex,—St. Botolph's Priory, Colchester,—and the picturesque remains of Walberswick Church, Suffolk (507), by Mr. Cade, who also exhibits a number of views of the Colleges in Cambridge.

THE BAROMETER AS AN ENGINEERING INSTRUMENT.

By JOHN M. RICHARDSON.*

(*Concluded from p.* 14.)

THUS far the results given by the level have been regarded as absolutely correct, and those obtained by the barometer as subject to error. But, after the comparisons which have been made, the question very naturally arises,—Which instrument gives the most reliable results? The question cannot be decidedly answered at present. Theoretically both the instruments give correct results, but each is subject to numerous errors. The chief sources of error in the case of the level are: (1) construction; (2) adjustment; (3) observation; (4) refraction; (5) dewpoint, as affecting refraction; (6) unequal expansion and contraction of the parts of the instrument; (7) curvature of the earth.

The errors arising from (1), (2), and (3) can be reduced to their minimum by careful selection, adjustment, and observation; those arising from (4), (5), and (6) cannot perhaps in practice be avoided; that produced by (7) can be partially corrected. The principal causes of error in the use of the barometer are eight, viz:—(1) construction; (2) adjustment; (3) observation; (4) dew-point, as affecting pressure of atmosphere; (5) unequal expansion and contraction of parts of instrument; (6) changes of temperature, as affecting pressure of atmosphere; (7) agitation of the upper strata of the atmosphere, currents, &c.; (8) daily variation.

Errors arising from (1), (2), and (3), as in the case of the level, can be reduced to their minimum by careful selection, adjustment, and observation; those arising from most of the others can be corrected, but they are usually small; and regarding the barometer as an engineering instrument, they would not perhaps be corrected, except the one due to changes of temperature.

The adjustment of the level is a complex and tedious operation, and requires so much time that it cannot be done before every observation. Hence an error of adjustment may exist for some time before it is discovered. The adjustment of the mercurial barometer is simple, requires but a moment, and has to be made before each observation. The liability to error of adjustment in the case of the barometer is not so great, then, as in the case of the level; but an error of adjustment of the former, although small, will probably cause a much greater error in the determination of differences of altitude than an error of adjustment of the latter.

An error of observation with the level will usually vary the result but little; but, as a very small change in the height of the mercurial column corresponds to a considerable difference of level, a slight error of observation with the barometer may introduce a very material error in the final result. Upon the whole, then, taking into consideration the other errors, as well as those to which allusion has been particularly made, the liability to error on the part of the level appers to be less than on the part of the barometer. Everything, however, will depend upon the care and skill of the observer; care in avoiding errors, and skill in eliminating those which cannot be avoided.

From this view of the relative liability to error on the part of the two instruments, and the examination of observations made with them, it follows, that although the level is probably the most correct, yet the barometer, when carefully used, will be a valuable auxiliary to the engineering profession.

It is to be hoped, however, that more comparative observations will be made with the two instruments; and it is respectfully suggested to scientific gentlemen who may visit Black Mountain, or who may have opportunity to do so at any other mountain, to run carefully a line of levels from the foot to the summit, driving a stake at every station corresponding to a change of level of 50 or 100 feet, and at every station so determined, to make careful barometric observations. The results thus obtained would probably be of great value, and would determine whether or not the barometer-differences of altitude are too great within certain limits, and too small within others. Some of the results of the observations quoted from the report of Lieut. Williamson appear to indicate the possibility of this being the case; if it is, and extended observations can alone determine it, the limits between which the barometer-altitudes are too great or too small can and should be determined. This subject will be dismissed after making some general observations upon the method of conducting a barometric survey.

According to Biot and others, in order to determine the difference of level of two stations by means of the barometer, simultaneous observations should be made at them: but this does not appear to be strictly necessary; for, besides the trouble and expense of having two sets of instruments and two observers, if the stations are sufficiently near for the same atmospheric conditions to prevail at them, they will hardly change during the time required for an observer to record his observations at one and pass to the other. If the stations are too far apart for the same atmospheric conditions to prevail at them, it is evidently unnecessary for the observations to be simultaneous.

How far north and south, east and west, do the same atmospheric conditions prevail? Has observation determined it? It is believed not. Here is a fruitful and valuable field for investigation. If two stations are separated by a considerable distance, and particularly if rivers, swamps, forests, chains of hills, or mountains intervene, it appears to be very improbable that the same atmospheric conditions, temperature, amount of moisture, clouds, winds, &c. &c., should prevail at them; and in order to apply the correction for horary variation it is only necessary to know the time of each observation.

In making a survey, however, it will be best to compare only those observations which have been made under pretty much the same atmospheric conditions. Thus, although it might do to compare together those observations made on a cloudy or a windy, or a fair and still day, it would not do so well perhaps to compare those made on a cloudy day with those on a fair day; or those made on a windy day with those on a still day, &c. Hence, having concluded the survey for one day, the survey for the next day should commence at the last station of the previous day's survey. Connecting the different days' work together in this manner, the final result, or difference of level of the two extremities, as determined by this chain of observations, should agree essentially with the result obtained by comparing together the independent observations made at the two extremities. Thus the barometer furnishes a check upon the observations made with it at intermediate stations.

It is advisable that barometrical surveys should be made during fair and calm days only; and, as the observations require but little time comparatively, and as they need be taken only where there are considerable changes of level, an engineer can so select his time as to execute the survey in good weather.

Travellers usually employ the "Mountain Barometer" (mercurial) for the determination of the altitudes of mountains, and for engineering purposes it is perhaps the best also. But the "Aneroid" is so portable and convenient, and requires such little time for making observations, that on these accounts it is preferable to the mercurial. The difference between the two is at most but little, and the aneroid is constantly approaching nearer

and nearer to perfection. As bearing upon the relative accuracy of the mercurial and aneroid barometers, the following mean result of fifty-six comparative and simultaneous observations made upon them by Belville, of the Royal Observatory, Greenwich, is given:—mercurial 29·61, aneroid 29·59. Twenty of the observations agreed exactly. The greatest difference was ·03, and it occurred only three times.

Formulæ and Tables.

I.—*From Williams's 'Practical Geodesy.'*

Let h=difference of level of two stations; M and m the barometer readings at lower and upper stations; T and T′ attached, and t and t' detached, thermometer at lower and upper stations. Then

$$h=68{\cdot}965517\,[8C6+t+t']\,[\log.\mathrm{M}+\log.(9600-\mathrm{T}+\mathrm{T}')-\log.m-3{\cdot}982271] \quad \ldots \quad \ldots \quad (14)$$

Example:

Barometers.	Thermometers. Attached.	Detached.
M=29·98	T=63°	t=62 lower station
m=26·17	T′=47	t'=45 upper „

Substituting in (14),

$$\left.\begin{aligned} h&=68{\cdot}965517\,[806+107]\,[\log.29{\cdot}98+\log.9584-\log.26{\cdot}17-3{\cdot}982271];\\ &=68{\cdot}965517\times 913\times[1{\cdot}476832+3{\cdot}981547-1{\cdot}417804-3{\cdot}982271];\\ &=68{\cdot}965517\times 913\times 0{\cdot}58304=3671{\cdot}1415; \end{aligned}\right\} \quad (15)$$

II.—*From Belville's 'Manual of the Mercurial and Aneroid Barometers.'*

Let h = difference of level of two stations; A the mean height of the barometers in inches; a their difference; b the number in the following table corresponding to the mean height of the thermometers. Then

$$h=\frac{30ab}{\mathrm{A}} \quad \ldots \quad \ldots \quad \ldots \quad (16)$$

(16) is the formula of Sir George Shuckburgh: it is empirical, and gives results rather greater than those of (14); but the experiments of Sir George are regarded as being very exact.

For the aneroid Belville gives this formula,—As the sum of the readings : their difference :: 55,000 : the difference of level.

Let h=difference of level of two stations; M and m the readings of the barometer at them. Then

$$h=55{,}000\,(\mathrm{M}-m)\,(\mathrm{M}+m)^{-1} \quad \ldots \quad \ldots \quad (17)$$

The results of (17) correspond pretty well with those of (16).

III.—*From Boye's 'Pneumatics.'*

Adopting the same notation as in (14), and representing by L the latitude of the place,

$$h=h'+h''-h'''+h'''' \quad \ldots \quad \ldots \quad (18)$$

$$\left.\begin{aligned} h'&=\left[\log.\left(\mathrm{M}\,[1+0{\cdot}0001001(32^\circ-\mathrm{T})-0{\cdot}0000104(62^\circ-\mathrm{T})]\right)\right.\\ &\quad\left.-\log.\left(m[1+0{\cdot}0001001(32^\circ-\mathrm{T}')-0{\cdot}0000104(62^\circ-\mathrm{T}')]\right)\right]\\ &\quad+60158{\cdot}5;\\ h''&=0{\cdot}00111\,(t+t'-64)h';\\ h'''&=0{\cdot}0028371\cos.(180^\circ-2\mathrm{L})\,(h'+h'');\\ h''''&=\frac{h'+h''-h'''+52252}{20886861}(h'+h''-h''');\end{aligned}\right\} \quad (19)$$

(18) is the most correct formula (theoretically) of the four which have been given. It takes into consideration nearly all of the errors which can be corrected in the calculation. For extreme theoretical accuracy, M and m should also be corrected for *horary variation*.

In applying (18) care must be taken to give to h'', h''', and h'''' their essential algebraical signs. h'' is usually positive, and varies from ·03 to ·06 of h'. The essential sign of h''' will depend upon the value of L. If L is less than 45°, cos.(180°−2L) will be negative; and the term, $-h'''$ will become $+h''''$. h'''' is always positive. If the latitudes of the stations differ, L may be taken as their mean. h''' and h'''' are usually so small that they may be omitted when only ordinary accuracy is necessary. Neglecting them, (18) becomes,

$$h=h+h'' \quad \ldots \quad \ldots \quad \ldots \quad (20)$$

The values of h' and h'' are obtained from equations (19).

The formula by which the results in the 'Report' were obtained is not given. This is a grave oversight on the part of Lieut. Williamson, or his computation. The principal reason for instituting the comparison between the two instruments was to determine their relative accuracy; and it is not sufficient to give merely the results of the computations; processes and formulæ should be given in full. Different investigators have deduced different formulæ, and these do not give the same results. In instituting a comparison between the two instruments the particular formula used in the computations should be given, for any other will not probably give the same results. For engineering purposes the formula should be as simple as possible.

For more particular information with regard to the philosophy of the barometer, its construction, &c., the reader is referred to Boye's 'Pneumatics,' Belville's 'Manual,' and Williams's 'Geodesy.'

NEW CHAPEL, ROYAL DOCKYARD, WOOLWICH.

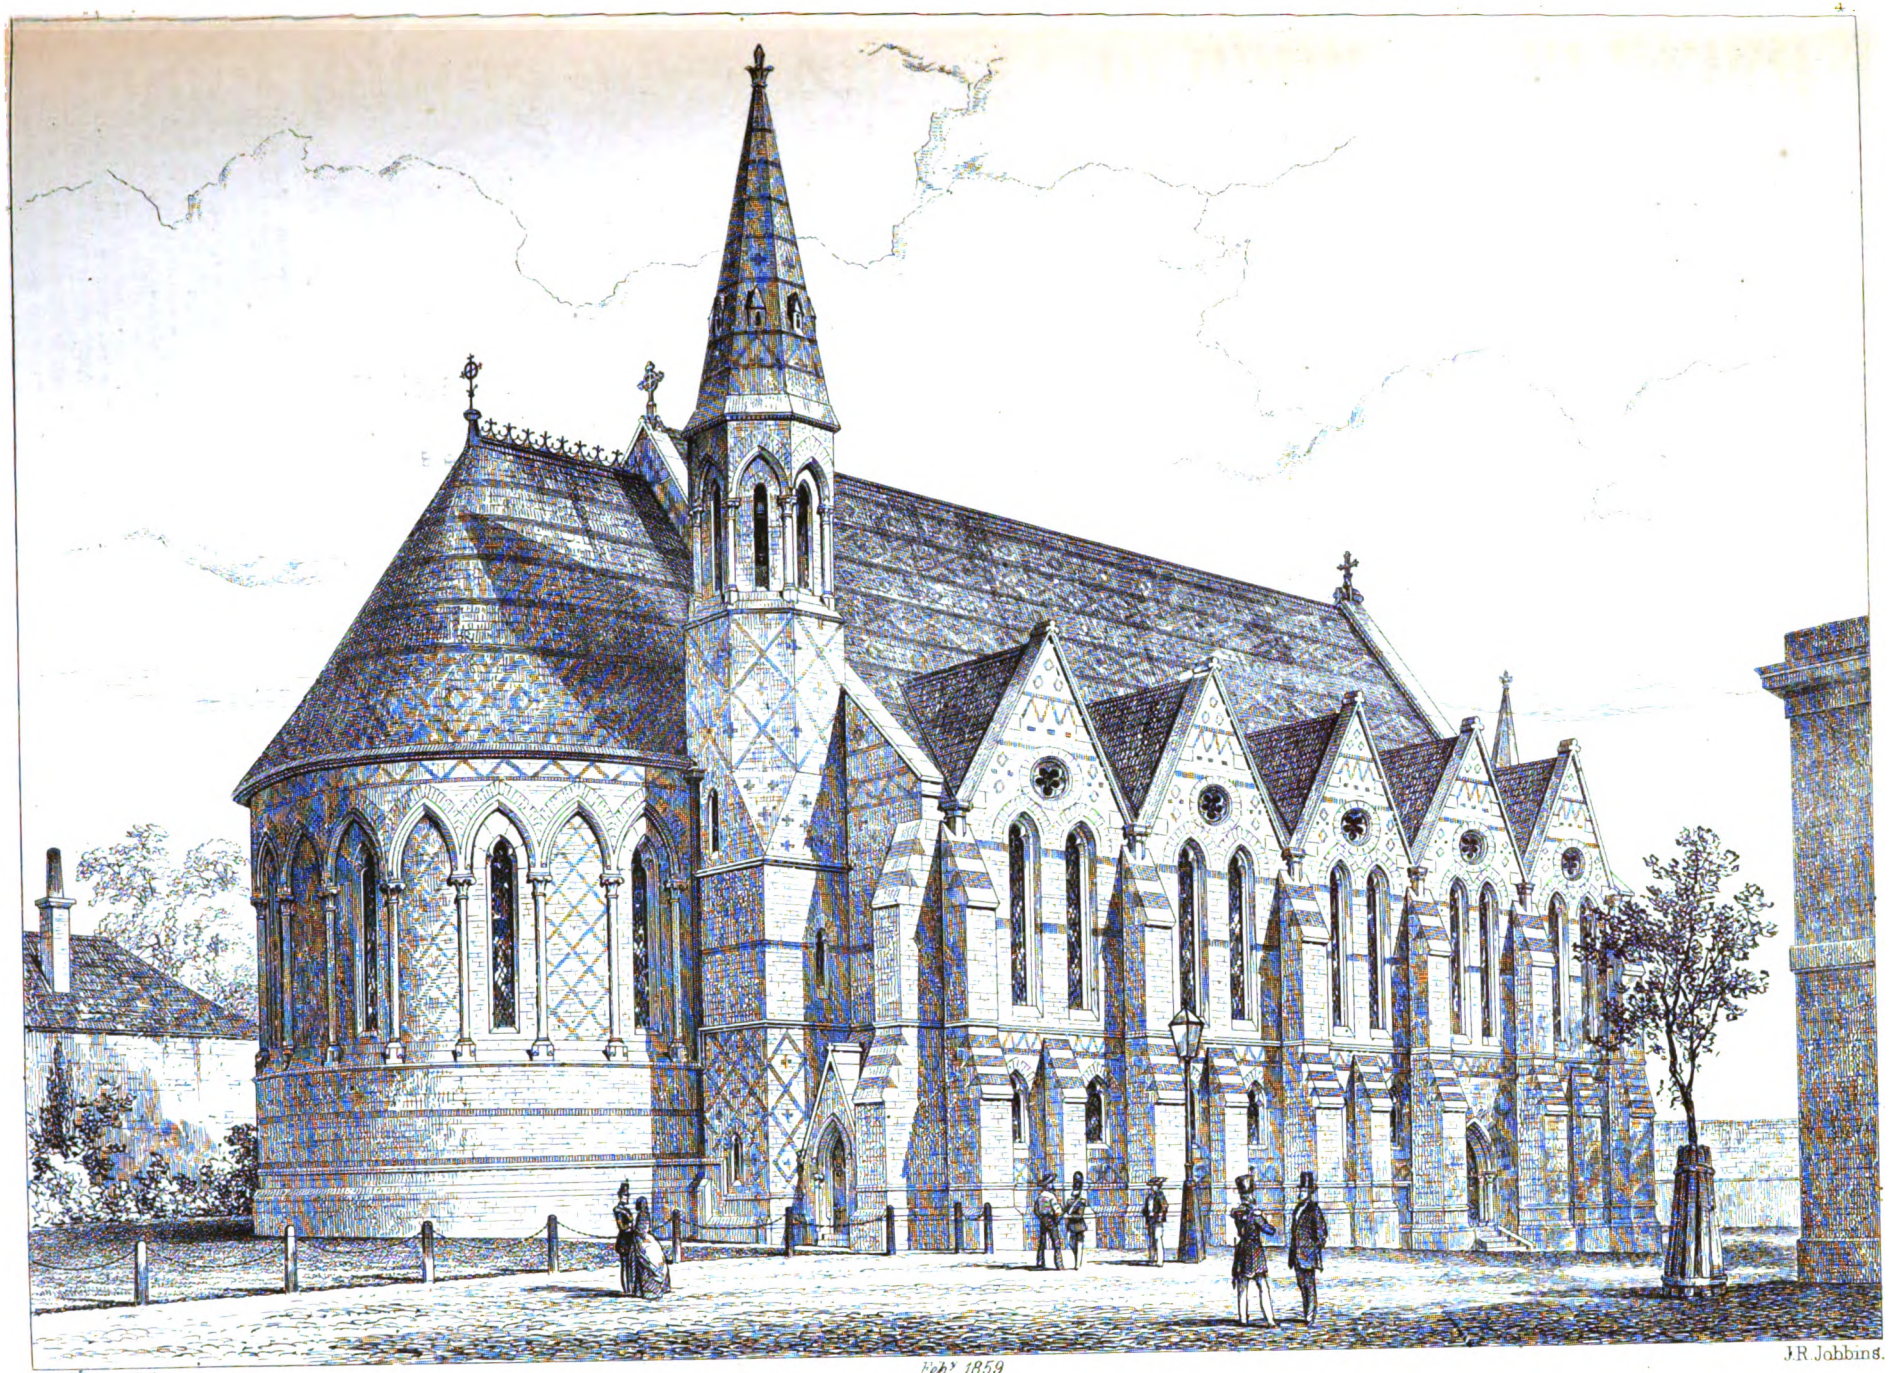
(With an Engraving.)

This building being now in all respects completed, we are enabled to give a perspective view of the exterior from the north-east. The site is close to the entrance to the Dockyard, and altogether a favourable one for displaying the features of the design from several points of view. The west-end faces a large open square, and is consequently treated boldly in its character, but we prefer the effect from the position we have chosen, as it embraces most of the leading parts, including the bell turret and the chancel apse complete.

Having in December last described at length the particulars of this erection, it is only necessary to refer our readers to the number for that month for such further information as may interest them.

ON THE GREEK CANON OF THE PROPORTIONS OF THE HUMAN FIGURE, QUOTED BY VITRUVIUS.

By Joseph Bonomi.*



It has been remarked, that although all nature bears the impress of law, to men in general she presents only a number of detached phenomena. To the diligent inquirer alone, or to those whose mental vision is acute enough to have discovered some link in the secret chain of her laws, does she gradually unfold all the relation which these phenomena bear to each other. Thus the laws which govern the analogy or proportion which the several parts of the human structure bear to each other, although very anciently sought, were probably not entirely discovered or entirely recorded till sixty years or more after the birth of Phidias, at which time Polycletus, a famous sculptor of antiquity, made a statue so exact in all its proportions, that it was considerd the most perfect model of a full-grown man. This statue furnished the canon or law of the proportions of the human figure, which from that period is said to have been observed by all the sculptors of antiquity.

Part of a canon or record of the proportions of the human figure is preserved in the second chapter of the Third Book of the Treatise on Architecture by Vitruvius, in which book that learned architect treats of the proportion, or analogy, which the several parts of an architectural structure should bear to each other, and enforces his argument by a reference to the human frame, in which he tells us certain affinities exist, which were always observed by the most celebrated of the ancient painters and sculptors. This part of the Treatise is obviously a quotation, probably from the writings of the ancient sculptors or painters then in existence, and most probably from the canon of Polycletus.

I will now proceed to read this part of the Third Book in the translation by Prof. Wilkins, notifying certain variations in an Italian version of the same text by Leonardo da Vinci,—"Nature, in the composition of the human frame, has so ordained, that the face from the chin to the highest point of the forehead whence the hair begins, is a tenth of the whole stature; the same proportion obtains in the hand, measured from the wrist to the extremity of the middle finger. The head, from the chin to the top of the scalp is an eighth, and as much from the bottom of

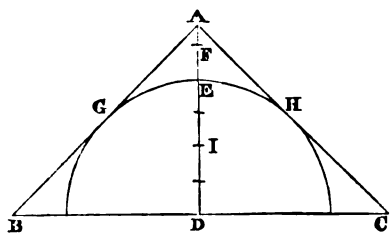
the neck.* From the top of the chest to the highest point of the forehead is a sixth; to the top of the skull, a fourth.† If the length of the face, from the chin to the roots of the hair, be divided into three equal parts, the first division determines the place of the nostrils; the second, the point where the eyebrows meet. The foot is a sixth part of the height of the entire frame; *the cubit* and the chest are each a fourth."‡

"The other members have certain affinities which were always observed by the most celebrated of the ancient painters and sculptors, and we must look for them in those productions which have excited universal admiration.

"The navel is naturally the central point of the human body, for if a man should lie on his back, with his arms and legs extended, the periphery of the circle which may be described about him, with the navel for its centre, would touch the extremities of his hands and feet." With respect to the extremities touching the periphery of the circle, it is clear from the diagram, that if the arms be raised above the horizontal, touching the top of the head, or not quite so high as the horizontal, the extremities of the hand will not touch the periphery. So likewise if the legs be expanded beyond the equilateral triangle, or more or less than 60 degrees, the feet will not touch the periphery.

"The same affinities obtain if we apply a square to the human figure; for, like the contiguous sides, the height from the feet to the top of the head is found to be the same as the distance from the extremity of one hand to the other when the arms are extended.

"The standards according to which all admeasurements are wont to be made are likewise deduced from the members of the body; such as the digit, the palm, the foot, and the cubit, all of which are subdivided by the perfect number which the Greeks call *teleios*."§



It will be observed that there is no such division in this ancient canon as that adopted by Audran, the Count de Clarac, and all modern artists,—the division of the head into four equal parts. It will also be observed that all the propositions here laid down relate to the longitudinal divisions of the human frame except only one, which bears reference to the width of the shoulders; for the transverse dimensions differ very considerably in every individual, and it is in these measurements alone that the difference between a Hercules and an Apollo, a Mercury and a Jupiter, are to be sought, but for which no law or canon is given.

With regard to the longitudinal proportions in this canon, however, I shall be able to show that they are the normal proportions of a full and well-grown man, equally removed from two opposite qualities of growth; namely, that quality of growth in which the characteristics of the infant are retained in a greater or less degree,—as for example, a large head, long body, and short extremities; and equally removed from that opposite quality of growth in which the characteristics of the adult are exaggerated,—as for example, a small head, a short body, and long extremities.

To illustrate the first mentioned quality of growth I have brought a small ancient statue of the Egyptian god Pthah, and for an illustration of the second quality of growth I must refer you to the engraving and description of a statue in the beautiful work of the Count de Clarac, vol. v. plate 840. The statue alluded to is in the marble of mount Hymettus, and therefore, probably, a Greek work, nevertheless it is remarkable for the disproportionate smallness of the head, and the length of the extremities.‖

Now, according to this canon, you will observe that the measure from the crown of the head to the sole of the foot is exactly equal to the measure from the extremity of one hand to the extremity of the other when the arms are extended. This exact equality of measure, we shall find, is the normal affinity or proportion which should exist between these two dimensions of the human frame; for if any given number of persons, whose occupations and habits of life are conducive to the full development of the structure, be measured, it will result that in nearly half the number the measure of the entire height will exceed, in various degrees, the measure of the extended arms; that in the other half the measure of the extended arms will exceed, in various degrees, the measure of the entire height; and that only a few in each section will correspond exactly to the proportion given in this canon. Thus, then, the normal proportion or affinity which should exist between these two dimensions of the human frame is established to be exactly equal, the mean measurement between the two great sections confirming the canon. In the same way, or by an analogous process, have all the other affinities recorded in the canon and set forth in the diagrams been ascertained.

I need not dwell in this room on the necessity of producing strictly (what may be called) geometrical elevations of the human figure in the elucidation of this subject, and also for explaining a most ingenious discovery appertaining thereto, by our celebrated countryman Mr. John Gibson, and by which in practice precisely the same proportions of the figure may be attained that have already been quoted from Vitruvius. This invention I am about to explain Mr. Gibson has allowed me to place in the hands of his brother artists in a small pamphlet on the subject of the proportions of the human figure.*

Mr. Gibson directs that the sculptor should draw a right angle triangle having the two sides AC and AB, that subtend the right angle, equal to each other. From the centre of the hypothenuse D, describe a semicircle which shall touch the lines A C and A B. Draw a line from D to the apex A. Divide this line from D to the periphery E, into four equal parts. Make EF equal to one of those parts. The diagram thus constructed contains all the dimensions of the principal divisions of the human figure. For instance, the hypothenuse B C represents a measure that is repeated three times. First, from the heel to the middle of the patella; secondly, from the middle of the patella to the superior spinous process of the ilium; thirdly, from the bottom of the abdomen to the pit of the neck. Thus the hypothenuse of the triangle furnishes the measure of the distances from each other of three very important points or divisions of the human figure, both in the perfectly erect position, and in that of standing at ease.

The sides of the triangle, AC or AB represent a measure that is repeated five times in the same figure; namely, first, from the top of the instep to the bottom of the patella; secondly, from the top of the patella to the pubis; thirdly, from a little above the navel to the pit of the neck; fourthly, from the top of the shoulder to the point of the elbow (of the straight arm); and fifthly, from the elbow to the knuckle of the middle finger. Thus the measure of five very important divisions of the human structure are ascertained by the sides subtending the right angle.

The remaining dimensions for completing the structure are contained in the line AD; for from D to I is the length of the neck, from D to E is the length of the face (measured from the chin at its juncture with the neck) to the highest point of the forehead. From D to F is the measure of the head from the chin to the top of the scalp, taken in the direction of the red line in the drawing; and lastly, from D to A is the measure of the foot from the heel to the end of the great toe.

All these measures obtain exactly when measured with the callipers on the finest Greek statues, and on the best living models; but you will observe, as indicated by the red lines on the drawings, these measures are taken obliquely, and in some instances inclining in two directions; as, for example, that from the heel to the middle of the patella inclines outwards in the front view, and forwards in the side view, which two obliquities reduce the vertical measure of the distance of the middle of the patella from

* This last sentence is irreconcilable, and does not occur in Leonardo's version.

† A *sixth* part is given to the distance from above the chest to the highest point of the forehead; and from the same point to the top of the skull is a *fourth* of the whole stature. In this sentence there is obviously a mistake in the numbers, which is corrected in part in Leonardo da Vinci's translation. It should be a *seventh* part is given to the distance from above the chest to the highest point of the forehead; and from the same point to the top of the skull is a sixth. The fourth is from the line which crosses the breast at the nipples to the top of the skull.

‡ Leonardo makes it a seventh. In the best antique statues it is something more than a seventh, but not quite so long as a sixth.

§ That is to say, those numbers (6 and 28) which are equal to the sum of their factors or divisors, were called τελειοι,—*e.g.* 3+2+1=6, and 1+2+4+7+14=28; and 6 is the number into which the cubit is divided.

‖ This statue was found in making an excavation in the Trastevere in 1849. It is larger than life, and represents an athlete using the strigillum, and is now deposited in the Museo Chiaramonti.

* 'Proportions of the Human Figure.' By Joseph Bonomi: second edition: Chapman & Hall, London, 1857.

Digitized by Google

the ground to the level, corresponding exactly with the middle of the patella, as obtained by the Vitruvian canon; so likewise do all the measures obtained by the triangle of Gibson coincide exactly with those designated or obtained by the four horizontal divisions or lines of the Vitruvian diagram. This accordance of the Vitruvian canon with the practical method invented by Mr. Gibson, is further demonstrated by the perfect similarity of both halves of the figure in the drawing, half of which is constructed according to the Vitruvian canon, and the other half according to the simple and practical invention of Gibson, a remark that applies equally to the two profiles of the same figure.

As before stated, all the proportions given by the triangle of Gibson obtained exactly when measured by the callipers on the finest antique statues, and on the best living models of both sexes; only those, however, which have but one inclination can be measured with the compasses on these geometrical elevations; this circumstance alone determines the inadmissibility of perspective delineations by way of elucidating the subject, for in drawings in which that essential element of the painter's art is admitted, no measure at all can be taken. The two profiles and front view of the same figure standing at ease are exhibited in the diagrams in strong black lines, while the faint red lines show the same figure in a perfectly erect position; by the change from the perfectly erect position to that of standing at ease one-fourth of the head, or in other words, a thirty-second part of the entire height is lost.

The centre of gravity is removed one inch and a quarter from where it fell in the erect figure of six feet high, namely, from between the ankles to nearly the middle of the ankle of the leg which sustains the whole weight of the body, while in the profile it remains where it was in the erect position. Also it is to be remarked that by this change of posture, where the black contour departs from the red contour on one side, there is an exactly corresponding departure on the opposite side, or, in other words, the excess on one side is balanced by an exactly corresponding loss on the other.

The remarks I have had the honour to address to you would be lengthened to an undue extent by referring to a work of Albert Dürer, on the 'Symmetry of the Human Body,'* illustrated by about two hundred woodcuts. However useful and curious this extensive treatment of the subject may be, it does not appear to me to supersede in any degree the valuable text of Vitruvius as elucidated by Leonardo da Vinci, and considered in connection with the practical discovery of our celebrated countryman, Mr. John Gibson.

THE APPLICATION OF STEAM TO AGRICULTURAL PURPOSES.

By W. Bridges Adams.

In the course of a valuable paper on "the Culture of Food," by Mr. Adams, published in the *Journal of the Society of Arts*, he makes the following remarks upon the application of steam to agricultural purposes—the importance of which induces us to quote them. After advocating the deposit of heat and manure in the form of steam or hot water combined with charcoal manure, by pipes *under* the soil (where the roots of the plants may find and appropriate them), instead of *upon* the soil, where they escape,—Mr. Adams says:

"Connected with railways for a long period, one of my principles was that the hard iron surface, which diminished friction and economised labour in transit, must be still more suitable in the process of working the land, where both transit and labour were requisite. In the year 1845 I wrote an article in the *Westminster Review*, propounding the theory of rails on cultivated land for the purpose of supplying steam power, then supposing stationary power:

'In farm districts the power need only be applied to road purposes when required, using it for farm purposes at all other times. In sober earnestness we propose to convey artificial heat beneath the earth on open land, so as to maintain the temperature suited to the growth and development of the vegetable tribes, by means of pipes of metal or earthenware circulating steam or hot water or air from a close boiler or stove: these pipes to be laid at depths of 4 to 5 feet, in the manner of deep draining. Also, by a similar process to inject the ground with gaseous manure, as ammonia and carbon, so that the heat and gases may be constantly ascending towards the surface, and thus be absorbed by the roots of the plants. We shall yet see the time when rails will be laid along the surfaces of our fields, whereon cylinder harrows will traverse, driven by the same stationary power, to break the soil into fragments fit for the growth of plants. When our land shall be drained, dried, moistened, heated, cooled, and injected with liquid and gaseous manures at pleasure, and moreover cultivated by power machines, we may be truly said to have conquered the earth, or a portion of it.'

Nothing practical that I am aware of came of this, though sundry "improvers" and projectors pronounced the idea "ingenious." Still, the ideas of heat and manure *injection* in opposition to surface applications, and the application of rails and steam power, remained in my mind a conviction, though not demonstrated publicly, to which I recurred from time to time in publications, other pursuits rendering it difficult for me to aim at practice. Early in 1850 I published a work called 'Road Progress,' advocating the amalgamation of railways and highways for agricultural improvement and steam farming in Great Britain and the colonies. The following is an extract:

'From the towns the parish roads diverge, and rails laid on them might be carried direct into the farmyard. Here, then, we have the produce at one end of the line, and the metropolis or other town at the other end.....From this farmyard lines of moveable rails would be found well adapted to take the dunging and manure by horse-trucks to the centre of each field; or a farm locomotive might be established thereon, a proposition not for ploughing, but for doing the same kind of work better by harrowing; or it might be used to pump water up to drain away, or to pour over the fields in irrigation; or to inject manure or heat, or both combined, beneath the surface of the land for the sake of improved produce. With a small portable saw-bench and morticing machine ready to connect to the engine, the farmer might, with the rude skill of his own farm labourers, construct from time to time all the woodwork he might require, as is the common practice with farmers in the United States. It is difficult to estimate the importance of carrying coals by rails direct into the farm. From that time the farm will take rank with the factory in labour-saving processes, and the production of food will be so cheapened as to put to rest for ever the fear of foreign competition. Without cheap coal farm operations can but be very imperfect.'

My next attempt at agitating this question of railways into farms with steam culture was, if I recollect, in a paper read before the Society of Arts, in December 1850.

'Siding rails would run into farmyards, and the markets would be at the stations and termini. Coals being thus borne cheaply on to the farm, farm machinery would rapidly increase, and farm labourers would acquire mechanical skill. Temporary rails would become a farm utensil, as they are now in the hands of road contractors, and contrivances innumerable would be the result.....And not mere grain and meat would be produced on the farms, but the heavy class of vegetables so important as human food, but which hitherto no town has possessed up to the extent of its consuming power.....The power of the locomotive might also be applied to inject land with steam-heat and gaseous manure through the system of drain-pipes. There is yet needing an influential landholder to be to the agricultural railway-maker what a Bridgewater was to the canal-maker, and a Devonshire has been to the horticulturist,—to multiply manifold his own revenue, while being the world's benefactor.'

In 1851, in an article in the *Westminster Review* on the Industrial Exhibition, I again agitated the question:

'Unless the rails so laid on occupation roads shall have one terminus in the farmyard and the other in the market, either directly or in communication with main lines of railway, the maximum of cheap transit for produce will not be attained. When this shall be done, and it will probably be by the agency of rails inserted in the surface of ordinary highways, the costly and artificial labour of the farmer in shifting his loads will cease, and the saving will become perfect.

'But there is more than this to which we have called public attention before. There needs a system of rails for transit on the farms. Time will show that permanent ways, as well as moveable, will be needed; but permanent way means a new laying out of the farms in rectangles, to which the system of steam digging may be applied,—not steam-ploughing, for ploughing is

* 'De Symmetria partium humanorum corporum.'

Digitized by Google

a process that never would have been invented had not horses and oxen been invented first. We do not plough with man-power, neither can we with steam-power to advantage.'

After the Great Exhibition I was not one amongst those disposed to scoff at the "agricultural mind." Considering their isolation from the hands of thickly congregated men in cities, the wonder really was how much the farmers had accomplished, and not how little. Considering that working farmers possessed but small capital, and mostly short leases and no freeholds, it was not wonderful that they did not dream of bringing the machinery of a cotton mill on to the land, and those who possessed the capital, the landlords, had but little belief in steam. Lord Willoughby D'Eresby did try to turn a locomotive to account by a system of ropes, but this was a failure, and most plans since have had reference to drawing ploughs by ropes. The practicability of using an engine bearing on the soil to dig by steam-power and propel itself has been much mooted, but till the advent of Mr. Boydell's engine it was an impracticability, and of questionable advantage even with that. My own view of the process of earth working was thus expressed in the article on the International Exhibition:

'For heavy land there needs a revolving engine made to cut with the sides, with an advancing movement, precisely as grooves are cut by machinery in wood. When there is hard work to do circular movement is the only method, whether for wood carving, metal turning, timber sawing, or earth cutting, and we are not sure that a series of vertical drills on a large scale, of the size of spades, cutting the whole surface to a sufficient depth, and travelling forward at the same time, would not be the most efficient mode of ploughing. We incline to think that the time will come when ploughing and drilling, sowing and harrowing, will all be performed at a single operation, like paper making. It is but getting together a mass of earth spinning-jennies, of stronger construction than those used for cotton and flax. The only impediment is too much moisture, but this may always be avoided by sufficient drainage.....We apprehend that it will be in the north—in Lancashire or Yorkshire—that the first strides will be made towards obtaining the real possession of earth for the purposes of agriculture.'

Thoroughly convinced of the practicability of such a system of cultivation by steam machinery combined with rails, I had purposed, amongst other projects, to give my imaginations practical effect, or rather to combine existing practice into a whole whenever leisure might obtain. It was therefore with no small pleasure that I listened to the paper read by Mr. P. A. Halkett before the Society of Arts, on the 8th of December last, on 'Guideway Agriculture, being a system enabling all the operations of the farm to be performed by steam power.' It was not left for Lancashire or Yorkshire to do this thing, but to Peter Alexander Halkett, of the Windham Club, St. James's, in our own London, and I understand a naval officer to boot, and not an agriculturist; showing that now, as often before, improvements come from outsiders looking on rather than from regular practitioners.

To any competent mechanic the diagrams would have sufficed without the paper, but on the following day I visited Mr. Halkett's machinery at Kensington, and found in Mr. Grafton a most intelligent and practical exponent of the whole system, which in general terms amounts to this:

The travelling platform frame of the builder, such as we see at the Houses of Parliament and Westminster Bridge, and at Portland and Holyhead, moving by man-power on rails on the tops of high scaffolds, is enlarged in width and breadth, and placed on rails on the surface of the land to be cultivated, raised to such a height as to clear the plants, and, instead of man-power, is moved by engine-power, which also serves to put in operation the various tools required for dealing with the land. The tramway frame of the builder is thus practically married to the portable engine of the farmer, and is furnished with tools from the workshop of the engineer. The mill that cuts iron like cheese has ceased to be a fixture, and is made moveable over the face of the land, to cut and carve the soil into fragments, to rake it into fine mould, to free it from weeds, and clean it from stones if needed. This at Kensington is the practical germ of the process that will multiply four-fold the farmer's crops; that will convert the farm labourer from an ill-clad uncultivated human being, into a well-clad intelligent mechanic, working under shelter from the sun and rain, and with all the advantages of fresh air for his workshop; that will enable this intelligent mechanic to work on a sugar or cotton plantation, with a steam fan if needed, keeping his body constantly cool; that will give to the man the practical dominion over tropical labour he thinks now only attainable by the negro; that will make as great a revolution for humanity as was done by the advent of railroads, which destroyed the practice of cruelty in overdriving post-horses; that will render the night equally available with the day for all the processes of cultivation. The plough, the harrow and the hoe, the rake and the dibble, broad-cast and drill sowing, may all be set in motion by steam, and hoeing between rows of wheat may at last be accomplished.

For the purpose of depositing liquid manure at the roots of the plants instead of on the surface Mr. Halkett has constructed a tool in imitation of the tooth of the poisonous serpent or the sting of the wasp. The liquid exudes through the end of the pipe which cuts the trench, below the surface. But there is yet a very important tool that requires adding,—a vertical drill with cutting edges, which, as it advances, will comminute and aerate the soil between rows of plants, and produce a far better result than the man-hoe.

The tank carried on the platform will be very available for liquid manure, but for the purpose of general irrigation a new method is desirable, as it would be impossible to carry sufficient water on wheels. Perforated pipes of earthenware should be deposited at two feet depth below the surface, provided with entrance for the water but no exit. These pipes being filled from the nearest level, the water will be absorbed by the spongy superincumbent soil, and carried to the plants without caking the surface. This is a most important process, for it will render level uplands more valuable than the low-lying lands called meadows usually selected for market gardens, as Greenwich and Deptford.

An arrangement of this kind would be peculiarly adapted for hot climates, were it only to save water. The valley of Valencia in Spain is a large triangular plain, sloping into the Mediterranean between two lofty mountain ranges, which unite where the river rushes down. This river, the Guadalquiver, would be in the warm season wholly absorbed for the purpose of useful irrigation, but probably one-third of it is evaporated by the sun, and another third wasted on surface weeds; and the scarcity of water is so great that perennially faction fights occur amongst the peasantry quarrelling for water, which have to be put down by the soldiery, and though scarcely a drop reaches the sea, large quantities of fine land lie waste.

On this system of cultivation by machinery it is obvious that a straight surface of soil is the best, and that a level surface will involve less power than an incline. It is obvious also that the longer the run of the machine the more convenient will be the operation and the less the cost of rails, as there will be less proportional amount of heading; and doubtless, as the system goes on, levelling of the soil will take place, as on roads, to facilitate draught. Other things being equal the level surface will be worked at less cost than the incline, as is the case when horses are used.

I now come to the question of the rails and machinery as set out by Mr. Halkett.

To work a railway economically with the least consumption of fuel it is essential that the rails should not deflect either vertically or horizontally. The greater the pressure the stiffer the rail must be, and the shorter the length over which that pressure extends the greater must be the strength of the rail. If traction be performed by the adhesion of driving wheels, the greater the number of driving wheels with a given load the more the pressure will be distributed, and the lighter may be the rail. As the cost of the rail is proportionately greater than that of the machine Mr. Halkett prefers to use light rails and a large number of driving wheels.

On an ordinary line of railway the wheels have a single flange in the inside, and the peripheries are in the form of cones and not of cylinders. The object of this is to compensate for curves on the rails. The result is a greater pressure tending to force the rails out and widen the gauge. For this reason strong cross tiers are essential to hold the rails together. For the purpose of cultivation these cross tiers are inadmissible, and therefore the wheels of the machine must be made cylindrical and with two flanges. In this mode there will be no tendency to vary the width of the gauge.

In using a single pair of wheels for the purpose of propelling in a straight line there should be no rubbing friction, provided

Digitized by Google

the wheels are exactly of the same diameter. And whatever is the number of the driving wheels the exactness must exist both in the peripheries and in the crank pins and connecting rods, or in the connecting chains if chains be used. It becomes therefore a question between stiff rails and few drivers, or light rails and many drivers, as to cost. If cast wheels be used not turned to exactness in the lathe some compensation must be provided to prevent the rubbing of the tyres on the rails, which would soon destroy both. Mr. Halkett, dealing at present with very flexible rails, which can scarcely be permanent, does not sufficiently estimate the amount of this difficulty which will occur when solid machines and sufficiently firm rails are used. Moreover, if stiffness be not provided in the rails, it must be in the frame. A flexible frame would not distribute the load, but would suffer every wheel to sink into the successive hollows.

The rail Mr. Halkett has chosen—a light single iron—is the worst form for strength that can be contrived, unless we suppose it to be firmly fastened down to a solid base. I have used such rails for light purposes in machinery, but it is a serious objection that they deflect vertically and widen literally, decreasing their vertical strength rapidly as their load increases. If with a given weight of metal Mr. Halkett does not find his rail deflect it will simply prove that he is using iron in waste.

The system is made to depend not on the strength of the rail itself, but on the substructure of burnt clay or concrete 15 inches wide. The cost is stated at £20 per acre, leaving a serious nuisance on the ground if at any time the course of the rails need be changed. There is no need whatever for this substructure, for at the same cost a self-contained rail of great strength can be applied on the surface in such a mode that it can be taken away without any waste, and removed to another position when required. If a rail be used so weak as to depend on substructure there will need a constant patching and mending. If a stiff rail be used the ordinary surface will be sufficient.

The frame, pair of engines and tools, are estimated to weigh about 24 tons, on twenty-four wheels, or a ton per wheel. As this weight is all adhesive or propelling, it will be equivalent to 6 tons of traction force, supposing no undue friction. If cylinders of 6 inches diameter be used with a 4 feet wheel and 16 inches stroke of piston, the locomotives will give out about 2580 lb. at the periphery of the wheel, and as little more than 250 lb. will be needed for the purpose of propulson at 13 lb. per ton, 2250 lb. will be left to work the machinery at a speed of 10 miles per hour.

But, if instead of a level there be an incline of one in 100, the resistance to traction will absorb about 740 lb.; on an incline of one in 25 about 2312 lb., nearly the whole force.

If the driving wheels be worked at a slower speed, with a toothed pinion at the periphery, there will of course be more available power for the machinery.

The system of Mr. Halkett in making a double engine for an enormously wide gauge by a connecting beam, thus keeping the chief load direct on the rails, displays great ingenuity, but whether the multiplicity of driving wheels in connection with it for the sake of a light rail will prove the best system remains yet to be seen, and it would be quite worth while to try the plan of Mr. Boydell with a similar structure.

There is little doubt that a gauge of 60 feet may be worked on this system, which will only require 250 yards of rail per acre, including headings, calculating a farm of a square mile or 640 acres, at a cost of £20 per acre, or £12,800 per mile. The machine may be estimated at £2000, making a total of £14,800, which for interest and materials will be £3 annual per acre. But the machine will go over the whole mile in forty-four hours, say three times a week, so that 4 square miles may be estimated to one machine. Reflecting that the rails of 4 square miles, or 2560 acres, only weigh 2500 tons, and the machine 25 tons—total weight 2025 tons, and total cost £53,200, and total annual interest and material £6384—it does not seem a matter beyond the reach of a company of tenant farmers with a moderate long lease, inasmuch as they can carry off the whole of the materials at the end of the lease, and the more especially with the probability of a double crop off the same extent of ground at half the cost of labour.

If this manifestly practical plan, doubling the strength and power of the English nation, be suffered to lie in abeyance, it will be a standing satire upon the agricultural bodies, ranking amongst them the oldest traditional names of our country."

BINOCULAR VISION.*

Of the thousands who gaze with delight upon the magical effects produced by that small instrument known as the stereoscope there are few who comprehend or attempt to assign reasons for the extraordinary optical illusions experienced through its instrumentality.

The following may assist in elucidating the principles of vision upon which these are founded:

It will in the first place be well to consider the difference between monocular and binocular vision. Nature has furnished us with several means of determining the distance of objects which may happen to come within reach of our visual organs. One is that of distinctness, a greater or lesser degree of which—other things being equal—gives an idea of greater or lesser distance in the object viewed. The second is through the change of focus required in the lens of the eye in refracting to a point on the retina, rays of light entering it with a greater or lesser degree of parallelism, thus producing in the brain a consciousness of unequal distances in the objects from which they emanate. The means above alluded to, it is evident, are enjoyed in almost the same degree when viewing with one eye as where both are used. By far, however, the greatest power with which nature has endowed us of discriminating distances is through the agency of binocular vision; or in other words, in the sensation produced in the brain by the different degrees of convergency of the optic axes required in obtaining distinct vision of the differently distant points of objects upon which they are directed. It is to this faculty that we are indebted for our most palpable evidence of differential distances, and for that consciousness of solidity and relief so remarkably experienced in the stereoscope.

It is evident, for example, when we are looking at a house or other object that has depth as well as breadth, from such a point of view as to enable us to see two sides of it at once, that we receive a differently perspective image upon the retina of either eye, or that we must see more of one side and less of the other with the right eye than with the left, or *vice versâ*. Thus accomplishing with one view what a person with but one eye would require two views at positions 2½ inches apart—the distance between the eyes—to accomplish. These are the differently perspective views of the stereoscopic cards, and it is the effort to reconcile these dissimilar pictures by converging the optic axes at points differently distant from the eyes which produces the wonderful effect above alluded to, and which enables us to experience all the sensations of delight which would be produced by the contemplation of the landscape itself. The stereoscopic pictures will of course never quite correspond. They are taken simultaneously with a camera constructed with two lenses, or consecutively with a camera with one moveable lens. The lenses of the stereoscope, besides magnifying the pictures, are so placed as to unite certain similar points of them, thus relieving the eyes of too great effort in uniting them entirely by convergency of the axes.

The means above alluded to, by which we are enabled to judge of differential distances, are of course much diminished by the distance that the objects viewed are removed from us. Our consciousness of different distances by distinctness is diminished through decrease of light. Our judgment through change of focus is diminished in consequence of the parallelism of rays from distant objects being so nearly the same as to require but little change in refracting them to a point on the retina. And lastly, the binocular effect is in a great degree impaired through the identity of distant views when seen from positions only separated by a base of 2½ inches. Nature has thus observed her usual economy in providing for our necessities alone. It being of little comparative importance to us generally to be acquainted with the relative positions of distant objects, whereas our personal convenience and even safety depend greatly upon our knowledge of those near at hand. We are therefore provided with much more ample means of determining the latter than the former.

It may not be out of place here to allude to another subject immediately connected with vision.

Sir David Brewster says, in allusion to the cause of erect vision from an inverted image, "That it has long been a problem among the learned." And further remarks, "That it is perfectly explained by the law of visible direction." Now, although it is evidently a consequence of that law, the question arises, why should we see objects in a direction perpendicular to the retina at

the point where their image meets it? In truth it is one of those facts that require no explanation, as there is nothing inconsistent or irrational in it.

There is no more reason that an inverted image should give us the idea of an inverted object than that the reverse should be the case, or that it should give the idea of a horizontal one. There is no unity necessary between the direction of an object and the direction of its image upon the retina. Nature has so associated impressions upon the retina with impressions on the brain that an inverted image on the former is evidence of an erect object to the latter. And we have no consciousness of anything to the contrary.

AXLEBOXES AND COUPLING RODS FOR LOCOMOTIVE ENGINES.

By W. A. Fairbairn, C.E.

This construction of axlebox has for its object the introduction of an elastic cushion or spring of vulcanised india-rubber between the axleboxes and framing of locomotive engines, for the purpose of allowing the wheels to accommodate themselves to curved portions of the railway, and thus to diminish the wear on the flanges of the wheels and on the faces of the axleboxes. The india-rubber spring is placed in recesses formed in the jaws of the horn plates upon each side of the axlebox, and a metal plate with a smooth casehardened surface is interposed, upon which the axlebox slides vertically with the inequalities of the road. The force of the spring action of the india-rubber is made sufficient to keep the axles of the wheels at right angles to the straight portions of the railway, but to yield to the friction of the rails upon the wheels in curved portions, and by this means to allow the axles to assume such a position as will place the wheels at a tangent to the curve. The elasticity of the india-rubber serves also to keep the axleboxes at all times in close contact with the faces of the horn blocks, so as to secure a good fit, and obviate the necessity for that constant lining which they ordinarily require in consequence of the wearing away of the working faces.

The construction of the axleboxes is shown in figs. 1 to 5, Plate V., which represent the india-rubber applied to the trailing or leading, and to the driving wheels of a locomotive engine. Fig. 1 is a half section, and fig. 2 a plan of an axlebox of the leading or trailing wheels; and fig. 3 a side view, showing the position of the india-rubber washers.

A is the axlebox itself, B the jaws of the horn plate between which the axlebox slides; these jaws are recessed to contain the india-rubber springs C, and the face plates D whch cover them. These plates are casehardened, and hence form an exceedingly smooth surface for the axleboxes to slide on; they rest upon the india-rubber springs C, and a space of $\frac{1}{8}$ inch is left between them and the jaws B of the horn blocks, allowing the axlebox to play $\frac{1}{8}$ inch either way in the direction of the length of the engine, whenever the strain upon the wheels is sufficient to compress the india-rubber to that extent. That the leading and trailing wheels may have still further flexibility of adjustment, a small play is permitted to the axlebox laterally in the direction of the axle by making the recess in the axlebox, in which the plate D slides, wider than the plate itself by $\frac{1}{2}$ inch. But to keep the axleboxes in position in straight portions of the road, the plates D are made wedge-shaped in plan, so that the elasticity of the india-rubber restores the axleboxes to their central position whenever the pressure on the flanges of the wheels is relieved. The inclination of the wedge is made such that $\frac{1}{4}$ inch movement of the axlebox laterally in either direction compresses the india-rubber $\frac{1}{8}$ inch.

The india-rubber is employed in the form of rings or washers $\frac{13}{16}$ inch thick; and it is found convenient, in order to maintain an accurate fit between the working surfaces of the axleboxes, that these washers when in position should be compressed $\frac{3}{16}$ inch, which is equivalent to a pressure of about 1 ton on each side of the axlebox, tending to maintain the contact of the working surfaces. With this pressure the axleboxes slide more freely on the casehardened surface of the plates D than in the usual construction; whilst the motion which permits the wheels to accommodate themselves to the curvature of the road does not in the least increase the oscillation of the engine, and prevents the excessive wear of the shoulders of the journals and of the flanges of the wheels, which are such fertile causes of unsteadiness in ordinary engines. A specimen was shown of the vulcanised india-rubber taken from the axlebox of the leading wheel of an engine, in which it had run 17,000 miles; it is still uninjured, and retains its elasticity as perfect as when first introduced.

In the case of the driving wheels of the engine, it is not advisable to allow so much play to the axleboxes; and hence, whilst the admirable fit between the working surfaces obtained by the above arrangement renders its employment advantageous, it is modified in this case, as represented in figs. 4 and 5, which show a half section and plan of an axlebox for the driving wheels of a locomotive. The india-rubber E consists of a flat band $12\frac{1}{2}$ by $2\frac{1}{2}$ inches and $\frac{3}{8}$ inch thick. It is covered by a wrought-iron plate F, casehardened as before, but not wedge-shaped, since in this case all lateral play is to be avoided. A longitudinal play of $\frac{1}{32}$ inch only is allowed on each side between the casehardened plate F and the horn blocks G, to permit the action of the india-rubber spring, which is compressed in this case so as to exert an initial pressure of about 15 tons on each side of the axlebox to resist the action of the force driving the engine. Notwithstanding this large pressure on the working faces of the box, it is found in practice to fall readily with the weight of the wheel itself. In the case of the driving wheel the advantage derived by this construction does not consist in the adjustment given to the wheels, but in the perfect fit at all times maintained between the sliding surfaces, the elasticity of the india-rubber making up for the wear of the axlebox, and obviating the necessity for lining up after a short period of running. The india-rubber also forms an elastic cushion to receive the shocks of the machinery. A small strip of leather shown at H, fig. 4, prevents the oil from gaining admission to the india-rubber.

The perfect freedom of motion, the small wear of the axlebox in consequence of the casehardening of the slides, the ease with which the engine passes curves, and the diminished wear of the wheel flanges are important advantages, which have been derived in practice from this construction of axlebox.

In figs. 6 and 7 is shown a similar application of an india-rubber spring I, to the outside coupling rods of an engine. In this construction of rods the use of cotters for tightening the brasses is dispensed with by employing a set screw K, at the end of the rod, secured by a lock-nut from risk of working loose. —*Inst. Mech. Eng.*

WOOD BEARINGS AS APPLIED TO THE SHAFTS OF SCREW STEAM VESSELS.

By John Penn.

Wood Bearings have been applied to the main bearings of screw shafts of steam vessels for the purpose of overcoming the serious difficulty experienced in the rapid wear of the ordinary brass bearings of those shafts. The application of these wood bearings has recently become greatly extended; and prolonged experience has given a remarkably favourable result in their durability and the small amount of wear to which they are liable.

One of the first cases of the application of these wood bearings was in H. M. steam sloop Malacca, of 200 horse power; these have now been at work three years and a half, and the result has proved completely successful. After the vessel had been at work a short time with bearings of brass, as usual, the bearings showed immediate signs of wear, and the same brasses were grooved out and small strips of lignum vitæ were put in, and although the screw shaft bearings were somewhat cut and rough, the wear of the wood was very little after running 15,000 miles; a very severe test, and where the bearings are quite new when the wood is applied, the wear is really nothing.

It was found previously that where brass and brass were used in bearings the wear was so great that repairs had frequently to be made, at great expense, after a run of 2000 or 3000 miles. The weight on the screw bearings is about 70 lb. per square inch; but from the experiments made it appears that ten times this weight might be applied with the wood bearings, and the wear would after running some years be practically nothing. Where the wood has been applied to smooth bearings, or bearings in good order, no renewal has in any instance been required, although some vessels were fitted as long ago as December 1854.

Digitized by Google

All the Government screw ships are now fitted with these bearings, and the system is coming into general use. It perhaps may be asked why iron shafts running on brass were not generally used: this would not do in wood ships, for it was found the iron bearings became rough and unequal from the chemical or galvanic action of the copper sheathing of the ship; but even in iron ships no bearing of whatever description has been found free from defects, except the wood bearing. It is always desirable where practicable to cover the iron shaft where it runs on the wood with a brass bush or covering; for an iron shaft, if the ship lies by idle for a few months, becomes rusty and tends to damage he bearing. This is the only advantage of covering the shaft with brass, for the wood wears as well on one metal as on the other, if kept constantly at work.

The mode of applying the wood bearings to the main bearings of screw shafts was described in a former paper, the wood being employed in narrow strips placed flatways of the grain, fixed in dovetailed grooves cut longitudinally in the brass bearings, with narrow spaces left between the strips of wood for a current of water for lubrication and to keep the bearing cool. This original construction is still adhered to and found quite satisfactory.

In figs. 1 to 4, Plate V. accompanying the present paper, is shown a more recent application of the wood bearings to receive the end thrust of the screw, by means of a large collar fixed upon the shaft at the screw or at any other desired position, which is capable in this construction of taking the entire thrust of the screw, thus removing the strain from the other bearings of the shaft or from the crank.

In this arrangement the pieces of hard wood, shown black in the figures, are fixed endways of the grain in a series of recesses or sockets in a brass disc A, through which the screw shaft B passes freely. This disc is either fixed to the stern-post C of the vessel, as in fig. 1, when the entire thrust is to be received at that point; or it is fixed to a cast-iron bracket or pedestal D, as in fig. 3, when it is required to take the thrust at a point of the shaft within the vessel. The pieces of wood project a little beyond the face of the disc A, and work against a brass ring E, which is fixed on the front of the screw boss F, as in fig. 1, or secured by a clip upon the shaft at the required position, as in fig. 3. The disc A and ring E, fig. 3, are both made in halves, bolted together by flanges for convenience of fixing.

When the wood bearings are outside, as in fig. 1, the lubrication is effectually provided by their continued immersion in the water; and in the case of the inside bearings, the pedestal D is cast in the form of a trough for containing water, as shown in fig. 3, by means of which the lower part of the bearing is kept constantly immersed in water.—*Inst. Mech. Eng.*

A NEW CONSTRUCTION OF RAILWAY SPRINGS.

By Thomas Hunt.

A considerable portion of the material used in the construction of the ordinary laminated steel spring gives, in the writer's opinion, but little elastic action, and in fact acts more as the base upon which the other portions of the spring deflect; and hence he has been led to the conclusion that two important defects are inherent in that principle of construction, namely, a superfluous dead weight of material used, and an unequal strain upon the several portions of it. It then occurred to him that if the plates of a laminated steel spring could be arranged so as to act upon the principle of a series of beams directly connected with each other, and so that the number of plates in action might be determined to some extent by the load (which in all carrying vehicles such as tenders, carriages, and waggons, is well known to vary considerably), these defects would be removed, and a spring of the greatest practicable strength with the minimum quantity of material be the result. Many experiments were made to clear up these points, all of which proved conclusive as to the superior strength and elastic action of the plan of spring described in the present paper over the common construction.

Various modes of constructing this spring are shown in Plate V. The cast-iron shoes are made with a series of steps, and the ends of the plates bear independently on the several steps of the shoes; the whole spring being inverted as compared with the ordinary springs, the bottom plates being the longest. Each plate is arranged to carry its proportion of the load independently to some extent of any other plate, by the steps being made gradually deeper in succession, so that only the longest plates bear at first, and the other plates take a bearing successively as the deflection of the spring increases, giving a uniform elasticity under a variable load.

By tapering each of the plates in thickness or in breadth from the centre to each end, a uniform deflection of the plates throughout their length is obtained. The result of this mode of construction is that a spring about two thirds the length of an ordinary spring gives out as much elastic action; whilst if the same depth be retained its carrying power is much increased; and hence it follows that to do the same work a much lighter spring will suffice.

The facility for giving as much deflection as may be deemed necessary to each plate independently is an important improvement in this construction of spring, as it avoids any undue proportion of the work falling on such plates as from their length should not receive it. In consequence of the independent action of each plate, they are not required to be fitted to each other as in the ordinary make of springs, and hence their cost of manufacture is lessened by the expense of so much fitting.

In Plate V. are shown the different forms of these springs that have been used.

Fig. 1, a wagon spring with curved plates tapered in thickness.
Fig. 2, a wagon spring with straight plates tapered in thickness.
Fig. 3, an engine spring with straight plates tapered in thickness.
Fig. 4, a tender spring with curved plates tapered in thickness.
Fig. 5, a tender spring with straight plates tapered in breadth.
Fig. 6, a plan of the spring shown in fig. 5.

The following table gives the particulars of experiments made on the comparative weight and deflection of the new springs and of springs of the ordinary construction:

Description of Spring.	Weight of Steel.	Length of Bearing.	No. of plates.	Breadth of plates.	Thickness of plates.	Camber.	Load	Deflection		Permanent set.
								Total	Per ton.	
	lbs.	Ft. Ins.		Ins.	Inch.	Ins.	Tons.	Inch.	In.	In.
Common spring	98	2 7½	12	3½	⅜	2½	2·70	1·62	·60	0.12
New curved spring	60	1 10	9	4	{ 1×⅜ / 8×¼ }	1⅜	2·70	1·12	·42	0·12
Common spring.	78	2 0	7	4	⅜	4½	2·05	0·75	·37	
New straight spring...	66	2 9	6	4	⅜ to ⅛	⅜	2·05	0·69	·34	
New curved spring	56	2 4	6	4	⅜ to ¼	1⅜	2·05	0·62	·31	

The wagons in which the new springs are working are 14 ft. 6 in. long, by 6 ft. 2 in. wide, and 1 ft. 6 in. deep inside, and intended for 6 tons load; but they have been frequently loaded to 9½ tons, and the straight springs were then deflected downwards about ½ inch, but were still doing their work efficiently, no failure having occurred with them.

There are now about 350 of these springs in use on wagons and tenders upon different railways; several have been two years in regular work, and the results are very satisfactory, none of them having failed.—*Inst. Mech. Eng.*

REVIEWS.

On Telegraphic Cables. Excerpt 'Minutes of the Proceedings of the Institution of Civil Engineers.' Vol. xvii. 1858.

On the Mechanical Conditions of the Deposit of a Submarine Cable. By G. B. Airy, Astronomer Royal. 'Philosophical Magazine,' July 1858.

On the Atlantic Cable. By William Gravatt, F.R.S. 'Philosophical Magazine,' July 1858.

Resuming from our last number the review of the mechanical investigations contained in the papers above cited, we proceed to consider the investigation by the Astronomer Royal in the *Philosophical Magazine* of July 1858. The principal results of this investigation appear to have been given by the Astronomer Royal in a paper read at the Institution of Civil Engineers in the preceding April. In the abstract of that paper, given in the volume first above cited (p. 141), Prof. Airy is reported to have said that "the desire to arrive at accurate instead of approximate results, had induced further investigations and new records of their results. It had lately been stated to him that the terminal velocity of the cable in falling through water would not much exceed 3 feet per second. This led to more accurate investigations, in which no part of the resistance of the water was omitted; and the general result was that for the safe circumstances, when the angle of inclination of the cable on leaving the ship ap-

Digitized by Google

proached very near to the limiting or critical angle, the views expressed by Mr. Gravatt were correct, the numbers given by Prof. Airy in a former table being considerably too large; and that for dangerous circumstances, when the cable on leaving the ship was very little inclined to the horizon, the numbers in the former table were very nearly correct." The former table here referred to is given at page 81 of the same volume, and was submitted to the Institution in the course of a discussion there.

The paper now to be considered comprises three distinct subjects: 1. The investigation of the form and tension of the cable when travelling forward and payed out uniformly, but not subject to any resistance from the water. 2. The investigation of the same things when the resultant resistance normal to the cable is assumed to vary directly as the velocity, and the law and coefficient of tangential longitudinal friction are assumed to be the same as for the former resistance. 3. The investigation of the same things when both resistances vary as the square of the velocities, and the application of that investigation to the case in which the cable assumes the form of a straight line. We shall notice each subject successively.

In investigating the form and tension of what is denominated the "travelling curve," when not subject to resistance, it is assumed that the form of the curve is always the same. Of course this is a possible case, and as Prof. Airy has made the same assumption for the cases where the resistance acts, without assigning reasons for the assumption, it may not be out of place to show that the assumption is reasonable. The most general case is of course that in which the cable has an oscillating motion, and doubtless it is in practice subject to oscillations. But where the velocity of paying out and that of the vessel are perfectly uniform, it may be safely considered that after some time the oscillations will cease, for it is clear that the resistance of the water will always tend to diminish, and finally to destroy them. The form of the curve, when it becomes permanent, may be regarded as defining the *mean* position of its parts, when they have excursions on either side of this mean position. But in general they will be small in extent compared with the length of the curve, and we may assume that they will have little effect on the tension, for the same reason that in the catenary of a suspension bridge slightly oscillating, the tension will differ little from the statical tension if the motion of no point is abrupt.

The method by which Prof. Airy conducts his first investigation is very elegant. The form of the curve is referred to vertical and horizontal co-ordinates (y and x respectively) of which its lowest point is the origin. The velocity of paying out (n) is taken equal to that of the ship, and by geometrical considerations expressions are obtained for the absolute velocity of each point of the curve in terms of these co-ordinates and the velocity (n). The absolute horizontal acceleration of each element, multiplied by its mass, is equal to the difference of the horizontal components of the tensions at its two extremities, and the vertical acceleration is similarly equated to the difference of the vertical components of the two tensions minus the effect of gravity. Finally, it is shown that the curve is the common catenary, and the equation for its tension is of the same form as for the common catenary, except that for the tension of the catenary is substituted T—a, where T is the tension of the travelling curve, and a is proportional to n^2.

It is important to observe that in working out this problem Prof. Airy assumes that the curve is horizontal at its lowest point, because it must necessarily be so if it have the "smallest conceivable tension" there. It would have been well, however, to have considered the case where there is no tension at the bottom; for it is clear that that case is the more analogous with practice, since in general the paying out is faster than is absolutely necessary, and the cable lies loosely at the bottom of the sea. In that case, neglecting the friction of the bed of the sea, it is clear that there can be no tension at the bottom of the curve, for if there were the deposited cable would not be at rest. Moreover, in the case where the velocity of the ship and of paying out are equal, the original equations ought to be and are applicable to the case where the tension at the bottom of the curve is zero; for the deposited cable, if not attached at any point, may be considered free to move with the slightest force. If that be the case there will be a point at a short distance above the bed of the sea where T is equal to a. Then Prof. Airy's equation $(T-a)\frac{dx}{ds} = c$ becomes impossible, unless c is zero. In that case the curve becomes a vertical straight line. The case may also occur in which n is so great that T—a is always negative; in that case the curve is concave in the direction of the ship's motion. This will appear by differentiating the above equation; in the equation so obtained, since neither of the other differential coefficients involved is negative, $\frac{d^2x}{ds^2}$ is positive, or (if $\frac{dx}{ds}$ be zero) is zero also. The former result indicates a curve convex in the direction of the ship's motion, the latter a vertical straight line.

If the curve be concave in the direction of the ship's motion, it will follow, since $\frac{dx}{ds}$ is positive, that the curve is concave downwards. The concavity is therefore opposite in direction to that of the common catenary. This result may appear surprising, but it is at once explained by the consideration, that if the parts of the descending cable move in a curve convex upwards, their centrifugal force may more than counteract the tendency of gravity to deflect the curve downwards. The quantity a, the magnitude of which determines whether this will be the case, is the numerator of the fraction which measures the centrifugal force.

By eliminating successively $\frac{dT}{ds}$ and T from Prof. Airy's equations of rectilinear motion (article 6), the same results may be obtained as are obtained by normal and tangential resolution, namely (firstly) that T ÷ radius of curvature is equal to the sum or difference of the centrifugal force and the normal component of the weight; and, secondly, an equation from which by integrating we obtain $T = y + C$, where C is the tension at the lowest point. We therefore, while fully admitting the accuracy of Prof. Airy's mathematical investigation, venture to object to the mode in which he states in general language his conclusions from it. He says,

"Hence we obtain this singular result, that the form of the travelling curve is exactly the same as the common catenary; and that the tension at every point is exactly the same as at the corresponding point of a similar fixed catenary increased only by an absolute constant a, which depends only on the velocity with which the curve travels."

The former branch of this proposition seems to us deficient in generality: in the latter branch of it there is not, we submit, sufficient consideration to the manner in which the physical constants are to be obtained. They may depend on the resistance which the paying out apparatus offers to the descent of the cable, or on the forces to which the deposited part of the cable is subject. Take an instance of the latter case. The result just obtained, $T = y + C$, will hold when the deposited cable lies loose on the bed of the sea and is dragged along it. Then C is the force sufficient to overcome the friction of the deposited cable on the bed of the sea; so that the tension does *not* depend "on the velocity with which the curve travels." It is to be observed that though Prof. Airy has taken the velocity of paying out = the ship's velocity, his equations do not depend on that assumption, which is quite unnecessary. His conclusion, as well as the expression for tension just given, are independent of the ship's velocity.

We have considered the problem thus fully, though it differs greatly from the corresponding practical problem relating to the deposit of a cable in water, because we are satisfied that a right understanding of the former tends to remove much of the difficulty which besets the latter problem. We now proceed to the second investigation of the paper under review, of which the subject is the investigation of the form and tension of the cable-curve, when the fluid resistance is taken to vary directly as the velocity with which the body meets the water, and the tangential resistance to follow the same law and have the same coefficient of resistance. With respect to this assumption, Prof. Airy observes as follows:

"The frictional resistance of the water to the movement of the cable is so great as entirely to modify the circumstances of its deposit. Some time since, I had prepared an investigation of approximate character, on the supposition that the friction is small, when I learnt from good authority that in consequence of the slenderness of the Atlantic cable, and the lightness of its materials, its terminal velocity in falling through water would not much exceed three feet per second; and that the ship's velocity would probably be more than double the terminal velocity of the falling cable. It was impossible after this to

Digitized by Google

consider the resistance as a small quantity for which an approximation to the first order might suffice; and I then undertook the investigation in its fullest generality, as regarded the magnitude of the resisting force.

"In regard to the law of the resisting force, another difficulty presented itself. It is known that with large velocities the resistance varies nearly as the square of the velocity. This law offers almost insuperable difficulties to mathematical treatment, if we do not restrict ourselves closely by limitations as to the form and position of the curve. But with the term depending on the square of the velocity, there is combined a term depending on the simple power of the velocity; and with movements so slow as those of the cable in some parts, the term depending on the simple power may *perhaps* be the predominant term. I have therefore considered that no error of the least importance would be introduced by assuming the resistance generally to vary as the simple power of the velocity, provided that the coefficient be so adjusted that the resistance at or near the terminal falling velocity may be correct. As far as any error is sensible it will be of this kind, that for the lower velocities I have assumed a too great resistance; the general effect of this however will be neutralised, by assuming the ship's velocity to be a trifle greater than I have taken it in the numerical calculations.

"There is another difficulty peculiar to the circumstances of a moving cable. The cable moves longitudinally as well as laterally, and there is a considerable longitudinal friction as well as a lateral resistance. I have no data for determining the coefficient of this friction. A small error, however, in the coefficient is not important, for the longitudinal motion of the cable is always much less than its lateral motion. Under these circumstances I have considered that the law and coefficient of the longitudinal friction might, without practical error, be assumed to be the same as those of the lateral friction."

The laws of longitudinal or frictional resistance to the motion of bodies in water are included among the elaborate researches of Colonel Mark Beaufoy, published in his 'Nautical and Hydraulic Experiments' (4to, London, 1834). These experiments were numerous and long continued, and appear to have been conducted with great care. It was ascertained by trial what motive force was requisite to move at various uniform velocities a floating body or "conductor," first by itself, secondly when a long "friction plank" was attached so as to be immersed at a given depth in the water, and to move in the direction of its length. The difference of the motive forces at each velocity gave the resistance due to the friction of the plank, which in one set of experiments had a surface of 46, and in another set, of 50 square feet. From both sets of experiments it resulted that the friction varied nearly as the square of the velocity. In the following table the results are copied from Colonel Beaufoy's work (p. 487) of the number of pounds required to overcome at a velocity of 1, 2, 4, &c. feet per second the friction of 50 square feet, and we have added the corresponding friction per square foot.

Velocity in feet per second	1	2	4	6	8	10
Number of lb. friction on 50 square feet	·177	·710	2·72	6·23	10·97	16·96
Ditto on 1 square foot	·0035	·0142	·0544	·1246	·2194	·3392

It will be observed that by this table the resistance increases at first more rapidly than, and subsequently rather less rapidly than, the square of the velocity. This diversity may however arise from an error in the experiments; for it obviously must be difficult to observe with accuracy the small resistance at very low velocities. The resistance per square foot may be nearly represented, by taking it at the velocity of 1 foot per second to be between ·003 and ·004, and to vary as the square of the velocity. The Atlantic cable is about 5-8ths of an inch in diameter, and 2 inches in circumference. Hence the friction of 1 foot of its length, at the velocity 1 foot per second, is about ·0006 lb. Messrs. Longridge and Brooks, in their paper (p. 39) reviewed in our last number, take this friction to be ·00054778 lb. Now the resultant normal resistance to a cylinder of which the length is 1 foot, and the diameter in feet $=d$, and moving through the water in a direction perpendicular to its axis with the velocity 1 foot per second, is about $\cdot 8d$ lb.; or in the case of the Atlantic cable the coefficient of resistance = ·0417 lb., or is about seventy times greater than the coefficient of friction.

Prof. Airy, however, takes the two coefficients to be equal. We believe that the discrepancy between his assumed data, and the data obtained by experiment, and his excessive estimate of the effect of the fluid friction, most seriously affect the accuracy of his numerical results. In the passage which we have just quoted, he stated that he has learned, "from good authority, that in consequence of the slenderness of the Atlantic cable, and the lightness of its material, its terminal velocity in falling through water would not much exceed 3 feet per second; and that the ship's velocity would probably be more than double the terminal velocity of the falling cable." It seems to us that the information was either inaccurate or inaccurately understood. The terminal velocity here referred to is that velocity at which the fluid resistance is equal to the weight in water; that resistance being, according to the hypothesis, the same for the cable moving either laterally or longitudinally. But we have seen how different the lateral and longitudinal resistances are in amount.

This terminal velocity is defined (p. 4) by the equation $e = \frac{bn}{g'}$, where e is the proportion of the ship's speed to the terminal velocity, g' the weight in water of a unit of mass, and bn the fluid resistance to which it is subject at the velocity n. The quantity e is, in fact, the resistance acting at the velocity n on a unit of the cable divided by its weight. This will be very different according as we take the resistance to be the normal or tangential resistance. It is important to know what is the value of e in either case, because that quantity enters Prof. Airy's fundamental equations, and has a most important effect on the results obtained from them. First let the normal resistance be taken to be that which determines e. The velocity of the vessel in paying out the Atlantic cable in deep water was between 4 and 5 knots an hour; say 7 feet per second, which by the formula we have above given, would correspond to a resistance of rather more than 2 lb. on each foot of the length of the cable. The weight of the same portion of the cable is about $\frac{3}{10}$ lb.; so that the value of e is about $6\frac{2}{3}$. Secondly, let the tangential resistance be taken to be that which determines e. In this case the resistance at a velocity of 7 feet per second is about ·03 lb., and dividing by $\frac{3}{10}$ as before, we find $e = \cdot 1$ nearly. Now the value taken for e by Prof. Airy is 2. It seems then that this value is either greatly less or greatly more than the value which e has in practical cases.

There seems no ground for believing that, because the value of e assumed by Prof. Airy is between the two values which it practically has, according as either kind of resistance is taken into account, the errors in the result arising from taking it too large may counteract those arising from taking it too small. It would be impossible to elucidate this point without almost reprinting Prof. Airy's investigation, which is extremely elaborate. For the sake of our practical readers we are compelled to adopt a summary method of criticism, and test the results obtained by this complicated analysis by experience. At page 11 a table is given, from which we extract the following results:

Angle made by cable at leaving ship	8° 34′	11° 22′	14° 9′	16° 53′
Tension at the point of leaving ship	71·33	36·78	21·36	13·26
Stray length of suspended cable	·052	·070	·088	·107

The unit of measure is here the depth of the sea; so that, when the angle at leaving the ship is between 8° 34′ and 11° 22′, the tension is between 71 and 36 times the weight of a length of cable equal to the depth of the sea.

It was ascertained by actual measurement that the angle of the Atlantic cable as it left the ship in 2000 fathoms water was 9° or 10° with the horizon (see volume first above cited, page 67). A piece of the cable 2000 fathoms in length would weigh about 4000 lb., and as the tensile strength of the cable is about 9500 lb. it follows that the ultimate tension cannot be so much as three times the weight of 2000 fathoms of the cable. But if Prof. Airy's tabulated results were correct, the cable would be able to bear between 71 and 36 times that weight.

It is remarked that "a small change in the stray length makes a great change in the tension." What is here meant by "stray length" is the ratio of the difference between the length of the curve and its horizontal ordinate to the vertical ordinate, or $\frac{s-x}{y}$. This quantity is involved in the fundamental mechanical equations of the investigation under consideration, and is spoken

Digitized by Google

of as the quantity "necessary for the slope of the suspended cable." It may easily be seen that where the curvature is very small this stray length is nearly proportioned to the *gradient* of the curve or its angle of inclination to the horizon, where that angle is small; and for given depths the greater the "stray length" is the less in general will be that angle, and the greater the length of the suspended cable.

It appears to us that practically the tension does not depend on this "stray length"—at least, in any material degree. If the tangential friction of the fluid be neglected, the tension is always expressed by the equation $T=y+C$, where C is the tension at the lowest point of the curve. This equation is obtained immediately by the method of tangential resolution above referred to, and holds whatever be the law of normal resistance. That is, the tension at any point is equal to the weight of a length of a cable equal to the altitude of that point above the lowest point + the tension at the lowest point. This result is independent of the length of the suspended cable and of its velocities.

When the velocity of paying out is equal to or greater than that of the ship, the tangential velocity of each point of the cable relatively to the water may be easily shown to have a downward direction. Hence the friction of the water has an upward direction, and tends to diminish the tension as given by the above formula. But the coefficient of friction is so very small, that, without the length of the suspended cable be enormously great, the friction will have inconsiderable effect in diminishing the tension.

We have left to ourselves but little space for noticing the third subject discussed by Prof. Airy,—the form and tension of the curve when the normal and tangential resistances have different coefficients, and vary as the normal and tangential velocities respectively. The evidence of experiment is so strongly in favour of these laws, that it cannot but be regretted that Prof. Airy has not devoted to the third and more practical investigation some of the labour lavishly bestowed on the second, which we confess that we regard as little more than a mathematical abstraction. In the third investigation the general equations of the second order are obtained on the hypotheses last mentioned, but no attempt is made at their general solution. Doubtless the mathematical difficulties are very great, but seeing how much Prof. Airy can do with what he terms "repulsive" equations, we have no doubt that it was in his power to obtain useful results from the general equations just mentioned. Two results obtainable from them we will notice, as they are not adverted to in the paper before us. The one is an expression for the tension which when the friction is neglected agrees with the important law of the tension above stated; the other result is a remarkable expression for the radius of curvature of the cable-curve. The one result is obtained by eliminating T, and the other by eliminating $\frac{dT}{ds}$ between the first two equations of page 14.

A particular application of the equations is given in the case in which the cable curve is a straight line. The case in which this is possible was pointed out in the part of this review which appeared in our last number. We venture to think that this case may be investigated in a manner far more simple than is adopted in the paper before us. The angle of inclination of the straight line is at once obtained by resolving forces perpendicularly to it; and the tension by resolving forces along it. In this case there is no difficulty in estimating the effect of friction as the tangential velocity, and, therefore, the friction of a unit of length is everywhere the same. In this as in other parts of the paper the effect of friction is greatly over-estimated.

We have thus freely noticed Prof. Airy's paper, feeling that with respect to a subject of such importance as this, no investigation, however high the authority by which it is supported, can claim exemption from candid criticism. To the mathematical theory of the subject the Astronomer Royal has given a contribution scientifically valuable, but not available for practical purposes on account of its errors respecting physical data.

On the Practical Application of the Principles of Mechanics to Wrought-Iron Girder Work. By J. H. Latham, M.A., C.E., Fellow of Clare College, Cambridge. Macmillan, Cambridge. 1858. 8vo. pp. 282.

The rule of thumb is fast losing its old despotic sway in engineering; and few things, perhaps, have contributed more to its downfall than the introduction and successful use in many of our great works of wrought-iron. The uniformity of this material in its powers of resisting strains either tensile or compressive, in its elasticity, in its specific gravity, insures the mathematician a footing in all questions connected with its use, such as other materials do not offer.

The consequence might be foreseen; we have, on the one hand, many of our chief practical engineers generalising from practical experiments, and reducing their results to mathematical formulæ to be applied in all cases; while, on the other hand, we find mathematicians entering with great interest into practical matters, and so directing their theoretical speculations as to be of the greatest assistance on the most doubtful points of practice;—in a word, we find practical men becoming theoretical, and theoretical men becoming practical. Of the latter class the author of the work under our notice is an example. To the learning of the University of Cambridge he has added, as he states in his preface, considerable practical experience also, having been employed for some years by the late Mr. Rendel, and, since the death of the latter, by his sons, in the arrangement and allotment of the material in the bridges designed by those gentlemen.

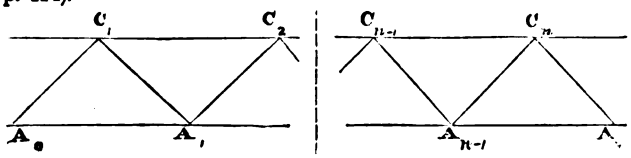
Our author's application of his mathematical knowledge to the points of girder-work thus submitted to him, together with a variety of practical hints suggested to him by the results of his mathematical investigations, form the marrow of the book. The attempt made to present practical information under the form of a regular Cambridge book, wherein all the argument is based on exact definitions and axioms, is bold, and hence arise some curious inconsistencies in the book. For instance, in the first chapter we find definitions of everything—a rivet, a plate, a joint, &c.; not that we quarrel with the number or fulness of these, for although they may be useless to any one who has had any practical experience of iron-work, yet for beginners our doubt is rather whether they are sufficiently explanatory. Any fulness here, however, is more than matched by the deficiency further on, where we are hurried into the highest mathematical reasoning on the subject of deflection, without a word of definition of the same; we are neither told what it is, nor how it is measured,—whether by an angle or a straight line.

Again, the same attempt has led our author to lay down the following axioms, and on these his main propositions are founded:

"1. If a bridge be made strong enough to bear a load, defined in weight and position, in any particular method or way, then it will be able to bear it. The lightest bridge, however, will support the given load by the easiest method.

"2. But unless you can prove that the bridge can support the given load safely, by some one method or another, no reliance can be placed on the bridge."

It is the second clause of axiom 1, that we would notice more particularly. The "easiest method" is a vague term; for our part, we are forced to think that the clause means nothing more than that the lightest bridge is the bridge of least weight. If Mr. Latham means to say that the lightest bridge is also the best bridge, we at once answer that there is stiffness, durability, cheapness, beauty, and many other things to be considered besides lightness, before we have the best bridge.



We admit that the investigations that follow refer entirely to lightness, and that viewed only in that light, they may be of the greatest use; but that by means of the above axiom their results can be made of any greater importance, we do most plainly deny. These, however, are but minor matters, and are rather necessary characteristics of the style adopted, than faults.

Before passing to the system of calculation for girders, we would give our warmest commendation to the very practical manner in which the author treats of joints; his aim in this matter, which has been most successfully attained, is thus stated: "My object has been, not to make the reader acquainted with a few empirical forms of joint, but to guide him, through all the ordinary resources available for rivetted joints, to skill in judging of their respective advantages." There is one omission, however, in this part of the work, which, though easily remedied, is too important to be passed over. We find definitions of *a rivet*, a rivet's efficiency, clear rules laid down for determining a *rivet's* effective strength in forming joints; but not a word do we find about *bolts*. Now it so happens that a rivet is treated throughout as a perfectly fitting bolt; consequently, all the reasoning that holds for one, holds for the other. It seems to us, therefore, that the rules laid down for rivets, with a view to bridges only, are of much wider application than, perhaps, even the author

Digitized by Google

supposed. We allude more especially to iron roofs and iron trusses of every kind; the rules are so clearly explained, and in a form so readily applicable to every requirement of shape or position, that they cannot but be of the greatest assistance to both engineers and architects in all designs of this nature.

We will now sketch as briefly as possible the method of calculation for wrought-iron bridges employed by Mr. Latham; premising that somewhat analogous investigations by Mr. Bow have been noticed in a review of his treatise on Beams (vol. xiv. p. 414).

Mr. Latham begins by investigating the case of a simple triangular girder, as shown in the figure, somewhat as follows:—Let W tons be the weight of the girder; (we omit to notice the load here, for the sake of brevity;) n, the number of triangles in the girder; α, the inclination of the bars to the horizontal members.

Supposing all the weight to be supported on the top of the girder, we have on each of the pins at $C_1, C_2 \ldots C_n$ a weight $\frac{W}{n}$.

First let us consider only the weight $\frac{W}{n}$ which comes on C_1. This weight, by the laws of the lever, must produce on the pier A_0 a pressure $= \frac{\text{horizontal distance of } C_1 \text{ from } B_0}{\text{span of girder}} \times \frac{W}{n}$

$$= \frac{n-\frac{1}{2}}{n} \cdot \frac{W}{n} = \frac{n-\frac{1}{2}}{n^2} \cdot W.$$

Now the vertical pressure on A_0 must be the pressure down A_0C_1 resolved vertically, or compression of $A_0C_1 \times \sin.\alpha = \frac{n-\frac{1}{2}}{n^2}.W$

$$\therefore \frac{n-\frac{1}{2}}{n^2} \cdot \frac{W}{\sin.\alpha} = \text{compression of } A_0C_1 \text{ due to weight } \frac{W}{n} \text{ on } C_1.$$

Similarly it may be shown that $\frac{n-\frac{3}{2}}{n^2} \cdot \frac{W}{\sin.\alpha} =$ compression of A_0C_1 due to weight $\frac{W}{n}$ on C_2, and so on for $\frac{W}{n}$ on $C_3, C_4 \ldots C_n$.

Hence total compression of $A_0C_1 = \frac{W}{n^2 \sin.\alpha} \overline{(n-\frac{1}{2}+n-\frac{3}{2}+\ldots+\frac{1}{2})}$

$$= \frac{W}{n^2 \sin.\alpha} \times \frac{n^2}{2} = \frac{W}{2 \sin.\alpha}.$$

In the same way it may be shown that

$$\text{Total compression on } A_1C_2 = \frac{W}{2 \sin.\alpha} \cdot \frac{n-2}{n}$$

$$\text{Total compression on } A_2C_3 = \frac{W}{2 \sin.\alpha} \cdot \frac{n-4}{n}$$

and so on for all the bars inclined upwards from left to right. Those inclined the other way, being similar in every respect, have the like strains.

Having thus obtained expressions for the strains on the bars, our author argues that the weight of all the bars as depending on the angle of inclination,

a the sum of the section of each bar $\times$ its length,

α the strain on each $\times$ the length of any one (since all are of equal length).

Adopting the usual analytical method for determining maxima and minima, he finds that the weight of the bars is a minimum when $\alpha =$ or a little greater than 45°, according as n is even or odd.

Next to find the weight of the top and bottom horizontal members:—We see that the strain on A_0A_1 will be equal to that on A_0C_1 resolved horizontally = strain on $A_0C_1 \times \cos.\alpha$,

$$\therefore \text{ tension on } A_0A_1 = \frac{W}{2 \sin.\alpha} \times \cos.\alpha = \frac{W}{2n \tan.\alpha} \times n$$

So compression on C_1C_2 = sum of compression on A_0C_1, and tension on C_1A_1 resolved horizontally

$$= \frac{W}{2n \tan.\alpha} \overline{(n+n-2)}$$

and tension on $A_1A_2 = \frac{W}{2n \tan.\alpha} (n+2n-2)$, and so on for C_2C_3, A_2A_3, &c.

Having thus found the strains brought upon every part of the girder, we can now consider the whole weight of it. This Mr. Latham does, and he shows that in cases where the depth of the girder is $\frac{1}{6}$ the length (as in bridges designed by Mr. C. H. Wyld), and also in cases where the depth is $\frac{1}{12}$ the length (as in designs by Messrs. M. and G. Rendel), the value of α, which gives a minimum weight for the girder, does not much exceed 45°; in fact the practical angle for the inclination of the bars pointed at by the results of the investigation is clearly 45°; and that angle our author adopts in all his after calculations. This proposition, briefly as we have stated it, will yet give the reader some idea of the reasoning on which the arithmetical computations that follow it are founded. Proceeding on a like basis with the above argument, they are nevertheless entirely independent, and are worked out in such a manner that they are open to any one who will have the patience to master them, even though he have no technical knowledge of mathematics.

The tables given in this part of the book, are applicable, not to the triangular girder only, but to the lattice, and in some sort to the plate-webbed girder also, these two last being considered as merely successive developments of the former. The lattice is but many systems of triangles, with equidistant parallel bars; the plate-web is only a lattice with contiguous bars.

The way in which Mr. Latham shows the passage from the lattice to the plate-web we shall state in his own language, reserving for the present the consideration of the validity of his method.

"We may pass in theory from a lattice to a plate-web as follows: If we supposed a lattice-girder, with its bars at a horizontal distance equal to that between the rivets which attach the plate-web to the booms (4" for instance), we should *then* be able—*first*, to calculate closely the maximum strains brought upon each rivet by the two lattice-bars attached by it to the boom, and consequently the resultant of those strains.

"If we *next* suppose every bar of this lattice, which slopes (say) down from left to right, to be widened out to $4'' \times \frac{1}{\sqrt{2}}$ (*i.e.* about 3") width, and made proportionately thin; then the sides of two contiguous bars will be in contact; and we may further imagine them joined so as to form a web-plate. They will form a plate strained by parallel strains down from left to right, at an angle of 45° with the horizon; the strains increasing towards the pier and diminishing towards the centre. We may *now* suppose the other lattice bars, which crossed the former at right angles, to be removed, for the strains thus superimposed on the new web-plate will be at right angles to, and therefore will not interfere with those already acting on it; and it only remains to make the thickness of the plate, and the diameter of each rivet connecting it to the boom, so large as to have together a bearing surface sufficient to pass the resultant of the strains which, as above, would have been brought upon each rivet in the lattice-girder, from the new web-plate to the rivet, to be by it transferred to the boom.

"This reasoning leads us to notice the following peculiarities in which a plate-girder differs from a lattice-girder; the reason of them is manifest:

"1. The theoretical weight of a plate-web, that is, the net section required by theory, is only half that required in a lattice-girder.

"2. While in a plate you can hardly hope to secure a bearing on its rivets of above $\frac{1}{4}$ or $\frac{5}{16}$ of its gross section along the line of rivets, in a lattice, on the other hand, a bearing can as readily be obtained equivalent to from $\frac{1}{2}$ or $\frac{3}{4}$ (in the ties), to from $\frac{3}{4}$ to the whole (in struts) of the section of each bar."

"3. In a plate-girder, since the web forms a continuous rigid vertical communication between the top and bottom booms, it is therefore, theoretically immaterial whether the load be placed on the top or bottom boom, or any part of the web.

"4. There is an extra weight in the plate-web due to covers and stiffeners; and there is more rivetting.

"5. The plate-web resists curvature of the booms, incomparably more than the lattice-web. If the plate were already taxed to its

Digitized by Google

full power as a supporting web, the curvature caused by deflection would probably split it; but (see 2) the plate-web is generally four times above its required strength."

We ought to add that an independent and more practical method is given afterwards for the plate-webbed girder.

Having said thus much of Mr. Latham's system, in which he professes to exhibit the application of mechanical theory to girder-work in *as simple forms* as possible, we would suggest the following proof of the strains on the bars of the triangular girder, which may be compared with that given above; we use the same figure and notation as before.

The pressure at each pier, and therefore at A_0, is $\frac{W}{2}$, this must be transmitted wholly by strain on bar A_0C_1, which is a strain of compression. Hence compression of A_0C_1 *vertically* is $\frac{W}{2}$, and therefore total compression of A_0C_1 is $\frac{W}{2 \sin. \alpha}$.

Consider now the equilibrium of pivot C_1.—The *vertical* forces acting are, pressure of A_0C_1 upwards; weight on C_1, $\frac{W}{n}$ downwards; and *vertical* tension of A_1C_1, which must act downwards.

Hence tension of A_1C_1 *vertically* $= \frac{W}{2} - \frac{W}{n} = W\frac{n-2}{2n}$

$$\text{Total tension of } A_1C_1 = \frac{W}{2 \sin. \alpha} \frac{n-2}{n}$$

Again, from equilibrium of A_1

$$\text{Total compression of } A_1C_2 = \frac{W}{2 \sin. \alpha} \frac{n-2}{n}$$

And similarly, total compression of $A_2C_3 = \frac{W}{2 \sin. \alpha} \frac{n-4}{n}$

and so on for all the bars.

This, we think, is not only a simplification of this one proposition, but might also be used as a key to a simpler method of numerical computation. True it is, that as we begin with the end bars, which have the greatest strain. we should have to use subtraction in our calculations, which Mr. Latham objects to for practical use, as being more liable to error than addition,—but still, the rapidity with which the strain on the first bar is arrived at would seem sufficient to counterbalance that objection. At all events, the one method might be safely recommended as a check upon the other.

In the above remarks we have noticed one part of the book only. We pass over for the present the investigation of the laws of Deflection, and a comparison of the Suspension Bridge, Suspended Girder and Hanging Girder, in regard to their respective weights and merits. The questions involved in these, requiring as they do considerable theoretical knowledge, are of the highest interest to all professional men; and we hope at some future time to be able to enter into them with the care which they deserve. Meanwhile we cannot part with our author without offering him our best thanks for the really valuable practical book which he has given to the world.

Designs for Factory, Furnace, and other Tall Chimney Shafts. By R. RAWLINSON, Esq., C.E. London: Weale. 1858.

There is no student of natural scenery who can have failed to observe how much of the character of a landscape is due to what is technically called the sky line, and how that by it may be only a slight diversion from a given point, that character will often become utterly changed. Yet there is no one who will say that in all the "freaks" of nature there is not really either a perfect consistency or a cause for the reverse, which at once reconciles us to the fact. Great is the contrast between the wild impatient forms of the Langdale Pikes and the placid wavings of the South Downs; between the towering steeps of Dovedale or Cheddar and the miniature beauties of the Isle of Wight; and, until man intrudes his civilised notions, all is satisfactory and delightful: but let him be permitted to range at will, dotting the panorama where and with what he chooses, and the spell is broken, nature's repose is disturbed, and the pleasant scene delights no more. What outrageous eyesores in this point of view have been deliberately planned and carried out in such ungainly forms as the Britannia and Saltash bridges, or the multitudes of villas which have sprung up (in the Undercliff of the Isle of Wight for instance) spotting and spoiling an ever-changing landscape, which but a few years since had irresistible charms. So in our cities and towns, while it is the boasted prerogative of Englishmen that they "must have liberty, withal as large a charter as the winds," this independence of action is a sad stumbling-block to anything like unanimity of feeling and effort, and thus the perverse irregularity of the buildings, public and private, which line our streets necessarily entails a loss of massive grandeur, without ensuring with the variety a compensating picturesqueness. We are not disposed to argue for that rigid monotony of plan which has dictated the setting out of many American cities, and which is carried out even to the names and numbers in their streets; but some such watchful guardianship should be exercised as would prevent the absurdities we have been hinting at; in this matter we may take a lesson from our neighbours, for "they manage these things better in France."

We are however being led too much away from the present object we have in view, which is, to introduce to our readers a handsome volume just issued from the press, and which bears practically on the question with which we started. It is notorious that those towering erections, factory chimneys, are as a rule uniformly hideous in appearance; whereas it is easy to conceive that there would be no great difficulty, by bestowing a little attention on the subject, to render them rather pleasing than repulsive in character. In ordinary cases (our large manufacturing towns for instance) the numbers which are upreared on a comparatively small area is a necessary evil; it is therefore the more desirable that their existence should be made as tolerable as circumstances and variety will admit; while in exceptional cases where a lofty erection has the presumption to assume to be the prominent feature in a scene, it is inexcusable if the utmost pains be not bestowed to render it in form, colour, and details such as shall satisfy the eye that it is at least an allowable, if not agreeable object. In the work before us, Mr. Rawlinson, an engineer of some experience, shows a variety of methods in which the subject may be met, and we are bound to say that his suggestions appear to be in the main excellent. The designs are numerous, and illustrated by perspective sketches; but several plates at the end of the book are exclusively constructional, and will be found worthy of study, as combining the science of the subject with artistic management.

The plates are 22 in number, and illustrate designs which all partake more or less of the campanile type; in plan some are square, others octagonal, or clustered circles, and most of them have an upper stage of a lighter character and more varied outline. We find suggestions for ordinary chimney and ventilating shafts (detached),—for a clock-tower and ventilating shaft in brick-work, terra cotta cornices, and cast-iron roofs, with a central staircase of cast-iron steps;—for water towers and engine houses in various materials;—for a pumping establishment for town water-works,—and for the engine-house, chimney, and water-tower erected at Worthing. Bricks of two colours were used here, and Caen stone dressings. The roof of the chimney is of cast-iron (open), the tank is also of cast-iron, and the roof over is of red tile. The tower is 40 feet square, the tank 12 feet deep, and will contain 110,000 gallons of water. There is a central staircase of cast-iron passing up the tower and through the tank.

To give an idea of the recommendations of the author we quote the following remarks:

"The lofty towers of Italy, and the minarets of the East, are, for the most part, constructed with bricks and mortar, and neither the one nor the other is better, if so good as the modern architect may have at his command. The proportion of brick to mortar in the foreign structures differs, however, most materially from modern practice.

"The bricks of Italy and of the East are generally very thin in proportion to area of bed—9 inches square by inch, or at the most 1½ inch in thickness. These bricks, or tiles, are frequently set or bedded in mortar as thickly spread as the brick; so that there is almost as much mortar as brick. The permanence of the work is in a great measure dependent on this liberal use of hard-setting, tough mortar. The tornado's sweep, and the earthquake's shock, have alike failed to overthrow these slender and lofty piles; though many times they must have shaken, vibrated, and bent under the furious effects of the contending elements, and tremblings of the earth. The elasticity and tenacity of the mortar has, probably, alone preserved the structures from sudden

Digitized by Google

overthrow. It is a modern practice to stint the use of mortar. Specifications generally set forth that a bed of mortar shall not exceed ⅛ of an inch. It will be a new clause—but not any less useful one—if at times it is specified that a bed of mortar shall not be less in thickness than half or quarter of an inch. In tall chimneys or towers the mortar should be of the best quality; it should be ground by horse or steam power, and should be used liberally.

"With thin bricks and thick beds of mortar the Italians used iron bolts for bond, and some of the Eastern minarets have poles of timber enclosed vertically in them. Timber cannot, of course, be used in tall chimneys, but hoop-iron for bond is well known to the profession, and its aid is highly desirable for many purposes. Rods or bolts of wrought-iron to give vertical tie may be used; but all tall structures should depend on the cohesion and gravity of the materials for stability and permanence, rather than on iron or other aids.

"Tall chimneys have elements of destruction to contend with which are absent in Italian tower and eastern minaret; namely, great heat, and gases which may affect and destroy both bricks and mortar. The only remedy against these elements will be, so to design and construct the chimney as to have an inner lining of the flue, which may be cut out, taken away, and be replaced without endangering the structure. A space, or air-chamber, betwixt the true shaft and lining, will be of great service in preserving the whole.

"Towers and minarets have, for the most part, internal stairs, or means of access up them. Our largest and tallest chimneys may easily have means of access provided, as, also, means for erecting temporary scaffolding for examination and repairs, should repairs be required. This hint will, I doubt not, be sufficient. An architect or an engineer should provide for all contingencies, and not build a tower or chimney 300 feet in height, and remove his scaffolding, without having considered the means of future examination and repairs. A recess with step and handirons, and putlock holes at regular stages, properly formed for easy use, may furnish means within the shaft. Openings through the shaft may form part of the design; such openings having the character of sunk spaces, the formed space being filled in, but affording means for the removal of the filling without fracturing the main work of the shaft. All tall chimneys or towers should have proper electric conductors secured in the best manner.

"Colour and ornament may be used in tall chimneys: contrast of colour may be made to produce ornament. The common bricks of almost any district may be sorted so as to produce contrast in tint or "tone"—red, and yellow or "cream colour." This tint of the bricks may be preserved and heightened by using mortar of the same tone or tint. Furnace ashes and lime will produce a dark mortar; pounded red brick or red tile mixed with lime will give a red tone to mortar; and cheap mineral colours may be added to mortar for pointing. The colour of mortar is sadly neglected, as, generally, the same white lime and sand are used for all tones of colour in bricks, and not unfrequently white putty-mortar is used for jointing the reddest, as well as the lightest coloured bricks;—the light-coloured work having harmony of breadth and keeping,—the red brick portion being frittered and broken up by the contrast betwixt bricks and beds and joints.

"In the designs now submitted, vertical lines are for the most part used, where existing structures (tall chimneys) invariably batter. There is great beauty in a vertical line.

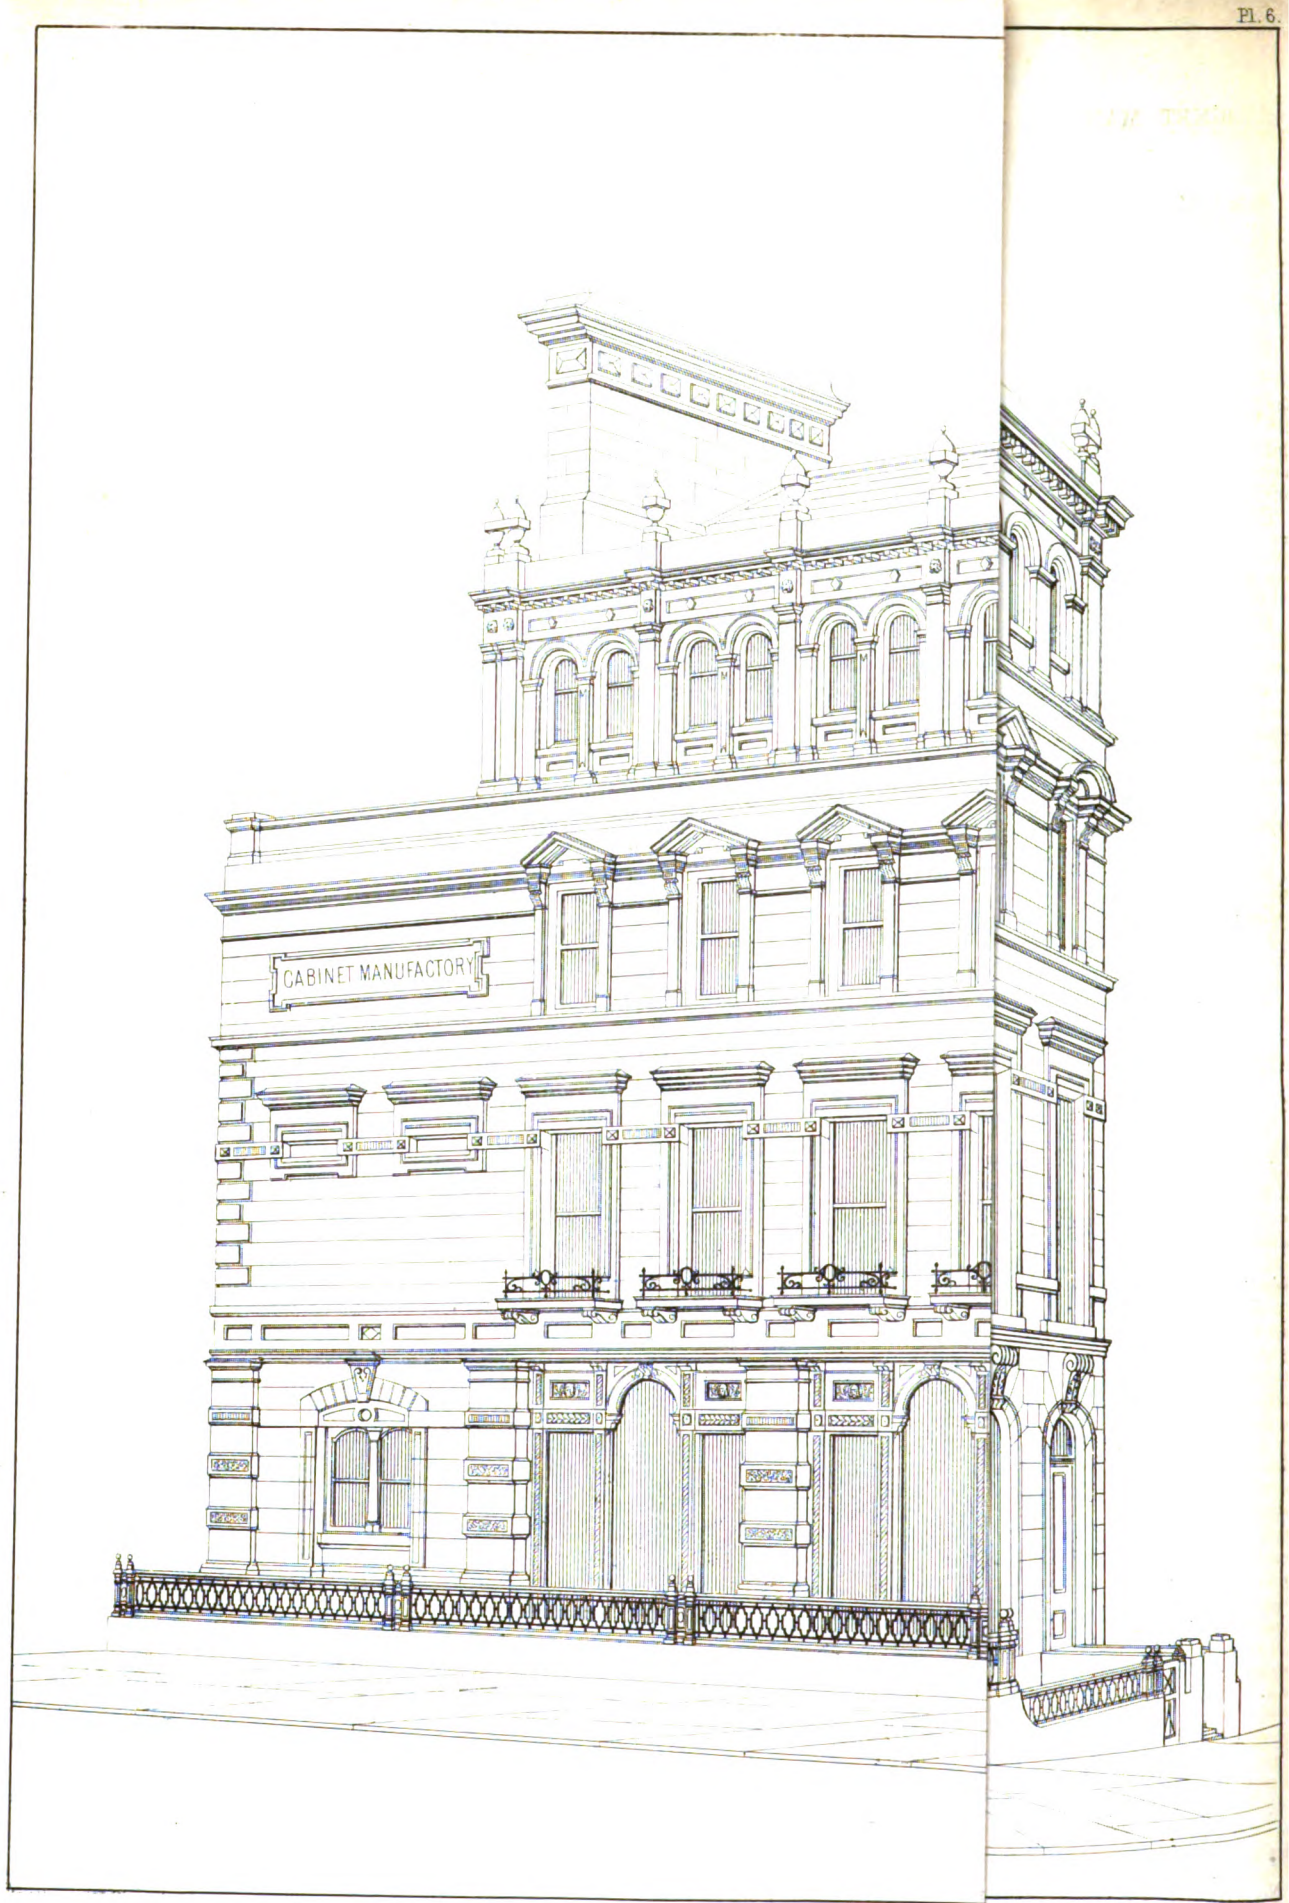
"Most of the designs are for detached structures; and it is desirable that tall chimneys should stand detached, on their own base. A special foundation should then be prepared; and the chimney will not depend on any building for support, nor injure nor be injured by vibration, nor by partial settlement in the foundations. The vertical form adopted almost throughout, may be objected to as offering a larger area for wind to act upon: the wind will not, however, injure a sound structure standing on a good foundation. The force of wind in our greatest storms rarely reaches 30lb. on the square foot; the gravity of any chimney is much greater than this. Eastern minarets and Italian towers stand not only storms of wind, but also shocks of earthquakes.

"In no case are quoins shown, either in plinth or in shaft, and their adoption is repudiated to the uttermost. Whatever material is used, must set in course with the bricks, or must form entire courses round plinth or shaft. This rule should have no exception, but should apply from foundation to summit. An external band of stone may be backed up with brick to receive the action of fire or heat; but, in such case, the stone should set in bond with some exact number of courses of bricks, so that the whole may be grouted and flushed into solidity.

"In arranging cornices and roofs on chimneys, it may be necessary to use iron bond and iron cramps. In such cases, great care must be taken so to use the metal as to run the least risk from contraction or expansion. It is practicable to combine iron with stone and brickwork, so as to ensure strength and safety; but the combination must not be lightly undertaken nor be carelessly made.

"Several modern tall chimneys have fallen in consequence of over-weighting at the top. A tall chimney, top-heavy, is easily made to sway or rock in a storm of wind, until the vibrations increase beyond the power of stability. Tall chimneys should diminish in thickness and in weight of material from base to summit: the top-finishing, in all cases, being as light as is compatible with security and endurance."

The best brick structures of England and of the Continent are deserving of more attention, as also the buildings in which alternate courses of bricks, stone, or marbles are used. Why should modern architects shrink from using colour more freely to obviate monotony, provided the eye and mind are gratified? The difficulties which once existed with regard to the use of bricks are now happily removed, and the results may be seen in many of the new buildings of London and elsewhere. Manufacturers are ready to carry out still further improvements, the great desideratum being facility of application, and the next novelty of effect. Any new forms of brick must work in bond or in course with common bricks, and be practicable not only to the maker, but also to the bricklayer. The dimensions of any new forms in brick or terra-cotta should also not exceed the easy manipulation of the material from the clay state to the finished and burned brick or tile; and the form in all cases should be one of strength, both before use and after it has been set in any building. The form and dimensions of a common brick are excellent; there is a union of strength, facility for handling, and adaptability to work any useful bond. There are many fine old brick buildings in England in which strings, cornices and chimneys are admirably wrought in the bricks of the period, and endure in almost pristine perfection when stone has crumbled to decay.



Drinking Fountains in Ancient Times and Abroad.—Public drinking fountains have always been considered in the East as a most essential part of social convenience. In ancient Rome public drinking fountains were plentiful, even on the public road, for the use of the cattle driven to the capital from great distances. A recent traveller, who made a pedestrian tour from Nuremberg to Regeansburg, states that in one of the now most secluded parts of this road-way of the middle ages, he found amongst brambles and wild shrubs the remains of one of the finest architecturally ornamented drinking fountains he ever met with. But it seems that the providing of a drinking place was once considered as one of the *manorial duties* which the landlord owed to his vassals and tenants. In the Imperial Palace (*Burg*) of Vienna, there is a well cut in the rock to a great depth, and yielding the best water within the whole compass of the city. At that well, in one of the yards of the Imperial Residence, iron ladles have been hung up from time immemorial for the public availing themselves of this superior beverage. The newly erected fountain, near the *Stubenthor*, entirely of marble and bronze, is one of the finest and chastest ornaments of the Austrian Capital.—[We shall feel exceedingly obliged to any of our readers or countrymen in Vienna, who will furnish us with a sketch of the above fountain.—Ed.]

TO CORRESPONDENTS.

We have received from Mr. Charles Henry Brooks a reply to the review, published in our last number, of the memoir by Mr. James Atkinson Longridge and him "On Submerging Telegraphic Cables." As the memoir was a joint production, each author may claim a right to reply to the review, but it would be inconvenient to occupy our pages with two replies and two rejoinders,—twice discussing the same questions. The reply ought therefore to be a joint production. Besides, we are not without hopes that discussion between the two authors may tend to considerably narrow the issues between them and us. They shall be fairly heard in a reply on which they are agreed. As the review was not written without due consideration, and the subject is difficult, the reply ought to be maturely considered. The authors cannot therefore be prejudiced by the delay which the course we propose will occasion.

CABINET MANUFACTORY AND SHOW ROOMS, LIVERPOOL.

(With an Engraving.)

It is to the spirited enterprise of private individuals that the town of Liverpool is enabled to boast of so many palatial looking edifices devoted to the purposes of trade. The architectural rivalry displayed in each shop or warehouse has in every town greatly contributed towards giving character and tone to a street or locality. When such competition involves the complete rebuilding of extensive premises and street-fronts, the architectural character of a town is felt and recognised, and when such erections have been carried out conformably with the taste, and under the immediate direction of an architect, they become not only indications of the tradesman's individual progress, but an important link in the great chain of improvement,—guiding the public to a correct appreciation of those architectural beauties necessary to enrich every great city.

From a number of such buildings recently erected in Liverpool we may select one possessing such qualities, serving to illustrate our preceding remarks, viz., the premises belonging to Mr. S. Abbott, cabinet manufacturer, of which we give a perspective view.

This building is situate on the west side of an open space at the confluence of Great George-street, Duke-street, Berry-street, and Nelson-street, having a frontage to Nelson-street 120 feet, and to Duke-street 30 feet long. It contains show-rooms for carpets, furniture, and paper-hanging (the largest being 52 feet by 28 feet), offices and packing rooms, all on the ground floor; handsome staircases lead to show-rooms of a similar size, to the height of two floors above, the upper floor being used as a store-room.

The south-end contains workshops, as also the basement under principal show-rooms. The north-end is occupied by the proprietor as a place of residence. The front is faced (with the exception of portico, cills, &c. to large openings, which are of Yorkshire stone) with Portland cement. The entire front is surrounded by low palisading in iron of an ornamental design, resting on a stone plinth. The total cost of building complete was £2756. It was erected from the designs of Mr. Henry Sumners, architect, Liverpool.

THE COMPETITION DESIGNS FOR THE NEW TABERNACLE FOR THE REV. MR. SPURGEON.

The great fact of the past month, next to the parliamentary discussion on the New Foreign Office, is the competition for Mr. Spurgeon's Chapel; the designs for which have been on view at Rea's Repository, close to the intended site of the new building, at the Elephant and Castle. The whole affair has awakened considerable curiosity, not merely attributable to the object itself and the distinguished prime-mover in it, but also to the peculiar terms of the scheme furnished to competitors in reference to the preparation of their drawings, and the adjudication of premiums. On these points it will be sufficient to remark that the present Surrey Music Hall was recommended as a basis both as to system of arrangement, and on account of its excellent acoustic properties;—that the stipulated accommodation was for 4000 persons, or 3000 seated and 1000 in "standing room;"—that there was to be a basement story providing a large lecture-hall for 800 persons, six vestries, with other offices, and a baptistery in connection with the floor above. The amount of expenditure contemplated was stated to be about 16,000*l.*, inclusive of the architect's percentage, and each competitor was requested to state what terms he was disposed to affix in this matter. Moreover, the designs were to be sent in under mottoes, but the names of the authors to be communicated (in confidence, of course) to the committee; and the awarding of the first and third premiums to be entrusted to ballot-voting among the competitors themselves, the committee reserving to themselves the disposal of the second premium. The several premiums were 50*l.*, 30*l.*, and 20*l.*, but that of the successful man to be merged in his commission, provided his design be carried out. One very singular clause in the instructions was, that "Gothic" designs would be altogether rejected,—the reason for this it is not easy to surmise.

In response to this appeal there were received some sixty-two designs, swelling into about 450 drawings, these happily were so disposed in the spacious "subscription room" above named, that each could be examined with the utmost readiness and convenience; a circumstance, it is needless to remark, greatly facilitating the arriving at the wished-for result. Yet, withal, it is a matter of regret that there was so little deserving of actual scrutiny; it being, we believe, almost unanimously agreed that, with scarcely an exception, so mediocre, not to say unsatisfactory, an exhibition has not for a long time been seen. The expression which pervades the majority of the designs is one of a decidedly civic or domestic character:—it would not be difficult to imagine that we are contemplating some town hall, assembly rooms, or less inviting subject, trickily decked out. The peculiarities of the case in a great measure favour this impression, especially when the flank elevations are in view, for the arrangements for the accommodation necessitating, in almost every instance, two galleries, and occasionally three, their existence is evidenced externally by corresponding tiers of windows. Then again, there is no exclusive or conventional means of indicating the precise purpose of this class of building, since the usual ecclesiastical symbols and accessories are eschewed, to a great extent, in dissenting chapels. In regard to the predominant architectural *style*, unquestionably the prevailing characteristic was an almost utter abnegation of the recognized rules. Gothic, we have remarked, was forbidden, but a tendency to Gothic features, such as the pointed arch and minor details, are occasionally observable. The nearest approach to these, with any consistency, is in a few designs which are founded on a Byzantine type, while the majority are decidedly of Roman or Palladian character, with here and there one of a nondescript kind, or of a professedly constructional form, in which metal is usually the all-important material. With all our partiality for the legitimate developments of practical art, we are prepared to endorse but few of such suggestions as here meet our view.

With regard to *plan*, the ordinary form proposed for the chapel is that of a parallelogram; in many cases the internal angles are canted or rounded off, in others the shape may be described as consisting of two semicircles lengthened, so as to make a kind of ellipse, while in some the internal space forms an exact square. The position of the pulpit, too, is variously shown; but owing to the size of the area required, it is generally at about one-third of the length down the chapel. That such a position, however favourable in many respects, would not be acoustically good has been repeatedly proved, and we are therefore not surprised at noticing that in several designs the pulpit is placed at nearly the extreme end, and before a kind of apse, constructed so as to throw out and distribute the voice, but both plans have their recommendations and the reverse. In front and below the pulpit we usually find the baptistery, a large open chamber communicating with the vestries: some of the designs, however, conceal it wholly by floors and moveable seats to slide over it, except when the rite of baptism is to be administered. In one case forethought is carried to so great an extent that the passages of communication are shown and described as to be laid flush with the ordinary floor, with perforated framework or grating "to receive the drippings!" The seats are generally arranged to suit a direct view of the preacher, and they therefore often radiate, instead of being throughout in strictly parallel lines. This remark applies also to some of the gallery plans, which are in this way most whimsically devised. The ceilings are almost universally adapted or closely imitated from that of the Surrey Music Hall; some few of these have the addition of dormer lights all round, which, however pleasing as an architectural embellishment, would tend very much to interrupt the free current of voice, and be therefore objectionable. The same applies to the lantern lights which are observable in some of the drawings.

A most important item in the plan is the means provided for the exits and the staircases, and it is one which is dwelt upon in every report we happened to look over; it is evident, too, that it is a point which has been carefully considered in the majority of cases, though with unequal success. It is not enough merely to provide width of stairs, but winders should be as rigidly as possible avoided, as also the inconvenience arising from intercepting crowds of people from different doors. This is a point which appears to have been hardly calculated enough, and there are comparatively few plans which provide, beyond the external lobby, any large space, open or sheltered, in which the throng of people may conveniently disperse. On many of the points we have thus enumerated it would be easy to enlarge, but it is time that we particularise a few of the leading designs.

Digitized by Google

And first, of course, the premiated designs, viz., with the mottoes 'Quod erat Facierum,' and 'Alpha,' the former proving to be by Mr. E. C. Robins, of London, and the latter by Mr. W. Hill, of Leeds. We are not disposed for a moment to question the propriety of this selection, especially in the case of the latter, yet, on the face of things, that there were more attractive designs will be readily admitted. Bearing in mind however the stipulations as to cost, style of getting up drawings, &c., and acting stringently (as no doubt they did) upon these conditions the number of designs available for selection from would be reduced to comparatively few.

The aspect of Mr. Robins' design may be characterised as of a town-hall kind; certainly by no means suggestive of a chapel, and some of the features which would have been useful as stamping the purpose of the building, the author makes a merit of disguising. We allude more especially to the staircases, of which there are four principal ones, one in each angle. These are contrived so as not to intrude on the area of the chapel, and thus cause obstructions to sound; so far so good, but from their form (an irregular ellipse) they will surely prove very inconvenient, involving as they do an unbroken succession of winders. Externally, there are no doors or any indications whatever of the existence of these staircases: the windows, which would naturally be accommodated to the raking of the steps, are ranged with those of the flanks, and the whole is thoroughly incorporated with the bulk of the mass, exhibiting only rounded corners, in themselves less satisfactory as a finish than a marked angle. Another serious defect in this plan appears to be, insufficient provision for ingress and egress. The doorways under the principal front are miserably small, the side lobbies by no means adequate to the requirements, and the centre one scarcely deserves the name;—possibly these objections can hereafter be rectified. The plan of the chapel itself is an elongated circle, and it has been very carefully arranged, though the position assigned to the pulpit is not quite satisfactory. The chief feature outside is an entrance portico, in the Roman Doric style, with coupled columns, the whole evincing much care both in the study and delineation. The estimated cost is £16,469.

The second premium remains as yet unbestowed, but the third premiated design claims our next attention. This is decidedly more chapel-like, in appearance than the one we have just noticed, and bears throughout a thoroughly practicable air. Like the former it has staircases at each of the four angles, and a portico at the end. In this case we have six columns, and the Corinthian order is employed instead of the Doric. The fault in this design is one observable in very many others, and indeed is almost unavoidable under the circumstances; we mean, too great a loftiness for its span. What else can be expected when the side elevation exhibits four tiers of windows? The plan is a parallelogram. The estimated cost is as follows:—carcase only, £11,000; finished complete, £14,450. The architect's commission to be 5 per cent. While mentioning the latter we may remark, that the request of the committee on this subject has met with various replies. Many of the competitors stipulate for the usual percentage, which is assuredly none too much when an architect's duties are conscientiously performed; others profess themselves willing to accept a less remuneration, and a few compromise matters by expressing a readiness to make a donation to the funds out of the usual commission.

A design which deservedly attracted much attention had the motto 'Ebenezer.' The principal front has an upper and lower portico of rusticated columns, coupled, and is marked at the angles with well studied towers surmounted by cupolas. The roof is curved, following the prescribed model. The general plan is simple and good, and the whole is estimated at, carcase, £12,000; finished complete, £15,000.

Perhaps the next set of drawings which we should notice are those submitted under the motto of 'The Temple,' and accompanied by printed specification and report. In respect of painstaking and elaboration these were equal to any in the room, but it is at once evident, that properly to carry out such a design would require a much larger outlay than is now contemplated.

'The Propagation of the Faith' is the title of an extensive set, which has many recommendations. As in the first-selected design the four staircases are quite exclusive of the area of the chapel, while both they and the portico arrangements are much better contrived. It must be evident how great an advantage is secured when the means of comfortably leaving a crowded place are well thought of; and this is evidently the case in the plan before us. "The building is also set back about 50 feet, allowing space for carriages to set down, and for persons on foot to congregate before doors are opened." With such a frontage there would be less inconvenience and interruption by street-noises, and the general elevation would gain much in dignity. It is a wonder that this idea has not been more frequently worked out. The plan itself presents some novelties, ingenious and otherwise, and there is merit in the sections. The architectural details of the elevations appear, however, to be somewhat faulty; no estimate is appended, but its cost would probably exceed the prescribed sum.

'Deo volente' has a peculiar plan, based on that of St. Sophia at Constantinople; consisting of segmental transepts and apse, the area in front of the pulpit being a square. There are two galleries, and additional ones in the transepts and at the west end. This is a better arrangement for seeing than hearing, while externally we lose that decision of outline which so large a building ought to possess. It appears to us also that though there is considerable ability shewn in the boldly designed tower and other features, the whole has too much the look of a country villa residence to be suitable. Estimates, carcase £9900; completed, £16,000.

'Hope' has a very fair principal elevation, but in no particular style. The roof is curved, and proposed to be covered with corrugated iron. The plan has as usual four staircases, each being 5 feet wide; the seat accommodation is 3010, and the "standing room" will admit of 1600 more, reckoning each person as occupying 2 ft. 6 in. superficial. The estimated costs, £9000 and £15,000.

The unintelligible motto, 'Phawbh,' distinguishes a peculiar set of drawings. The plan is a very lengthy parallelogram, the pulpit being placed against one of the long sides, with a recess behind containing the organ;—the only arrangement of the kind we have noticed. The exterior is heavy in design, and by no means prepossessing; the ceiling is elliptical, in one span, and some of its panels serve for ventilation. The exits, it may be observed, are well planned. Estimate, £15,000.

'Fiat Justitia' is very faulty in design, and has an enormous pediment in front, unrelieved by the slightest enrichment. The hideous skylights visible on the slope of the roof are enough to condemn all. The staircases are at the pulpit end, arranged in the form of transepts.

'Byzantine' has but two staircases at the angles, and is otherwise open to much objectionable remark. The elevations are wretched.

Much better is the design a little further on, distinguished by *a triangle enclosed in a circle*. The exterior is simple, and on the arcuated type, while the interior is well devised. There are two rows of galleries, and the pillars to the different stories are respectively of the Doric, Ionic, and Corinthian styles.

'He that Soweth plenteously shall Reap plenteously' is in plan nearly a square. There is very little architecturally to attract attention. The whole has too much of the "residential" character, despite of the poverty of some of the windows. Style, Italian, and estimates £11,000 and £15,000.

'Meliora' is also an Italian design, with some recommendatory features, the exterior having a more chapel-like appearance than most. The plan is, however, confused. Estimates, £7520 and £16,120.

'Gloria in Excelsis' has the true Music Hall roof, but its general appearance reminds one of a conservatory.

'Faber suæ Fortunæ' will not be indebted for his motto to such designs as the one here submitted. Nothing scarcely could be worse, unless it be its neighbour, 'Amity.'

'Religio' is an unpretending design in the Lombardic style. The windows are detached and absurdly small, giving the side elevation a truly prison look. The seats are curved on plan.

'Conor' is an *attempt* truly, and nothing more.

'Via ad Cœlum' has been aptly supposed to be borrowed from the Kremlin, though the author describes the style as "one that admits of the free use of modern appliances and improvements," adding, that "every tendency to Gothic has been avoided." It is all pilaster and window, with four uniform octagonal towers, and needle-like spires at the angles. It could not be executed for the money.

'Pro Propaganda Fide' is an Italian design, not without some good points as regards architectural composition, but utterly unsuited to the present case.

Digitized by Google

'Nomen alibi' has a roof in three segmental spans. The exterior is showy but tasteless; there is nevertheless some contrivance in connection with the entrances under the porticoes, which are partly recessed and partly projecting.

'Dignissimo' has not a very attractive exterior: the ceiling is honey-combed, and has a range of skylights in the centre. The seats in the chapel are placed in part obliquely, as in some other designs.

'Faith' has a plan better arranged than most: the proportion of length to width is 2½ squares nearly, and the open space at the entrances must be noticed as a good feature. The architectural portion is rather ambitious, and would probably prove over the mark in cost.

'Metropolitan' has a radiating plan, with sloping floors. The galleries are supported on classical columns. The general treatment of the elevations is heavy. Estimate, £15,454, including £500 for Caen stone dressings, but not for the statues shown on the perspective.

'Unity' is square on plan, 84 ft. 6 in. each way; the ceiling is gathered over into a circle, and is surmounted by a dome. The architecture is Byzantine, and feebly designed; the estimated cost £9500 and £18,200.

Let the House be Builded' is a very homely design, in brick; the plan resembles that of the Surrey Music Hall. 'Mea Gloria Fides' (on the same screen) has seats on the ground floor slightly curved, and externally has a handsome semicircular Corinthian portico.

'M' has its leading ideas borrowed from the Free-trade Hall at Manchester, and the design is on the whole satisfactory; abundant means of exit are contrived. The accommodation is for 3206 persons, and the estimate is put down at £16,000.

'In Good Faith' has some clever points, but they are not altogether happily worked out. The area of the chapel is 137 feet by 102 ft. 6 in., with a clear passage of 10 feet at the sides. Four spacious "crush" staircases are provided.

'Honi soit qui mal y pense' is in the Lombardo-eclectic style (at least it is so described). Considerable care has been bestowed in the getting up of the drawings, and it is evident that they have also occasioned much study. A prominent feature externally is a covered way, arched, and extending across the whole entrance front; this would be an expensive though convenient addition, but cost seems to have been little regarded in preparing this design. The author "regrets that the committee should have lowered themselves by requiring architects to state the commission they require on outlay."

'K' is a design which evinces considerable talent, but injudiciously applied. The style is Italian, simply treated.

'AR—O—ES' marks an unfinished set, not devoid of ingenuity and good taste.

'The Tabernacle' is chiefly noticeable for the bold conception of its interior: its sound practicability may, however, be questioned. "Four columns carry arches of 30 feet span, and a wooden ceiling; and the galleries, circular on plan, are carried independently by iron columns."

'Non nobis Domine' is a reproduction of the Surrey Hall, translated into a Basilican medium. The cupolas too closely resemble the pepper-boxes of our National Gallery to be satisfactory.

'In Domino Confido' has too much of a domestic look. There are four staircases at the angles, crowned with high truncated roofs. The plan is a parallelogram, and well arranged.

'A1 for £4000' is chapel-looking, so far as simplicity is concerned, there being only few architectural features; these, however, are unobjectionable.

'Omega' is a very feeble production. The windows have rusticated jambs, and do not harmonise with other parts of the design. Internally there is a dome 44 feet square at the base, and 100 feet high, carried on four pair of slender cast-iron columns.

'AZ' has another variation of the Music Hall roof, adapted to a square area of 10,558 feet super. The cupolas outside over the staircases are undeniably ugly.

'Lex' is, on the whole, a plain good-looking design (if we except the skylights), and is well arranged. The plan is a parallelogram, and the exterior has a bold portico and two turrets. The accommodation is for 3080 persons and 1000 "standing." Estimate, £15,000.

'Templa quam Dilecta' is very bold and effective, at the same time costly. It has a six-column Doric portico,—well designed cupolas at the angles,—and a roof of the Music Hall kind, but playfully broken by a series of small dormers, though these, it is probable, would interfere with the transmission of sound. The available area is 150 feet by 103. The pulpit arrangements are very *flighty*. The ceiling good, proposed to be carried on four large arches, rising from single columns,—a venturesome suggestion, we take the liberty of remarking.

'Press Forward' must be enumerated among the whimsical contributions to this exhibition. It is one of those on the Crystal Palace type, the roofs being constructed on the ridge-and-furrow principle. Estimate, £31,000!

'Ubique' is another metallic design, worthy of the "iron age." The authors seriously urge an investigation of its claims; but after bestowing on it a due share of attention, we are at a loss to discover the pre-eminent recommendations it is said to possess. Accommodation for 6000 persons.

'Spes' again introduces us to the Surrey Music Hall, but has some pleasing differences. It is one of the best of those founded on that type. Estimate, £15,500: and the author asks for his commission and measuring 8 per cent.

'Fortuna Sequatur' has a rectangular plan, 137 ft. 6 in. by 82 ft. 6 in. The architectural features classic, of a very ordinary description.

'Fides Salutis Via' presents a boldly treated mass, with, in general, rusticated parts.

All Above Ground.' One of the many curious mottoes, but distinguishing a design of considerable merit. The plan of the chapel is octagonal.

'Hit or Miss' proposes a showy Corinthian portico as a frontispiece, to be built in cement! Need we pursue the scheme any further?

'Finem Respice.' This set of drawings is stated to be based on the "new" style, *i.e.*, we presume, a sixth classic order, judging from the shafts of the portico, which are octagonal instead of circular, and set angularly. The general effect of this portico, nevertheless, is that of the ordinary Corinthian kind. The roof does not appear to grow happily behind the side walls, and several other portions are capable of great modifications and improvements. Estimate, £16,500.

We have thus commented freely on the designs for this chapel, and by way of conclusion can only repeat the observation with which we started, that the exigencies of the case have been far from met, and that the architectural standard has not been, in our opinion, fairly acted up to by any one of the numerous competitors whose works we have been examining.

ON SUBMARINE TELEGRAPHS.

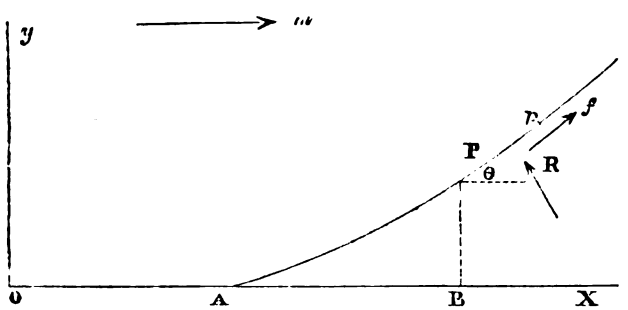
By Homersham Cox, M.A., Barrister at Law.

Engineering in its great and rapid progress in modern times has attracted the attention of mathematicians to many problems of the highest scientific interest, and all capable of more or less complete mathematical solution. The number of these problems is continually increasing, and among the most interesting and most important of them is the investigation of the mechanical circumstances of the submergence of submarine telegraph cables.

The subjects which it is here proposed to discuss are of great practical importance, viz., the *form* which the descending cable assumes, and the *tension* to which it is subject under conditions such as occur in practice.

On both these subjects very elaborate investigations have been published, including those published by the Institution of Civil Engineers last year, and the Paper of Prof. Airy, reviewed in the last number of this *Journal*. From the very difficult analysis contained in those papers it might be inferred that the investigation in question is one which a person without considerable mathematical powers could not expect to comprehend. I am not without hope of being able to show in the course of this Paper that, so far at least as the more practically important aspects of the subject are concerned, it may be rendered intelligible without a great demand on the mathematical powers of the reader, and that even the non-mathematical reader may by moderate attention assure himself of the validity of the general principles involved in the investigation. I may state at once that the simplifications which it is the object of this Paper to present arise partly from the question being confined to the case most analogous to practice, viz., where the tension of the cable on the

Digitized by Google



bed of the sea is inconsiderable, and partly because the method of resolving forces, known as the method of Tangential and Normal Resolutions, is here adopted.

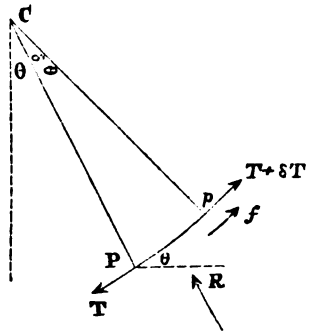
When the submergence of the cable commences it is doubtless subject to *oscillatory* motion, and throughout the process of submergence is liable to be swayed by the action of the waves and the pitching of the vessel: variations of the depth of the sea are another cause disturbing the motion of descent of the cable. These disturbing causes may however, for many practical purposes, be neglected. With regard, in the first place, to what may be called the regular oscillations of the cable—that is those which would occur if the ship were sailing uniformly over a smooth sea of uniform depth:—these oscillations are continually reduced and ultimately destroyed by the resistance of the fluid, for the same reason that the oscillations of a pendulum, vibrating in a resisting medium, are continually reduced and ultimately destroyed. With regard to the direct action of the waves on the cable it is to be observed that that action extends only to a depth which is a very small fraction of the extreme depths of the sea, which it is most important to consider. I believe also that, on account of the very oblique direction of the cable in the water and other causes, the effect of the pitching of the vessel is much less important than is commonly imagined. The investigation of this effect however, as well of the effect of variations of the depth of the sea, cannot be well considered until the problem of submergence under circumstances of perfect regularity has been investigated. The effects of disturbing causes in modifying the results of that investigation may be treated independently.

It will therefore be here assumed that the ship moves uniformly without oscillation, that the depth of the sea and the velocity of the paying-out apparatus are constant, and that the line of the descending cable is invariable in form, and advances uniformly with the ship, and lies in the vertical plane passing through the ship's axis.

Before entering on the mechanical part of the subject it will be desirable to state the geometrical relations involved in it. Let Ox be the horizontal line in the bed of the sea and plane of the cable; A the point where the cable meets the bed of the sea at

Fig. 1.

the time t; O a fixed point from which A has moved during the same time; Pp an element of the length of the cable inclined to the horizontal, at the angle θ. Let the horizontal arrow indicate the direction of the ship's motion, and let m be the velocity of the ship, and n that with which the cable is payed out from the ship.



Let AP$=s$; P$p=\delta s$; OB$=x'$; AB$=x$; PB$=y$; $\sin\theta=\frac{dy}{ds}$; $\cos\theta=\frac{dx}{ds}$; $\frac{ds}{dt}=-n$.

The velocity with which Pp meets the water normally is the component of m resolved perpendicularly to Pp, or $m\sin\theta$. The velocity with which Pp passes tangentially through the water is due partly to the velocity of paying out and partly to the horizontal progress of the line Ap. The tangential velocity due to the former is n; the tangential velocity due to the latter is m resolved along Pp, or $m\cos\theta$. The difference between these two, or $n-m\cos\theta$, is the tangential velocity of the element Pp relatively to the water ... ... (1)

These two expressions will be used in measuring the resistances tangential and normal to the cable.

The velocity of paying out is assumed to be greater than the velocity of the ship, so that $n-m\cos\theta$ is positive, and the friction of the water acts on the cable in an upward direction. Draw the normals CP, Cp (fig. 2) to the element Pp. C is ultimately the centre of curvature of the curve for the point P. CP is inclined to the vertical at the angle θ, at which Pp is inclined to the horizontal. Let the angle PCp be $\delta\theta$; CP$=\rho$; T the tension at p; T$+\delta$T the tension at P; Rδs the normal, $f\delta s$ the tangential or frictional resistance of the water on the element δs.

Fig. 2.

First suppose there is no velocity (m) due to the progress of the vessel, but that the only motion is that of paying out. Then the element Pp may be considered as a particle moving uniformly with the velocity n in the path APp. Therefore, by known principles of the dynamics of a particle, the tangential components of the forces acting on Pp may be equated to zero, and the normal components may be equated to what is called the centrifugal force.

Let the weight of the element δs *in water* be $Mg\delta s$. The component of this force resolved tangentially is $Mg\delta s\sin\theta=Mg\delta y$.

The equation of tangential forces is therefore

$$\delta T+f\delta s = Mg\delta y.$$

Hence integrating, and assuming the tension to be zero at the bed of the sea, we have

$$T=Mgy-f\int\delta s \quad ... \quad ... \quad ... \quad (2)$$

whatever be the form of APp. The assumption that there is no tension at the bed of the sea will be reconsidered presently.

Again, resolving forces along CP, and putting the centrifugal force equal to $M\delta sn^2\div\rho$, we have

$$M\delta sn^2\div\rho=(T+\delta T)\sin\delta\theta-Mg\delta s\cos\theta+R\delta s.$$

Now in the limit $\rho\delta\theta=\delta s$; $\sin\delta\theta=\delta\theta$. Therefore, dividing all the terms of the equation by δs we have in the limit

$$Mn^2\div\rho = T\div\rho-Mg\cos\theta+R;$$

or

$$(Mn^2-T)\frac{d\theta}{ds}=R-Mg\cos\theta \quad ... \quad ... \quad (3)$$

Substituting in this equation the value of T found by (2), we have a differential equation to the line of the cable.

The above results have been obtained on the assumption that there is no horizontal motion; but they will be unaltered if that motion exist, if we suppose the fluid resistances to be the same in both cases.

This conclusion is an immediate deduction from D'Alembert's theorem, by which what are called the "effective" forces of a system statically balance the impressed forces. The equations expressing this equilibrium are the same whether the velocity m be or be not impressed. For we assume the impressed or actual forces external to the system (the weight and fluid resistances) to be the same in both cases; and the "effective" forces are hypothetical forces which measure the accelerations of the different parts of the system: these however are unaltered, for the velocities only, and not the accelerations, are varied by the velocity m being supposed to be impressed. Consequently the equations of motion are the same whether the velocity m be supposed to exist or not.

It may be useful to refer to some illustrations of this principle. A piece of mechanism in motion will have certain strains due to its motion; but it is clear that those strains will not be affected by conveying the apparatus in a vessel which glides uniformly in a straight course in smooth water. Similarly a ball thrown in the air by a person on land will describe the same curve as if similarly thrown in the cabin of the vessel, the resistance of the air being supposed to be the same in both cases.

It may also be observed that the above results (2) and (3) are obtained directly without reference to the case in which m is zero.

OA (fig. 1)$=mt$, OB$=x+mt$. Also $\frac{dx}{dt}$ is clearly equal to $m-n\cos\theta=m-n\frac{dx}{ds}$; and $\frac{ds}{dt}=-n$. Therefore

$$\frac{d^2x'}{dt^2}=\frac{d^2x}{dt^2}=n^2\frac{d^2x}{ds^2}.$$ Similarly, $\frac{d^2y}{dt^2}=n^2\frac{d^2y}{ds^2}$

Digitized by Google

Hence the equation of horizontal and vertical motion are respectively

$$M ds\, n^2 \frac{d^2y}{ds^2} = d(T\cos\theta) - Mg\delta s + f ds\cos\theta + R ds\sin\theta$$

$$M ds\, n^2 \frac{d^2x}{ds^2} = d(T\sin\theta) + f ds\sin\theta - R ds\cos\theta.$$

These equations agree with those given by Prof. Airy in article 24 of his paper in the *Philosophical Magazine* for July 1858. But neither the following nor any other method of solving them appear to have been hitherto published.

Multiplying the first equation by $\cos\theta$ and the second by $\sin\theta$, and subtracting, we obtain the equation from which (2) is obtained above. Again, multiplying the first by $\sin\theta$ and the second by $\cos\theta$, and subtracting, we obtain equation (3), (remembering that

$$\left.\frac{d^2x}{ds^2}\cdot\frac{dx}{ds} + \frac{d^2y}{ds^2}\cdot\frac{dy}{ds} = 0\,;\ \frac{d^2y}{ds^2}\cdot\frac{dx}{ds} - \frac{d^2x}{ds^2}\cdot\frac{dy}{ds} = \frac{d\theta}{ds}\right)$$

The equations (2) and (3) therefore apply when the ship moves with the velocity m.

In (2) it has been supposed that the tension at the bed of the sea is zero. This assumption is made because the cable is payed out at a greater velocity than that at which the ship sails. Consequently the cable is deposited at the bottom of the sea in coils or "puckers." For it is clear that if while the ship has sailed (say) a hundred miles, over a sea of given depth, a hundred and twenty miles of cable have been deposited on the bed of the sea, that cable cannot have been deposited in a *taut* line. Therefore (neglecting the friction of the bed of the sea), if the least tension were applied to this deposited cable it would tend to straighten it. We are justified therefore in assuming that the tension at the bottom of the sea is zero.

Hence we obtain from (2) the important result, that if the friction of the water on the descending cable be neglected, the tension at any point is equal to *the weight in water of a length of the cable equal to the altitude of that point above the bed of the sea.*

Substituting from (2) in (3) we have for the differential equation to the line of the descending cable

$$(Mn^2 - Mgy + f\int f ds)\frac{d\theta}{ds} = R - Mg\cos\theta \ldots \quad \ldots \quad (4)$$

We will in the first place neglect the friction f, and the velocity n. The last equation then becomes

$$-Mgy\frac{d\theta}{ds} = R - Mg\cos\theta,$$

which represents the form of a flexible line *suspended* from the ship, and not descending through the water, but drawn through it by the ship.

By the ordinary hypothesis of fluid resistance, which will be reconsidered presently, the resistance varies as the square of the relative velocity of the fluid and solid. Hence it appears from (1) that $R = Am^2\sin^2\theta$, where A is a constant depending on experimental data. Put $Mg = 2c\,.\,Am^2$ and $\cos\theta = q$. Then the last equation becomes

$$-2cy\frac{d\theta}{ds} = 1 - q^2 - 2cq.$$

Differentiating $q = \cos\theta$, we get

$$\frac{dq}{ds} = -\sin\theta\,.\,\frac{d\theta}{ds} \text{ whence } \frac{dq}{dy} = -\frac{d\theta}{ds}$$

Therefore from the above equation

$$-2cy\frac{dq}{dy} = q^2 + 2cq - 1 = (q+c)^2 - (1+c^2)$$

Let $1+c^2 = b^2$. Then

$$-\frac{dy}{2cy} = \frac{dq}{(q+c)^2 - b^2} \ldots (5); \quad \text{or } \frac{1}{2c}\log\frac{a}{y} = \frac{1}{2b}\log\frac{q+c-b}{q+c+b} \ldots (6)$$

where a is the constant of integration. From the last equation

$$\left(\frac{a}{y}\right)^{\frac{b}{c}} = \frac{q+c-b}{q+c+b} \ldots (7) \quad \therefore \frac{y^{\frac{b}{c}} - a^{\frac{b}{c}}}{y^{\frac{b}{c}}} = \frac{2b}{q+c+b} \quad \ldots (8)$$

The above is a general solution involving an arbitrary constant a; but in the case before us we find that, q being restricted in value by its geometrical meaning (the cosine of an angle) we are compelled to select a particular value of the integral. Since q is always finite, and since the denominator of the fraction on the second side of (7) is always positive, it follows that that fraction is always finite. In order that the first side of (7) may also be finite when $y=0$, we must have $a=0$. Therefore equation (8) becomes

$$1 = \frac{2b}{q+c+b} \text{ or } q = b - c = \sqrt{(1+c^2)} - c \ldots \quad \ldots \quad (9)$$

This is the equation to a straight line. It may be easily found that the value of q given by (9) is the same as would be obtained by making the second side of the equation which follows equation (4) zero; in other words, the normal force R is statically equal to the effect of gravity resolved normally.

The above result has been obtained on the supposition that n and f in equation (4) are neglected; but the result is the same if n and f are taken into account. This we shall proceed to show by an entirely independent method, which, besides its generality with respect to n and f, is more general than the preceding method with respect to the law of the normal resistance. This has been hitherto assumed to vary as the square of the normal velocity with which the fluid meets the cable; but the law in question is found by experiment not to be strictly accurate, for it has been ascertained that a solid which moves in a given direction through water, always at the same velocity, but with different inclinations to the direction of motion, does not meet with resistances which vary exactly as the squares of the angles of inclination (see *Encyclopædia Britannica* article Hydrodynamics). The actual law of resistance is uncertain; but this much is obvious, that if different parts of the cable are differently inclined to the horizon those parts which are more nearly vertical, being more directly opposed to the fluid, suffer greater normal resistance than those parts which move through the fluid more obliquely. Consequently, the greater $\frac{dy}{ds}$ is, the greater is R; and this conclusion holds whether the law of resistance be taken to be that of the square or any other power of the velocity.

If in equation (3) $\cos\theta$ be put $= \frac{dx}{ds}$, and $\sin\theta = \frac{dy}{ds}$, and therefore $\cos\theta\frac{d\theta}{ds} = \frac{d^2y}{ds^2}$, we get

$$(T - Mn^2)\frac{d^2y}{ds^2} = (Mg\frac{dx}{ds} - R)\frac{dx}{ds} \quad \ldots \quad \ldots \quad (10)$$

From equation (2) it appears that T increases with the altitude above the bed of the sea, for the effect of friction to diminish the tension is always much smaller than the effect of gravity to increase it.

It is quite clear that the direction of the cable is never vertical; for if it were so at any point the tension at that point would not have any effect to draw the lower part of the cable through the water: and it is certain that the horizontal effect of friction (which is small) would not suffice to overcome the horizontal effect of the normal resistance. Therefore $\frac{dx}{ds}$ is never zero or negative. Hence in (10) for the value of y which makes $T = Mn^2$ (since the first side of that equation is then clearly zero) the quantity in the parenthesis on the second side must be zero also.

If (10) represent a straight line, $\frac{d^2y}{ds^2}$ is zero. If $\frac{d^2y}{ds^2}$ be not zero, let it first be a positive quantity for values of y greater than that which it has at the point where $T - Mn^2$ is zero. Since $\frac{d^2y}{ds^2}$ is positive, $\frac{dy}{ds}$ increases from that point. Therefore R increases, and $\frac{dx}{ds}$ diminishes. Hence $Mg\frac{dx}{ds} - R$ is negative; and the second side of (10) is negative. So ought also the first side of the equation to be negative. But since T has also increased, the first side of (10) is positive; or the assumption that $\frac{d^2y}{ds^2}$ is positive, leads to an absurdity.

Secondly, let $\frac{d^2y}{ds^2}$ be negative for points above that at which $Mg\frac{dx}{ds} - R$ is zero. Then $\frac{dy}{ds}$ diminishes, R diminishes, $\frac{dx}{ds}$

Digitized by Google

increases, and $Mg\frac{dx}{ds}-R$ becomes positive. But at the same time, since $T-Mn^2$ is positive, the first side becomes negative; or this hypothesis also leads to an absurd conclusion.

The only possible hypothesis then, is that $\frac{d^2y}{ds^2}$ is zero always, or that the equation (10) represents a straight line.

It follows that *when the velocity of paying out, and the velocity of the ship and the depth of the water are constant, the descending cable assumes the form of a straight line, inclined at such an angle that the normal resistance at every point is equal and opposite to the effect of the weight resolved perpendicularly to the line.*

The reasoning on which the above conclusion depends, requires that there shall be value of y for which the first side of equation (10) shall be zero. This will always be the case if the tension be zero at the bed of the sea. If however there be tension there, and its amount be greater than Mn^2, there will be no point for which the first side of (10) is zero, and consequently the reasoning by which the conclusion is obtained is not applicable. In all other cases the equation (9) represents the inclination of the cable.

It appears from equation (9) that the inclination of the straight line of the cable does not depend on the frictional resistance, nor the depth nor the velocity of paying out, but merely on the quantity c, which is half the ratio of $Mg : Am^2$, or of the weight of a unit of length to the normal resistance on that unit at the velocity m.

The resultant resistance of water normal to the surface of a cylinder, a foot in length, where the velocity perpendicular to the axis is m feet per second, and the diameter d feet, appears to be about $\cdot 8dm^2$. In the case of the Atlantic telegraph cable d is $\frac{5}{8}$ inch $=\frac{5}{96}$ foot. Also the velocity of the ship when in deep water was from 4 to 5 knots per hour, *i.e.*, from 6·7 to 8·4 feet per second. The weight of 1 foot of the length of the cable in water is about ·3 lb. Hence we have $\cdot 8m^2=56$ at 5 knots an hour, and $=36$ at 4 knots an hour. Therefore $\cdot 8dm^2=2{\cdot}91$ in the former case, and 1·87 in the latter case. Therefore $Mg \div Am^2$, or $2c=\cdot 16$ in the latter case, and $=\cdot 103$ in the former.

If $q=\cos\alpha$, the equation (9) gives $q=\cdot 92$ in the latter case, and $=\cdot 95$ in the former case nearly; or the angle of the inclination of the cable to the horizon is between 23 and 18 degrees.

Mr. James Bodie, master R.N., who accompanied the expedition on which the Agamemnon was employed for laying the Atlantic telegraph, states in his 'Observations on Telegraphic Cables,' (Devonport, 1857) that he observed the angle which the cable made with the surface of the sea, at nearly any rate of speed of the ship, to be from 11° to 22°. Mr. Webb, in his paper read at the Institution of Civil Engineers, 23 Feb. 1858, states that he observed the angle to be 9° or 10° in a depth of 2000 fathoms, but he does not state the velocity at which the ship moved when the observation was made.

The length of the oblique line is the depth × cosec α = the depth multiplied by 2·56 or 3·23, according as the inclination is 23 or 18 degrees. Again, the length of this oblique line multiplied by $\sin\alpha$ (*i.e.*, by ·39 or ·309) = the depth. Therefore the tension is from $\frac{4}{10}$ to $\frac{3}{10}$ of the weight of the oblique line, if the effect of friction be neglected.

We may now take into account the effect of the friction of the water in diminishing the tension. The friction on 1 foot of the length of the Atlantic cable moving through water with a tangential velocity of 1 foot per second is about ·0006 lb. (see last number of this *Journal*, p. 64). Now the tangential velocity is $n-m\cos\theta$. Take n the velocity of paying out to be $5\frac{1}{2}$ knots an hour, or 9·3 feet per second, which was nearly the highest velocity at which the Atlantic cable was payed out. Take $m=8{\cdot}4$ feet per second and $\cos\theta=\cdot 92$, as found above. Then the tangential velocity is about 1·5 feet per second; and the friction on 1 foot of the cable (being as the square of this velocity) is about ·0013 lb., or (since the cable weighs ·3 lb. to the foot) the friction is about ·004 of the weight of the cable, or about 1 to $1\frac{1}{3}$ per cent. of the tension it sustains at its summit if there be no friction.

The inclination of the cable as above computed, is between the degrees of inclination observed by different observers. I am disposed to think that the smaller of the observed angles was nearest in value to the actual angle of inclination to the horizon of the Atlantic telegraph when the speed of the vessel was great. The hypothesis on which the angle has been here computed are, firstly, that when a cylinder moves perpendicularly to its axis through the water, the resistance to motion is the square of the velocity multiplied by a constant; secondly, that when the cylinder moves obliquely, the resistance perpendicular to its axis is the same constant multiplied by the square of the velocity resolved in the same direction. Experiment seems to show that the first hypothesis is quite close enough to the truth for our present purpose, but that the resistance to oblique motion is greater than the second hypothesis would give. That being so, the angle of inclination to the horizon is less than that above computed

It is however important to remark that the three principal conclusions of this paper do not depend on a particular assumption of the law of resistance; but hold when *any probable* law is assumed. These three conclusions it may be worth while to recapitulate. They are:

1. That the tension at any point (neglecting friction of the water) is the same as the statical tension would be if the cable hung vertically.
2. That the effect of friction under ordinary circumstances is to reduce the statical tension little more than one per cent.
3. That the form of the cable is a straight line, so inclined that the weight and normal resistance are at every point statically balanced.

Lincoln's Inn, Feb. 1859.

NEW CHURCH, PENTREVOELAS, CARNARVONSHIRE.

A NEW church for this village, arising chiefly through private munificence, was recently consecrated by the Bishop of St. Asaph. It is a simple unpretending structure, but well suited in every respect to the locality. The plan consists of a nave, chancel, and south transept; there are no aisles, but a small vestry is attached to the chancel on its north side. Preparations have been made for the erection of a south porch, but at present there is no protection of the kind. The walling is of local materials, roughly dressed, and the buttresses are of low plinth-like character, reaching but partially up the walls. They are introduced, moreover, at the main angles of the building only. The windows are usually lancets, coupled so as almost to look like the ordinary two-light arrangement, and the plinth is formed by a very bold set-off, rising directly from the ground. At the west end, and on the south front of the transept, are two long single-light windows, while at the east end is a triplet; these, although severe in their character, are nevertheless quite in keeping with the rest of the design. The bell turret is of stone, and at the west end, its thickness being partially carried by a row of stone corbels. It is gable-roofed, and has openings for two bells. The side profile has string-mouldings and buttresses running through the full thickness of the wall. The chancel arch is of large span, the roofs, both of church and chancel, are of rafters framed polygonally. The accommodation is for about 200 persons.

MELBOURNE CHURCH, DERBYSHIRE.

MR. G. G. Scott has been called in to advise and report upon the restoration of this very curious ancient church, which dates back to a period little short of the Norman conquest. Its plan is a remarkable one, both in point of arrangement and the massive symmetry observable throughout. Though its western façade has never, probably, been completed, its eastern tri-apsidal termination is almost obliterated, its high-pitched roofs are lowered, and several other features are grievously mutilated, it still retains, particularly within, very much of its nobleness of character, and if restored, though but in a partial degree, would exhibit them to far greater advantage. The church consists of a nave of five bays, with a western narthex and side towers, there is also a central tower with transeptal additions, and a very narrow chancel. Although the whole span of the church, including the aisles, is but 46 feet, the walls are no less than 5 feet thick, and all the rest is in proportion. The great characteristics of the interior are, the narthex before mentioned, and the central lantern, yet both are at present lost to it. It is of course urged that these should be immediately restored.

The masonry in general is considered to need a good deal of

Digitized by Google

reparation, besides the removal of the whitewash, for in addition to reckless mutilation, it has apparently suffered at some early period from fire. The architect was desirous of replacing the present roofs by others of a high pitch and more suitable design, but, as funds are restricted, this is (for the present at least) not contemplated. By the general rearrangement now proposed, accommodation is provided for 670 persons, besides that which would be available in the very wide central passage, which is purposely left for chairs when occasion requires. Over the narthex is an ancient stone gallery, which is intended to be appropriated for children.

The general estimates are as follows:—

For the reparations and restoration of the fabric, including the restoration of the western doorway, the timber ceiling over the lantern, roofing in the western towers, &c. ...	£1000
The refitting, reflooring, &c. (in deal)	500

THE NEW FOREIGN OFFICE.

This subject has in various ways, but more particularly in the House of Commons, been brought of late somewhat prominently under public notice. Mr. Tite, who never loses an opportunity of opposing the Gothic revival, seems determined not to let the grass grow under his feet during the present session of parliament. As early, therefore, as the eleventh of last month he opened his campaign against the appointment of Mr. Scott to the new government buildings. After a hasty outline of the history of the competition, in which he omitted any allusion to the most striking features, or the abandonment of its results by the late government; and after admitting that the evidence of Mr. Burn and the assessors had naturally led to the setting aside of the first prizemen, Messrs. Coe and Hofland,—he stated that Messrs. Banks and Barry, to whom had been awarded the second premium, felt aggrieved at the preference being given to Mr. Scott (he having obtained the third place by the decision of the judges). He then proceeded to a rather unsparing censure of the style of the design itself, charging against it the stereotyped catalogue of defects with which it has been so long the fashion to assail it, though, in his hearing when sitting on the select committee, these had been disproved, not only by the evidence of Mr. Scott himself, but by that of various witnesses whose personal bias might have led them in the opposite direction. Mr. Tite was followed by the ex-premier, who, in a string of *ad captandum* jokes, endeavoured not only to throw discredit upon the style, but to reduce *ad absurdum* the reasons given by Lord John Manners for his appointment of Mr. Scott. A day or two later an earnestly-expressed letter from the latter gentleman appeared in the "Times," pointing out how entirely the charges brought against both his design and its style had been refuted in the evidence given at the before-named committee, and appealing urgently to members of the House of Commons against the attack made upon him.

On the following Friday, however, the discussion was revived by Sir Benjamin Hall, who seems as if indulging the weakness of feeling annoyed that the scheme on which he had so greatly and so justly plumed himself should fall into the hands of his successor. Lord John Manners, however, met his remarks vigorously, showing that Sir B. Hall had taken the utmost pains when in office to secure to himself the fullest freedom of choice between the premiated designs;—that his Government had not only availed themselves of this freedom, but had ordered the appointment of a non-competitor;—that it was the present Government who, by consenting to a committee of inquiry had revived the honours of the competition;—that the committee had pronounced the two styles to be equal as to all practical advantages;—and, finally, that the report of the committee had placed the three first premiated designs before him on terms of perfect equality, simply recommending that he should make his choice *from among them*. He closed by quoting an opinion expressed some time back by Mr. Tite himself, that no man of taste would wish to see buildings erected on that site in the style of those which had received the first premiums for the Foreign and War offices.

Lord Palmerston and Mr. Coningham soon repeated their outbursts against Gothic architecture, as boldly as if their old statements had never been answered. The House, however, by this time discovered that party-feeling had much to do with this line of conduct, and, having ascertained from Mr. Scott's letter the fallacy of many of the allegations, they listened with evident impatience.

Now we have no wish to become the partizans of either school of architecture, nor to assume to ourselves duties rightly belonging to the Judges, the Committee, and the First Commissioner, but we decidedly object to the discussion of such difficult questions as that now under consideration by persons unacquainted with them, and still more strongly deprecate the use of oft-refuted statements as the principal weapons in a controversy. Can the member for Bath so soon have forgotten that the windows of the Gothic design in question were considerably larger than is usually found in public buildings in the Classic style;—that they opened as ordinary sashes;—that their several lights were of great width;—that they were proposed to be glazed with large sheets of plate glass? He certainly had once been aware of this, inasmuch as he sat as one of the members of the committee before whom it was given in evidence, and was himself an active man in making the inquiries which elicited the information. How then comes it that from his observations in the House the contrary of all this might be inferred? Mr. Tite had heard, too, from the evidence of at least unbiassed individuals, that neither in convenience nor in economy of cost could one style claim any preference over the other. Why then should he, in his place in parliament, state the reverse of this? Mr. Scott had expressly said that he should make no attempt to "Gothicise" the surrounding buildings, and the honorable gentleman must have been aware that all the competitors (whatsoever their style) had supposed that the State Paper Office was to be removed: why then should he allow Lord Palmerston to state the contrary on the former point, and to attribute the latter to Mr. Scott alone, making it appear, too, that it was proposed on the score of *style*?

As to the question of the fairness of the decision come to by Lord John Manners, so much confusion seems to exist, that it may be worth while to attempt to clear the matter of some of its perplexity, by recapitulating a brief outline of the circumstances.

1. At a meeting of architects convened by Sir Benjamin Hall previously to the competition, he assured them that it should be open to all styles;—that the premiums would be awarded not by himself, but by judges to be nominated for the purpose; but that he did not hold himself pledged to appoint the architect who should be selected to receive the first prize, but (to use his own words) "left it open to himself to determine, if he should think proper, upon recommending to the Government *any* of the designs which might be premiated by the judges."—(See evidence, question 1148).

2. It was found by the committee that Mr. Burn and the professional assessors had, in the lists made without any communication one with another, agreed in placing Messrs. Coe and Hofland, to whom was allotted the first premium, only *sixth;* and that while they placed Messrs. Banks and Barry first for the one building, and Mr. Garling first for the other, they had placed Mr. Scott second for *both*,—a position which Mr. Burn (in answer to question 1189) gave it as his opinion was "the most distinguished of any."

3. Among the seven premiums awarded for the Foreign Office, *three* were bestowed upon Classic, and *four* upon Gothic designs. Among the former, according to the judges, Messrs. Coe and Hofland stood first, and, among the latter, Mr. Scott. If, however, the opinions of the professional judge and of the assessors be preferred, Messrs. Banks and Barry stood first in Classic, and Mr. Scott double-first in Gothic; for in their opinion he was first in his style for both buildings.

4. The committee, in their report (paragraph 10) pronounced the two styles to be perfectly equal in the advantages they offer, and, by calling special attention to the difference between the award of the judges, and the private lists of Mr. Burn and the assessors, they virtually pronounced the designs to be—to say the least—equal the one to the other.

5. Between, then, these equal styles and equal designs, why, we would inquire, should Sir Benjamin Hall attempt to deny to his successor the same freedom of choice which he had taken so much care in reserving to himself? On what grounds does Mr. Tite admit the evidence of Mr. Burn and the assessors to the extent of displacing Messrs. Coe and Hofland, and reject it as establishing an equality between Messrs. Banks and Barry and Mr. Scott?

Digitized by Google

And, finally, on what conceivable plea does the ex-premier attempt to argue that *he* was doing right in rejecting all the competitors, and Lord John Manners wrong in exercising the power reserved by his predecessors in choosing between the three first prizemen, whose styles and designs the committee had in effect declared to be on an equality, and between whom they had expressly recommended him to make his choice?

We will only add, without expressing any opinion here as to the relative merits of the designs, that the selection having been made by the responsible minister, and having been followed up by the appointment of the same architect to the New India Office (in conjunction with the official architect to that board) it would be a really dangerous precedent were these appointments now reversed: and, further, that Mr. Scott's position in his profession,—as proved by his numerous works, by his being elected a member of the Royal Academy, and by his having received, within the last few days, the award of the Victoria gold medal from his brother-architects of the Institute,—furnishes a practical guarantee as to the propriety of the choice arrived at.

ON TIMBER FRAMING.*

By S. C. Capes.

(*With an Engraving.*)

The chief practical object in framing timbers is to arrange them in the best position to withstand, with the greatest economy of material, the various forces which are likely to be brought to bear upon them, and this desirable result is only to be obtained by judicious combinations of the materials to be used; but unless the effect of pressure and the resisting powers of the different materials be understood, how are such combinations to be designed?

It is wholly unnecessary to advance reasons for adopting correct principles in preference to being guided by opinions, as opinions are often hastily formed upon confined and imperfect views of the real nature of the subject, and we can seldom if ever refer with any degree of certainty to the grounds on which they are founded; but a maxim drawn from science can always be examined and traced to its origin.

It is therefore only through a knowledge of the rules for ascertaining the respective strength of timbers in proportion to their scantlings and positions, together with the composition and resolution of forces, that any one can expect to arrive at excellence in the art of designing frames of timber; as without this knowledge it would be impossible for him to understand clearly what is to be aimed at in such designs, or even know whether any design of his own would answer its intended purpose or not. I will therefore now as briefly as possible give you a few of the leading rules, together with some practical remarks upon construction, as we may have occasion to refer to them hereafter in the comparison of the several examples of construction which I have brought before you.

Timber is exposed to three principal actions:—1. Cross strain. 2. Tension. 3. Compression. Cross or transverse strain is the amount of weight applied to the sides of a piece of timber tending to produce fracture in its cross-section. The strength of timber to resist fracture in this direction is as the breadth and square of the depth directly and inversely as the length. The general formula being

$$\frac{Cad^2}{l} = W.$$

That is, if you want to find the weight that will break a beam of wood supported at each end and loaded in the centre, you must multiply the breadth of the beam in inches by the square of the depth, also in inches, and by the constant or tabular number for the material used—which for the best Baltic timber we may take as 400—and divide by the length in feet;—the product will be the breaking weight in pounds. When the weight is distributed over the whole length of the beam it will require double this weight to break it. When the beam is fixed at one end only, and loaded at the other, it will only require one fourth of the result to break it. When the weight is equally distributed on a beam fixed at one end only, one half of the result will break it. The permanent load should never exceed one third of the breaking weight.

* Paper read before the Architectural Association.

2. Tension is the amount of force or weight applied to the ends of a piece of timber, tending to tear asunder in direction of their length the fibres or particles of which it is composed. The strength to resist the force or weight that produces fracture is as the area of the cross-section acted upon. Hence multiply the area of the cross-section in inches by the constant representing the power in pounds, and the product will be equal to the weight in pounds the rod or piece will just support; the constant for fir timber being 11,000 lb., but the greatest constant load should never exceed one fourth.

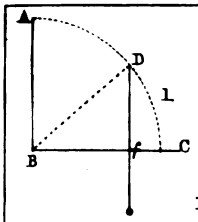
3. Compression is the amount of weight having a tendency to crush the material. The rules for determining the dimensions of a piece of timber to support a given weight without sensible flexure, are very complicated; but this may be taken as a guiding principle, that if the height of a column or post exceeds a certain multiple of its least sectional dimension, it will give way, not by crushing, but by bending, and will ultimately be destroyed by the cross strain. This flexure occurs in oak or fir timber when the height exceeds ten times the least dimension, the resistance decreasing very rapidly in proportion to the increase of the number of times the least dimension is contained in the height. A post in height 100 times its diameter is incapable of maintaining an upright position.

If a piece of timber AB (fig. 1) be inclined on its base, its strength to support a vertical effort diminishes in proportion to its inclination; so that if from its upper extremity a vertical, D*f*, be lowered, and from the points of the base B, a horizontal line BC be drawn, the strength of the piece will be less in proportion as B*f* is larger; whence it results that the strength of a strut AB is to that of an inclined piece of the same scantling as the length AB is to D*f*, or as the radius to the sine of the inclination of the timber.

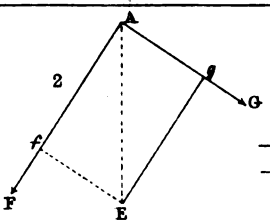
Before setting to work to design any system of framing, the following important proposition in mechanics, which shows the composition and resolution of forces at a point, should be thoroughly understood:

Proposition.—If the adjacent sides of a parallelogram represent the component forces in direction and magnitude, the diagonal will represent the resultant force in that direction.

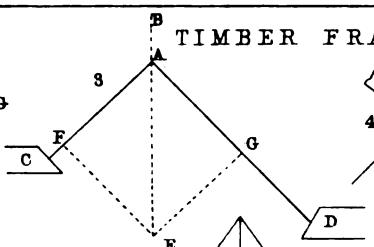
Let A*f*, A*g* (fig. 2) represent in magnitude and duration the forces FG acting at A; complete the parallelogram A*f*, E*g*, and draw AE.



Suppose, for instance, an upright piece of timber pushed in direction of its length by a load at B (fig. 3), and abutting on the ends of two beams AC, AD, which are firmly supported at CD; and as they cannot move, the pressure they sustain from the post BA is in the direction AC, AD. To ascertain what each of these timbers sustain, we must produce BA to E, taking AE from a scale of equal parts to represent the number of tons or pounds by which BA is pressed; drawing EF and EG parallel to AC and AD: then AF measured on the same scale as AE will give the number of pounds by which AC is strained, and AG the strain AD.



To properly brace a piece of carpentry so as to resist any force that may be applied to it, and to give the necessary stability, requires careful arrangement and considerable knowledge in the art. In framing one timber into another it must be remembered that all timber is liable to shrink when dry, and when wet to expand. On this account all joints should be made with reference to their contraction and expansion, which sometimes tends to split off portions of their framing; and as all framing will settle more or less, the carpenter will see how important it is to make the joints of struts, &c. (fig. 4) when first fitted, bear on the opposite edge to what they will have to do when finally settled. To remedy this course Tredgold proposed to make the joint in the form of an arc (fig. 5), in order that the pressure on every part might be equal. Great care is also required when the framing has to bear considerable weight, to prevent the ends of the timbers eating into the sides or bearings of those against which they abut; for this purpose sheets of lead or iron plates and shoes are now often used.



One great consideration in designing timber framing is so to arrange that it can be constructed of such scantlings as are easily obtainable in the district where it is intended to be used. Great ingenuity is frequently shown in joining comparatively short pieces of timber together, where great length is required for ties, beams, &c., by a system called scarfing (fig. 6); but it is perfectly clear that the joint cannot have half the strength of an entire piece.

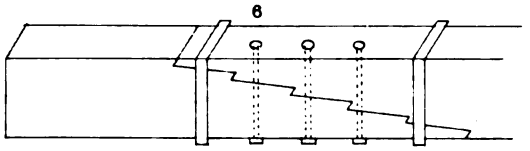
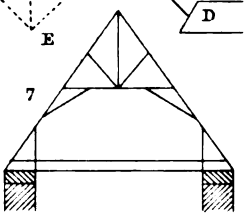
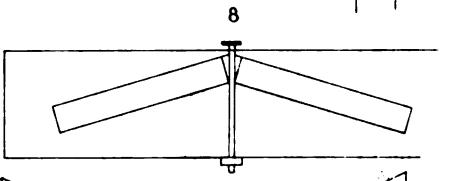
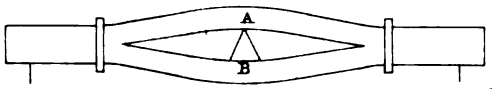
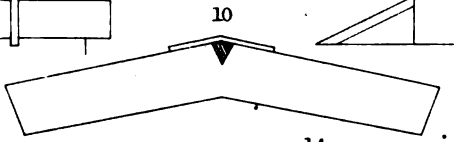
TIMBER FRAMING.

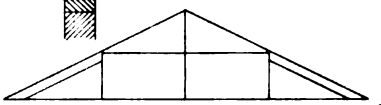


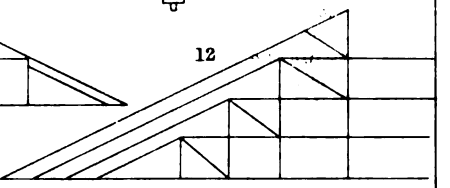


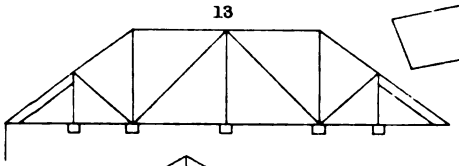


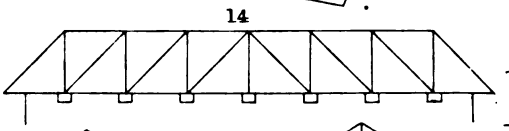


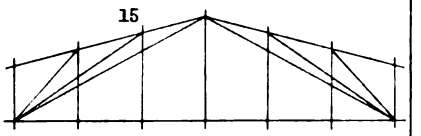


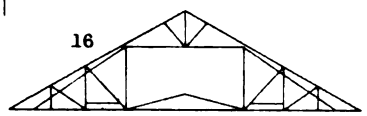


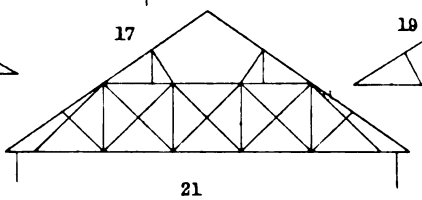


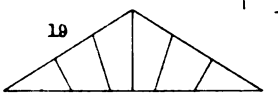


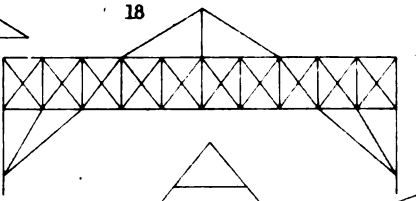


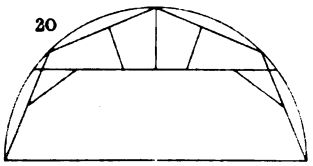


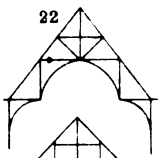


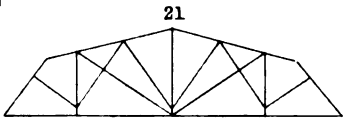


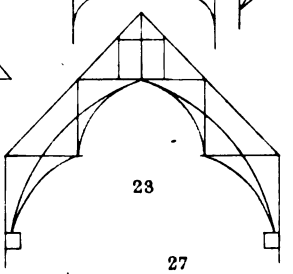


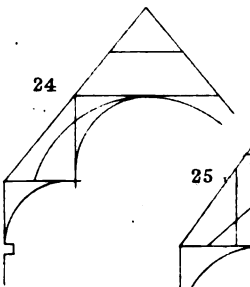


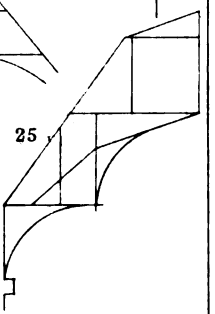


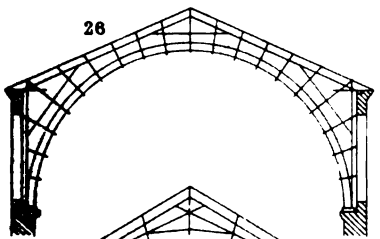


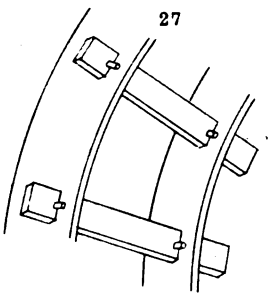


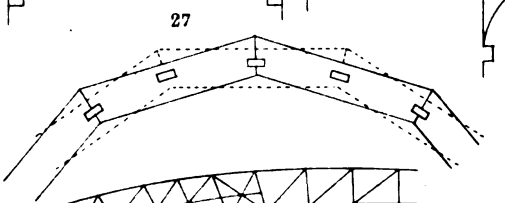


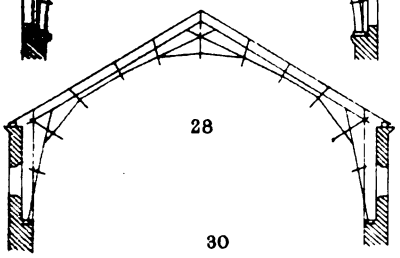


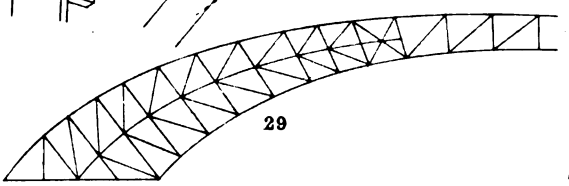


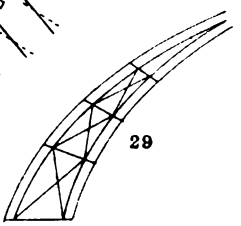


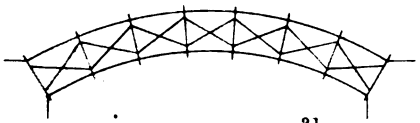


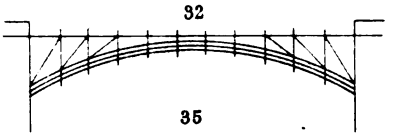


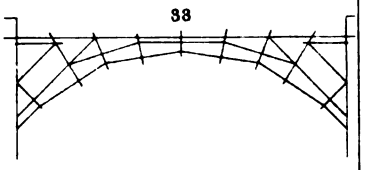


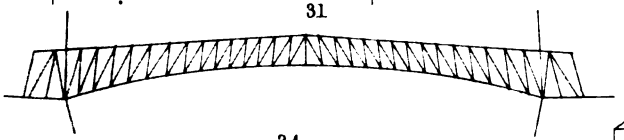


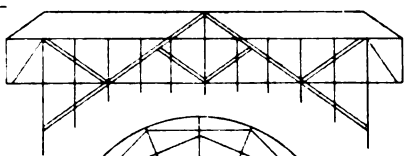


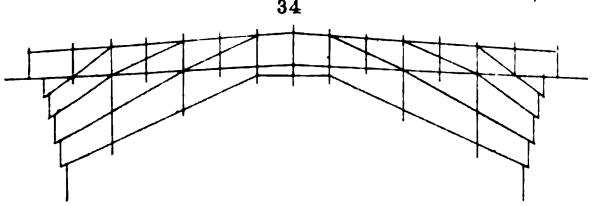


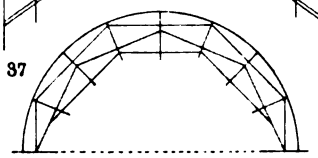


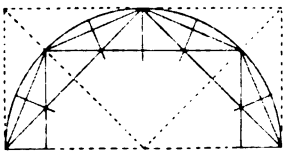












Digitized by Google

The necessity for timber framing arises most frequently in girders, partitions, roofs, bridges, centres, and scaffolding. Nearly all descriptions of framing may be divided into two classes, viz., girders and arches; the former exerting only vertical pressure upon the points of its support, and the latter horizontal or angular pressure, in accordance with its form.

The earliest use of timber was doubtless in the construction of rude huts, which we may suppose to be formed by trunks of trees, or posts, with one end fixed into the ground, and inclined or pitched one against another in a triangular form, serving for rafters, which would support such materials as might be placed upon them for the purpose of keeping out the wet, heat, or cold. An improvement upon this method would soon follow with the desire of raising the roof upon rough walls or embankments, so as to enable the inhabitants to walk erect beneath it; in which case it would soon be found necessary to provide some means for preventing the ends of rafters from forcing out the walls, which would either be done by tieing each pair together with a horizontal beam secured to the rafter feet, or by strengthening the walls with an increase in the width of their base;—the one afterwards developing itself into the so-called tie-framing, exerting only a vertical pressure on its supports,—and the other into thrust-framing, supported by solid abutments.

We may naturally suppose that in the earlier times, before the science of construction was understood, and the nature and properties of timber to withstand the various strains were discovered, that a great excess of material was often employed; and where timber was plentiful its economic use was not considered. In examining the oldest examples that have been described or escaped destruction, we see that the use of suspending pieces, such as so-called king, queen, and other posts, was either unknown or ignored; and, although posts were used in similar positions, they were employed more in the character of struts, and were not supposed to assist in hanging up the horizontal tie-beam, which was usually of great strength, sufficient to carry any weight likely to be brought to bear upon it. As construction became more developed the scantlings of the timbers were decreased, and each piece became more proportioned to the office it had to perform. Advantage was taken of the enormous power necessary to crush and tear asunder timber in direction to its length, as well as the unchanging principle of the triangle, to construct framing in accordance with its form; and by firmly securing the principal inclined timbers to the ends of the horizontal pieces, to make use of the power thereby obtained at the apex of the triangle to suspend therefrom vertical timbers, hanging up thereto the tie-pieces, and forming abutments for smaller inclined timbers, obtaining thereby an increase of strength with a decrease of material.

The introduction of iron for straps and bolts offers us many advantages in the construction of framing which the carpenters of the middle ages do not seem to have been acquainted with, as they generally formed all their joints in such a manner as to answer as far as possible the same purpose, the shoulders of all timbers being accurately cut and framed, and secured by oak pins. Oak was also extensively used by them as a material for framing, which would consequently cause the joints to have much greater strength than could be obtained in fir timber. The early Gothic roofs were very simple in construction, consisting often of rafters and collars, with tie-beams independent of the other timbers, and merely connecting the wall-plates. In some of the high-pitched roofs of our parish churches we find, at about half their height, the principals connected by a collar, upon which stands a tree-post (fig. 7), strutting up the principals. Beneath the collar are usually thrown in two braces, which are framed into it and the rafters. Such a roof, with a tie-beam to hold in the plates, will endure for ages. The tie-beams were usually in depth equal to $\frac{1}{18}$ of their length between the walls, and all the rest of their timbers in proportion.

Before entering upon any remarks on the thrust and hammer-beam roofs of the middle ages, I will finish my explanation of the several examples of tie-framing or trussed girders.

Trussed girders where depth is limited are usually formed of two pieces of timber bolted vertically together, with a core of oak or other hard material let into inclined grooves, and well secured at the ends and middle, and having a king-bolt at apex (fig. 8). A piece of iron or lead should be introduced at the abutting ends of truss, and sufficient play left in the grooves for the flitches to camber when the king-bolt is tightened.

One of the most simple methods of trussing is by cutting the girder horizontally for a considerable distance in direction of its length, and wedging between the upper and lower portions,—the ends of the cutting being prevented from splitting further by means of bolts or straps. Mr. J. Laves, of Hanover, brought this system extensively into use in that kingdom. He gives a little more depth to the upper portion A, than to the lower portion B (fig. 9).

Some have taken advantage of the difficulty of crushing timber in the direction of its length, and have applied it ingeniously for obtaining strength in girders. A saw-cut is made across the middle of the girder to a depth of one-third of its vertical thickness; it is then bent upwards (fig. 10), and when the cut has opened sufficiently a wedge is introduced into it, thus making it camber, and consequently stiffer. It has been proved that beams so cut and prepared are one-sixth stronger than those of the same scantling unsawn.

The most simple and economical truss to openings up to 30 feet span, and one most usually adopted, is the ordinary king-post. Above 30 feet span the introduction of two or more suspending pieces becomes necessary. We find this principle adopted very early in Italy, and particularly in the roofs to the Basilicæ at Rome. In the church at Rome of St. Paul's, without the walls, erected about 400 years ago, where the span is nearly 79 feet, was a finely constructed roof: it consisted of pairs of trusses placed 15 inches apart, each pair resting on the walls with a distance of 10 ft. 6 in. between them. The manner in which the trusses were framed together was very simple, and formed a remarkably strong roof. A king-post received the upper ends of the principal rafters, which were about 22 inches by 15 inches; a collar or straining piece abutting against the heads of two queen-posts, the position of which was retained by additional timbers placed under the principals, and forming a double thickness where the greatest strength was required (fig. 11). The tie-beams, 28 inches by 15 inches, were formed by scarfing two lengths of timber together, and securely strapping them with three stout irons. The collar was placed at two-thirds the height of the king-post, and by the introduction of the pair of queens the tie-beam was hung up in three places to prevent its sagging. Such a suspension of the tie-beam by the middle, and again at 14 feet on each side of it, exhibits a thorough knowledge of the true rules which should direct the carpenters. No tie-beam should exceed the length of 15 feet without some precaution similar to these being adopted to prevent it drawing in the wall-plates and crippling the truss. In this example we have an early instance of suspending the tie by means of the heads of the king and pair of queen posts, and which system is now universally adopted. For roofs of considerable span an arrangement of horizontal and vertical ties has been successfully employed, each horizontal timber becoming both a strut and a tie.

The roof of the Riding School at Moscow, as it at present exists, is framed somewhat on this principle (fig. 12). A series of ties and struts in succession are united into one simple and complete truss. These are placed 13 feet apart; the tie-beams formed of two thicknesses of timber scarfed together, each 12 inches square, forming a depth of 24 inches. At every 3 feet of its length were introduced iron bolts 1 inch in diameter. Double keys of oak driven into notches formed at equal distances between the two beams, assisted in resisting the horizontal drawing of the extremities. The middle of the tie-beam was drawn up 13 inches by the middle or centre post, which is 32 feet in length, or one-fifth of the total span. Above the chief tie-beam are three others, placed horizontally at equal distance, which are tied together in a similar manner. The rafters, formed of several stout timbers, are capable of supporting considerable weight when held firmly at their abutments; and the tie-beams, strongly bound together to prevent any drawing out, may be suspended to the principals. A series of iron straps or bands passed round the feet of the principal rafters, and secured to the tie-beams, effectually prevent any rising or spreading of the main timbers.

Palladio's bridge, near Bassano (fig. 13), is an amplification of the queen-post and strut principle. The following is a description of it: five transverse beams, 12 inches square, are disposed at equal distances in a span of about 108 feet, making them 18 feet apart. These bearers carrying the roadway are bolted to the tie-beam and five suspending pieces, the heads of the latter forming abutments for the principals and struts, all the timbers of truss being 12 by 9 inches. Considerable increase in strength is obtained by cambering the tie-beam. These trusses form the parapets, and are secured by iron straps and bolts at the extre-

Digitized by Google

mities. They are capable of supporting considerable weight without any sensible deflection; their height is about 16 feet, or nearly one-seventh of the span; and the introduction of the series of triangles—a form least liable to any change—gives great strength to this bridge.

I here call attention to another of Palladio's designs for bridges (fig. 14), supported like the last by a truss on each side, its length being divided into eight bays by transverse girders suspended by stirrup irons and bolts from the post, framed into head and cill of truss; these posts are braced strongly. But the strength of this truss is not equal to the other design, the centre bays being liable to drop, as the bearing is too great for the depth of girder. In this construction the first bays forming the abutment should have four depths of cill; the second three; and the third two; thus the ends of the bridge would appear to rest on corbels gathered over from the abutments. The height of the truss is about one-tenth of the span.

The principle adopted in the celebrated bridges at Schaffhausen Zurich, Landsberg, Wittengen, &c. (fig. 15), is to throw the weight directly to the ends of the tie-beams, and not, as in the preceding designs, distribute it over the whole length, the braces acting in the same manner as the extra depth of cill there proposed.

The former roof over Exeter Hall, with a span of 76 feet, is of a very strong form, having its tie-beam, 14½ by 7½ inches trussed in the centre, so as to obtain a considerable extra amount of compressive strength. Principal rafters and collar 14 by 7½ inches, with queen-post 8½ by 7½ inches in smallest section. Over the collar is a king-truss, with the principal rafters, 8½ by 7½ inches, running from king-head, and tenoned into the tie-beam of queen-truss, giving considerable extra depth to the queen principals. The space between the queens and the abutments of rafters is divided into three bays by pairs of suspending pieces, 12 by 4½ inches, clipping both tie-beams and principals, and bolted thereto with stirrup-irons; struts and straining pieces being introduced to take advantage of the incompressible power of timber in direction of its length.

The roof over Drury-lane Theatre (fig. 16), as designed by B. Wyatt, is of 80 feet span, and of very similar construction, the timbers being generally of greater thickness in proportion to their depth than the former, so as to obtain more lateral stiffness, which is further increased by the additional purlins placed between the two principal rafters. The suspending posts and straining pieces are of oak.

In the roof over the Boston Depôt of the Boston and Albany Railway (fig. 17), is a very fair specimen of the diagonal bracing, which is applied very successfully in America. The trusses, 94 feet span and 16 feet apart, being each formed of a tie-beam 9 by 12 inches, the principals, 8 by 12 inches, laid flatways, and rising 31 ft. 4 in. At half the height of the triangle so formed is a collar 7 by 12 inches, which is divided into three equal parts; from each division is dropped a 1½-inch iron rod, suspending the tie-beam, and each bay filled in with diagonal bracing 5 by 5 inches, bolted together at the intersections, the suspending rods also passing through and screwed up to the underside of longitudinal timbers, 6 by 8 inches, to stiffen the roof; similar bearers are secured at the top of the collar to the two centre rods, against which abut struts to the principals, and at the junction of struts and principals similar rods and bearers are introduced. Purlins, 6 by 8 inches, are placed every 10 feet apart, which carry the rafters, 4½ by 3½ inches, 2 feet apart, and covered with inch-boarding. Strengthening corbels are introduced to the ends of e-beams.

Somewhat similar framing is used in Long's American bridges (fig. 18). Deep outside girders are formed by a series of diagonal bracing, with upright posts framed between string-pieces, and connected with each other in a similar manner at top and bottom, forming a kind of tubular girder, the centre posts being carried up above the level of girders to receive two inclined timbers forming a king-truss above the girder so as to stiffen the centre and to throw the weight more directly upon the abutments, which in large spans are also strutted to give additional strength.

The bridge at Chambley, near Montreal, is of somewhat similar construction, iron ties having been introduced for the timber posts, and the king-truss omitted on the upper portion of girder.

Following out this principle, I now call your attention to the lattice-girder bridges, of which a good example is at Richmond in America, for a span of 150 feet. The lattice framing is composed of fir planks 12 by 3 inches, arranged so as to lie across each other at right angles; at the points of intersection they are united by oak trenails 1½ inches diameter, which pass entirely through them. The outside girders are connected together at every 12 feet by cross timbers diagonally braced, the upper cross timbers forming carriages for the road-bearers, which are placed longitudinally.

Pfeiffer executed several trusses in Germany which derive considerable strength from the introduction of inclined timbers serving the double purpose of holding up the tie-beam to the principal rafters and strutting up the latter (fig. 19). Where timber acts as struts and ties an iron bolt is almost indispensable to secure the joint. These inclined timbers were placed in pairs and halved to the ties and principals. This system answers very well for moderate spans, but I should not recommend its use where any great distance exists between the points of support.

Another system of roofing was carried out to a great extent by Mansard, by whose name it is usually called, the object being to keep down the height of the walls, and getting a more capacious apartment within the roof; the whole is usually arranged within a semicircle (fig. 20), but its system may be said to consist of four pieces, or rafters, hung together in such a manner that if inverted they would naturally assume the form given to them. The tie-beam in this instance is usually one of the common joists of the floor. Sometimes the ties are omitted, in which case a considerable lateral pressure is exerted on the walls, having a tendency to push them out of the perpendicular.

Polygonal tie-trusses are often introduced into roofs and bridges where the height of framing is required to be kept down, the principals abutting against straining-pieces inclined but little from the horizontal line, as in the drawing I have brought before you (fig. 21), which is very similar to the framing designed by Sir C. Wren for the roof-trusses of the Sheldonian Theatre, and of the same span, viz., 80 feet, each being divided into four bays with king and queen posts, and struts running in like directions; the tie-beam of the larger drawing, being only 9 by 4½ inches, has two iron suspension rods in addition to the post.

There are several roofs of theatres which exhibit many ingenious modes of construction, involving the combination of several systems before and to be hereafter described; but it would occupy too much of our time to enter into lengthened descriptions of them. The great object generally to be obtained is to get as much clear space and available height in the roof for scene painting and other purposes; the purlins being oftentimes trussed, as in the example of the Napoleon Circus, and the floor which forms the tie suspended therefrom.

In the middle ages all judicious timber roofings ceased in buildings of pretensions about A.D. 1400, and gave place to roofs without ties,—a principle of construction which bears a nearer analogy to masonry than to carpentry. The timber roofs of the Gothic architects were generally executed in oak, and richly moulded. In our churches we find them formed of pairs of rafters, the feet of which, where tie-beams are omitted, are framed into a piece of timber laid across the thickness of the wall, into which, flush with the inner face of the wall, is framed an upright strut. Collars are introduced at about two-thirds the height of the roof, and braces similar to those described for tie-roofs (see fig. 7); or, as in many instances, extra strength was given to the trusses by inserting a framed timber pointed arch in lieu of braces. These were carried down some distance below the wall-plate, so as to throw some portion of the weight of roof upon the corbels built into the wall, and upon which the arch braces rest.

By lengthening the foot-piece in the foregoing examples, so as to project beyond the inside face of the walls, we obtain the hammer-beam, from the end of which an upright strut was carried to the underside of principal rafter, and curved braces introduced both to support collar and hammer-beams (fig. 22). In some instances two ranges of hammer-beams are introduced, the collar being placed very high up in the roof, thereby increasing considerably the liability to spread and exert great thrust against the walls.

Many of the roofs constructed in the fourteenth, fifteenth, and sixteenth centuries are of surprising beauty both in form and workmanship. That over Westminster Hall was finished about 1399, in the reign of Richard II., the principals being 68 feet in span and about 18 feet apart, each formed of a pointed arched rib in its section upwards of 2 feet each way, spanning the width of hall, intersecting at about half its height with a massive hammer beam of similar scantling, and extending on one side to the feet

Digitized by Google

of principal rafters, and on the other to a similar extent; so that, if secured on a central pivot, this timber might be acted upon as a scale beam or lever of the first order, and if loaded equally at both ends would remain in its horizontal position, while the entire weight would be concentrated on the pivot and thrown on the supporting arch (fig. 23). Mr. Thomas Morris, in an essay on Westminster Hall,* read before the Institute of Architects, 24th June, 1850, goes on to say that,—"If, taking the hammer-beam as a base, we draw a perpendicular line from the inner extremity it will be found to cut the surface of the roof just midway between the roof and the ridge, and taking this surface line as the hypothenuse, a triangle will be completed. This triangle will be found to have an exact counterpart in the upper half of the roof; but as the weight is proportionate to the superficial area, it is only necessary to explain that this area is divided longitudinally into two equal parts; that under this divisional line a purlin exists upon which is collected the weight of the upper half of the roof, and this weight is transmitted by a vertical post to the inner end of the hammer-beam. The lower half of the roof discharges in like manner its weight on the outer end of the same timber, and the equipoise is thus rendered perfect."

Although I do not quite agree with the opinion that this equipoise is perfect, yet, as the earliest known example of importance of the hammer-beam roof, I must allow that its design evinces a masterly knowledge of the principles of construction, and which was never surpassed in any subsequent example.

Eltham Hall, 36 feet in width, is spanned by trusses 17 feet apart (fig. 24), the length of the rafters about four-fifths of the width; so that it has not so great a pitch as Westminster Hall. In this example the arches and struts are obtusely pointed and struck from four centres; the whole weight is thrown on the top of the walls, the bottom struts being scarcely of any use in distributing the weight downwards. These trusses have a much greater proportion of timber to that of Westminster.

Hampton Court Hall, completed about 1537, is 40 feet wide, and its roof is of very superior construction to that of Eltham,—the hammer-beam projecting full one-quarter of the span, while that at Eltham only one-fifth; and the weight of the roof is carried down a considerable distance below the hammer-beams by the wall-posts and struts (fig. 25).

In examining the principles of these beautiful roofs, of which we have so many remaining in England, we find that the pressure against the walls is sometimes too oblique; and the buttresses have yielded after the strong plates laid upon the walls had given way, as in the case of Eltham; and in many cases little or no provision was made for properly trussing the principals, which are often found crippled with the weight they had to carry.

In more modern times a system of framing assimilating to the semi-arch is generally employed where ties are omitted, and has all the properties of arch construction.

In 1561 Philip de Lorme published a method of constructing roofs and domes with timbers, or rather short planks. One of these roofs covered the stables of the Tuilleries at Paris, and after remaining sound and secure for 234 years was demolished to make way for some improvements in the palace. The arches were formed of two planks, 9 inches in width, cut into convenient lengths for the required form; this seldom exceeded 4 feet, and were applied to each other in thicknesses to form the rib, and so laid that the ends of one set came in the middle of the others. Mortices were then made in them, through which were longitudinal ties, and these had a small wooden pin passed through them on each side of the circular ribs to keep them in their upright position and to prevent them twisting (fig. 27).

In some of the buildings executed by this architect, when the span of the roof exceeded 60 or 70 feet two ribs were used, so put together that they partook of the character of hollow voussoirs and were very strong.

Another instance of the success of De Lorme's construction was the original dome of the Hall au Blé at Paris, 120 feet diameter, built by Legrand and Molino. This roof was destroyed by fire, and is now replaced by an iron one.

In London we have an example of this system of roof over the central compartment of the Pantheon, Oxford-street, 38 feet span, designed by Sidney Smirke.

Some objection has been made to this mode of construction on account of the labour required in cutting the number of mortices, making the longitudinal ties and introducing the pins; therefore in some instances the mortices have been omitted, the planks bolted and spiked together, and the ties nailed to the upper and lower edges, the latter as ceiling joists or boarding. Nevertheless there exists in these roofs considerable waste of material and great labour as compared with some other roofs of similar spans.

Colonel Emy, a French engineer, proposed in 1817 an improvement on De Lorme's system, by using the planks in the reverse position; in fact being precisely the laminated arch of the present day. On first sight it may appear that De Lorme's plan is the strongest, as the depth of the planks is greater than their width, from their being placed edgeways: in the other system thin boards are bent upon templets to the proper curve, and kept from separating by iron straps and bolts, as also by radiating struts, which are in pairs, notched out so as to clip the rib between them; the joints are much fewer, and the fibre of the wood coinciding with the curvature of the rib gives it considerable elasticity, so as to slightly yield rather than break under any violent strain. I bring before you two examples,—one, a segment rib of 64 feet span, springing from a plate on the floor of a store-room, which floor forms a tie; the other a semicircular rib over a riding school at Libourne, of 68 feet span, erected in 1826 (fig. 26).

The principle of this roof is good. The principals, wall-posts and arched rib form two triangles, firmly braced together, and exert very little thrust on the walls, most of the weight being thrown vertically on the wall at foot of ribs. The walls, though of considerable thickness, are further strengthened by buttresses. I may here mention that the roof of King's-cross Station is constructed of laminated ribs, but maintained to their semicircular shape by being fixed to iron stanchions, built into the wall and weighted therewith.

Colonel Ardent, who found some difficulty in obtaining in many parts of France fir planking at reasonable prices, and where squared oak timber was in abundance, designed some roofs for riding schools according to the accompanying sketch (fig. 28), which as you will observe, follows very closely upon Colonel Emy's principle. Considerable lateral stiffness is obtained by a deep cross strutted ridge, while in Colonel Emy's roofs a series of longitudinal timbers at back of arch are inserted for the same purpose. Other roofs of far greater span have been constructed by the same engineer (Colonel Emy), who after many experiments suggested the employment of a double curved rib, having different radii; these held in at the springing were in the spandrel braced by timbers ranged like St. Andrew's crosses; iron bolts or timber binding-pieces, pinned at the sides, hold the masses together.

In circular buildings, domes and roofs may be constructed by omitting the usual ties, and introducing continuous or annular binding pieces at the springing of the roof, of sufficient strength to prevent its spreading unequally; each portion of the roof counteracting any effort on the part opposite to it. In this case the total dependence is upon the strength of the binding-pieces, rings or plates being such as are able to perform their duty without fatigue. I give the Napoleon Circus at Paris, designed by M. Hittorff, as an example. The plan of the building is a polygon of 20 sides, and upwards of 130 feet internal diameter; the external walls are comparatively slight, and the roof, without any intermediate support, is formed by trussed principals, abutting and pitching against strong framed oak rings. At each angle of the building are three-quarter Corinthian columns, upon which a considerable portion of the weight is thrown.

In these, and in all other descriptions of framing which are not designed upon the girder principle, the slightest alteration in the abutments will destroy the entire system, which is entirely dependent upon the immovability of its points of thrust for the continuance of its shape, use, and existence; therefore this thrust principle must be always inferior in point of construction to those I have previously described as girders.

One of the four designs left us by Palladio consists of a timber arch formed by radiating binding pieces connecting top and bottom rib, and strengthened by diagonal framing (fig. 30). This principle has been much employed in roofs and bridges. Dublin Exhibition roof, of 100 feet span, was upon this system. The upper and lower ribs were composed of thicknesses of planks laid vertically. The other design of Palladio's, with which I found fault for being weak as a girder, has been very successfully adopted as an arch of 340 feet span over the Schuylkill, at Fairmont, near Philadelphia. It had no other support but that of the two abutments: the versed sine was 38 feet, and width of carriage-way 30 feet; all the posts, which were of large dimensions, radiated to the centre, and the abutments were formed of

* See *C. E. & A. Journal*, vol. xiii. p. 249.

Digitized by Google

solid masonry, carried up to a considerable height above the bridge (fig. 31).

The laminated arch now finds most favour when arches of large span are required for viaducts or railways; and, where sufficient caution has been taken to prevent too much motion from their elasticity, have been found to answer very well.

Cressy, in his Encyclopædia, remarks that when the opening of the arch is considerable, the movement of carriages and sometimes the action of the wind alone occasions oscillations in the horizontal direction, which injure the carpentry, and become very dangerous. The greatest care should be taken to prevent this. In the oscillation of an arch the entire system of its carpentry may participate in its movement, or it may be only partial,—for example, the floor may to a certain extent move independently of the arch: still it is very important to oppose these effects. There are therefore, placed between the first course of pendant binding pieces near the springing, inclined struts, which secure the union of the floor and the arch; and it appears that this disposition gives to the arch all the solidity and stability which could be desired. It is scarcely necessary to observe that the framing of all these pieces should be secured by bolts, without which the union could not be obtained (fig. 32).

Many thrust-bridges are constructed of timbers forming polygonal arches, similar in character to the roof of Colonel Armand, but, being composed of too many pieces, are often defective (fig. 33).

Whatever may be the combinations in constructions of carpentry, the object should always be the transmitting of certain efforts to points of support by means of a system of levers subjected one to the other. Now we can distinguish in such a system two different equilibriums, which we may designate, equilibrium of position, and equilibrium of resistance. The first takes place when the efforts exercised on each lever are so combined with their respective situations that the system does not tend to produce any movement. The other consists in making each lever have the necessary force for the resistance of the pressure exercised on it.

A system of levers may be maintained in repose by two different means: first, it may be disposed in such manner that the conditions of the equilibrium of position should be exactly satisfied; secondly, the levers should be so subjected to each other by framing or auxiliary pieces, as binding pieces or braces, that it should be impossible for them to change situations with regard to each other, so long as the resistance of this framework is superior to the efforts which tend to make the form of system vary. In this latter case we are not required to satisfy the conditions of the equilibrium of position.

In the case of bridges, where the weight they have to carry is a constant moving weight, the levers should be placed so that they do not tend to any change of form under the load. It is consequently evident how disadvantageous it is that the two halves of a principal should be divided into a great number of articulations, forming so many points of rupture, leaving them no resistance but that which arises from the strength of the framing. It is therefore very difficult, when the number of levers is considerable, to fortify them sufficiently so as to procure for each half of the span a resistance capable of making equilibrium to the pressure which it exercises in the direction of the length. It is for this reason that the bridge at Calais, and many others, are defective, from being composed of too many pieces, which must be subject to considerable shrinking, and thus become shortened: when heavy loads pass over, they have a tendency to open and derange the whole framing.

In the bridge at Berne, over the Kandel, constructed by Ritter in the year 1764, (span 166 feet,) its height above the water has allowed the struts to be placed in a more judicious position, and inclined almost parallel with each other. They are all about 11 inches square, and the longest is about 75 feet (fig. 34).

The bridge over the Soane, at Lyons, designed by M. Gauthey, for an opening of 164 feet, was upon the foregoing principles. It was intended that this bridge should have three sets of longitudinal timbers, one passing through the middle, which would have given two independent thoroughfares (fig. 35). I may here remark that although Soane, Berne, Wittengen, Schaffhausen, Simmut, and a few others were at one time named as works of carpentry not to be surpassed, yet the binding of timber into arched forms has in more modern times been found not only stronger but more economical and durable.

Mention has been made of several of these bridges: I will now add to the list that of Mellingen, 157 feet span, with an arched rib formed of six pieces of fir, each 10 by 10 inches, bolted on each other; and one over the Seine, 104 feet span, with four thicknesses of timber 10 inches square, as above. One at Bamberg, over the Regnitz, in Bavaria, of 206 feet span, with a versed sine of 16 ft. 6 in., of ribs formed of three pieces of timber in the centre, 14 inches square, and five pieces at the ends of similar scantling. Many others by the same engineer, Weibeking, of spans averaging 100 and 200 feet, also exist in Bavaria. M. Weibeking usually gives 25 feet for the ordinary width of his bridges, and the rise in roadway 1 in 24. He found that timber bridges, when constructed on his principle, would settle 1 foot in 72; so that to have a rise of 1 in 24 when finished it must be framed for a rise of 1 in 18, which will be sufficient for moderate spans; but the greater the span, the greater must be the rise.

The subjects of centres and scaffolding deserve some little attention at our hands, being quite as important a branch of study; for upon the proper construction of the centering for arches the stability of the arch depends. In constructing the arches of a bridge of any considerable span, where the form is that of a semicircle or semi-ellipsis, after the voussoirs are laid to a certain height, the timbers of the centre are compressed, occasioning the crown or upper portion to spring, producing a considerable change of form. This inconvenience can be partially obviated by loading the summit as the process of laying the voussoirs advances; but this precaution will not prevent the centre from altering towards the haunches. Whenever a tie-beam is omitted in that part where greatest pressure occurs, compression and change of form are the consequence. Centres with tie-beams are always to be preferred to those formed by parts of polygons inscribed within each other, as when constructed without horizontal timbers in the direction of the greatest compression, they must yield very considerably.

In order to find a combination of pieces of timber which shall resist the effect of the voussoirs, we must first determine the position of the tie-beam. For this purpose, whatever may be the shape of the arch, draw from its springing and crown two tangents meeting at a right angle, through which drop a line perpendicular to the curve, and its intersection with which will determine the position of the tie-beam (fig. 36). Perronet in his system, as published in his work on Bridge-building, has omitted the tie-beam, and the examples given may be regarded as composed of a number of trussed or framed voussoirs (fig. 37), and are subject, as he found, to great disarrangement if not loaded very carefully.

In some instances fixed centres are preferred to the moveable ones before described, in which case the framing is built up from a solid foundation, or several points of support, as in scaffolding; and many ingenious plans have been adopted for easing the framing, to allow the superincumbent weight to find its equilibrium before entirely removing the cradling on which it had been placed.

The usual method in England of erecting scaffolds with round upright poles and horizontal ledgers, with putlocks resting on same and having a bearing on the wall, is familiar to you all, and does not require much knowledge of construction to design for ordinary purposes; but in some cases the architect, where the buildings to be erected are of an unusual description, has to design also the scaffolding requisite for its erection; and in such cases, as greater strength and solidity are required, it is usual to employ squared timber: very great strength, combined with simplicity, is often observed. The scaffolding to Nelson's Column, London, is a good example.* This was designed and executed under the direction of Mr. Allen. The whole was composed of unsawn timber, and the total height was 180 feet. The upright timbers are slightly tenoned into the horizontal, and where the joint was made iron dogs were driven into the timbers in a diagonal direction across the joints; these afterwards were easily withdrawn, and the timber but little injured. The scantling of all the timbers was 14 inches square, the base of the scaffold was about 92 feet square, without measuring in the raking braces. There were in all seven stories, and the whole strengthened by flying wind braces, which were supported by cross transoms, projecting outwards about 6 feet from the perpendicular of the scaffold at each stage. At the summit worked a travelling machine.

* For a description and drawings of this scaffolding, see *C. E. & A. Journal*, vol. vi. p. 409.

A MODE OF CONSTRUCTING CANNON, WHEREBY THE STRAIN PRODUCED BY FIRING IS DISTRIBUTED THROUGHOUT THE MASS OF METAL.

By Capt. T. A. Blakely, R.A., M.R.I.A.*

(*Concluded from page 50.*)

Besides the great increase of strength to be obtained by making the exterior portions of a gun do their duty, my mode of construction permits the use of metal in smaller masses; but this advantage and others it shares with many old guns, and with many schemes for making guns. In the Museum of this Institution are several ancient built-up cannon, and the construction of many others in India and elsewhere is well known. The most complete of that kind I ever heard of was one made by Mr. Dundas, of Dundas, of longitudinal staves of wrought-iron, accurately planed and fitted, and held together by cylindrical collars or rings. A 9-pounder made by him, and looking externally exactly like one on my principle, was fired at Shoeburyness at the same time as the other, but burst at the third round with 6 lb. of powder and two shot. This would at first sight lead one to suppose that Mr. Dundas's plan is inferior to casting a gun of iron; such is, however, by no means the case, for I believe Mr. Dundas could make a larger solid-shot gun than can ever be made of cast-iron.

Mr. Joseph Whitworth, of Manchester, made guns consisting of cast-iron cylinders, slit up the whole length, and hooped like the others. His marvellous mechanical genius taught him that the interior would stretch when the exterior was but little strained, and he accordingly made his gun so that the stretching should not injure it. The difference between Mr. Whitworth's plan and mine is, that he prevents the disproportionate stretching of the inside from injuring it; whereas I prevent the disproportionate stretching itself to a great extent, without losing circumferential strength, as he does by slitting the core. I like his plan better than that of Mr. Dundas, because I think cast-iron the most suitable material to put next a shot.

I mention these guns to show you that I am aware that I have been anticipated in all the advantages my mode of construction possesses except one, viz., that I make several different layers of the metal take a full share of the strain, so that thickness gives strength; whereas in all other modes some parts are so nearly useless that increasing the size adds little to the strength. I can thus make cannon of almost any size, and have no hesitation in saying that mortars could be manufactured large enough to bombard Portsmouth from such a distance that the ship firing could not be seen nor the report of the gun heard. Cast-iron, we know, can only make a 32-pounder gun, and no thickness will enable it to bear a pressure of 6 tons per inch once, or 4½ tons per inch often, which would have a similar effect. In like manner it can easily be proved that 9 tons per inch pressure would destroy a cylinder of any thickness of brass. Steel has not yet been made in very large masses, and a wrought-iron 68-pounder even has yet to be made. Now, in monster guns the pressure of the powder must reach 17 or 18 tons per inch. This is the reason that such guns have not yet been made; but it is evident that if a gun can be made strong enough to bear the full pressure of gunpowder confined in it, it can bear the lesser pressure resulting from firing even the heaviest shot or shell with full charges. Now we have made cylinders to bear this pressure; I hold one in my hand that has borne it; the limit hitherto put to the size of shot by the difficulty of getting a gun to fire very large ones is therefore removed, for guns can be made which powder cannot burst.

This limit being removed, the only one which remains is expense; and this, in many cases, will be much lessened by increasing the size of the projectile. Of course, for every purpose the smallest effort should be made which can fulfil that purpose. To kill a snipe we use snipe-shot, to kill a duck duck-shot; but it would be useless to fire snipe-shot at a duck 70 yards off. Equally so is it to fire 32-pound shot at granite walls from ships 800 yards from them. One shot weighing 320 lb. would do more damage than not only ten, but a hundred 32-lb. shot. Experiments should be made to find the smallest shot which can destroy granite batteries as existing at present; and, if such are to be attacked, shot known to be large enough should be used.

Colonel Wilford, in a lecture recently given at the United Service Institution, stated that Portsmouth is to be defended by batteries of heavy guns, and that probably some of them will have a range of 5000 or 6000 yards. These will probably keep at bay any ships coming merely to bombard the town and dockyard with only 13-inch mortars, because their effective range is under 4000 yards. But, if any power did want to bombard Portsmouth without being annoyed by the land batteries, the way would be to use mortars having a longer range; still, of course, the smallest that would answer the purpose. If a range of 6000 yards is sufficient, it would be waste to use mortars ranging 7000; but to use them with a range of only 4000 would be a much greater waste.

Surely it is worth while to inquire (carefully, and putting aside all prejudices) if such mortars can be made; because, if they can, we may as well arm our coast with bows and arrows as with guns of a shorter range than that of those which can be brought against them. Now, I firmly believe that with common iron, scientifically put together, 30-inch mortars can be made to bear charges of powder of about 2 cwt., the shells weighing about 18 cwt. These would range fully 6000 yards, for the resistance of the air would have a retarding force on a 30-inch shell but one-third as great as on a 10-inch shell, because the surface acted on would be only ninefold larger, while the mass would be twenty-sevenfold heavier.

Even if I am mistaken with respect to the capabilities of common iron, there can be but little difficulty in building a mortar to bear even double the greatest strain that gunpowder can produce, if we use some of the iron lately manufactured.

Mr. Howell makes 10-ton plates of a metal whose tensile power is 50 tons per inch. Mr. Holroyd has a metal of which he cast a 12-pounder gun which bore a test very nearly (if not quite) as great as that borne by my 9-pounder. Had Mr. Holroyd's gun been made so that the outer layers could do their share of work, instead of being so nearly useless as the outside of any thick cast tube must be, I cannot believe that it could ever have been burst by gunpowder. Captain Uchatius and Mr. Krupp also have produced a kind of steel-iron capable of great endurance, and others are on the same track. My own opinion at present is strongly in favour of cast-iron for the interior part of a gun, on account of the rigidity of that metal. The material for the outer layers should be chosen on a consideration of the work to be performed by the gun. If it be destined for a maritime fortress, where weight is no objection, common wrought or even cast-iron may be employed.

For a very large mortar (say of 60 inches calibre, to throw a shell of 7 tons 10 miles), the strongest material must be used, and plenty of it; and it must be subdivided into a great number of layers, each to be strained. As mortars are seldom liable to direct fire from the enemy, wire can be employed for their exterior, being easily put on, or even replaced if damaged; but for guns subject to direct fire I would myself prefer a substance less susceptible of injury, even though the exact initial tension be less easily given. A little experience in forcing one slightly conical tube over another will enable us to judge the strain quite accurately enough.

I am aware that many attempts to make monster cannon have failed, and that there is a strong opinion that such cannot be made. Mr. R. Mallet lately made two 36-inch mortars, at a cost it is said of 40,000*l.* One of these was disabled by a charge of 40 lb. of powder, although the full charge should have been 400 lb. I think this breakdown cannot be fairly looked upon as decisive, because Mr. Mallet thinks he can repair the damage, and also generally because nearly all first attempts fail. In this particular instance there were obvious reasons why the mortars should not succeed. These I published in the 'Mechanics' Magazine' some weeks before the first trial. They were (I may say in general terms), that the mortars were made only twice as strong as they could have been cast, whereas five times the strength of any possible thickness of cast-iron was absolutely necessary. I thought it incumbent on me to state this before the trial, because Mr. Mallet's first plan was to make the mortars on the principle I have endeavoured to explain, and the failure I foresaw could therefore have been used as an argument against it by those who did not know that Mr. Mallet had afterwards modified his plans.

As the abandonment of the principle by so scientific a person would be, however, a still stronger argument against it, I must remark that he informed the British Association at its Dublin meeting that he did so only to some extent, and that on account of the difficulty of accurately applying the principle, and under the

* From the 'Journal of the United Service Institution.'

Digitized by Google

impression that he could obtain sufficient strength without the necessary accuracy.

I have little doubt that now he could make 36-inch mortars that would not fail. A first trial on so large a scale in one sense, and so small a scale in another, presented peculiar difficulties.*

Another large gun lately made has not given satisfactory results. The 13-inch wrought-iron gun presented to the country by the Mersey Steel Company, though never fired with more than 50 lb. of powder, is already cracked in the inside, just as was to be expected, partly from the causes I have endeavoured to point out, as creating a tendency in cannon to crack or rather tear in the inside, partly from the outside of such a large mass cooling so long before the inside. The latter circumstance must tell against any system of making cannon in one mass, whether by casting or otherwise; but I conceive that I have already given reasons enough for abandoning such a plan.

The 13-inch gun was made of a long hollow cylinder with sides 6 inches thick. On this were shrunk red-hot rings or cylinders, making up the thickness of metal at one part to 15 inches, under the erroneous impression that thickness gives strength. Had the cannon been left in this state it must have been much stronger than it is; but it was heated to a welding heat at an enormous cost, and with an exercise of mechanical skill which few (if any) other persons could have brought to bear.† The consequence was that the tension which was on the outer parts, in consequence of their grasping the inner cylinder in cooling, was removed, and they are now able only to employ a slight portion of their strength, whereas it is evident that, had the tension remained, they could employ the same force they now can, added to that they would constantly have exerted: a full charge of powder could then have been used. Without these remarks it would be impossible to remove the impression which prevails,—that large guns have been tried and have failed; I am sure, therefore, that Mr. Clay, who manufactured the great wrought-iron gun, as well as Mr. Mallet, will be glad I have made them, because, if my reasoning be sound, the cause of science which these gentlemen have so much at heart will be advanced, while any unsound reasoning can be immediately detected and exposed.

The most important objection to the system of construction I advocate is, that the longitudinal strength of the gun is lessened by it. For mortars this is unimportant, as the longitudinal strain is scarcely perceptible; but in making guns care must be taken to have strength between the breech and the trunnions. If the internal tube be trusted to for this strain, we must remember that it is also to be strained in another direction, and is further weakened by being pressed between the gas of the powder and the superimposed plies of metal. Still a large margin remains wherein we can add circumferential strength without unduly weakening the piece lengthways; for the present cast guns are stronger in the latter direction than in the former in the proportion of 12 to 1.

It may save trouble in considering the question if I here candidly enumerate every objection which I have heard urged against my plan,—

1st. A member of the Ordnance Select Committee feared the parts would not vibrate in unison. The reply is obvious,—if the first expansion does not cause rupture, each successive pulsation being less than the first has less destructive power.

2nd. The Ordnance Select Committee reported in June 1855, that the plan was dangerous, and not worth further experiments, even at my expense, because "the *expansive powers* of wrought and cast iron are different." Now this difference is a positive advantage when the more expansive metal is put inside, as I suggest, cast-iron extending nearly double as much as wrought-iron with the same pressure, so that the extension of the outside which would be due to the exertion of a force of only half a ton if the thick cylinder were of cast-iron throughout, would give a force of double that amount if the exterior be of wrought-iron. However, the use of different metals forms no essential part of my plans, though it facilitates their practical execution.

3rd. After the wonderful success of my 9-pounder at Shoeburyness the Ordnance Select Committee reported that they had known of the plan since 1807, and that it was identical with others. In the note (see below) I have shown how diametrically opposed are my views and those of the advocates of welded wrought-iron guns. The ancient built-up guns and Mr. Dundas's are still weaker than the welded guns, the latter, after the interior has cracked, being in the same condition as the former when new. The Ordnance Select Committee seems to attribute the great strength I gain as due only to the substitution of wrought-iron for cast-iron. Now the outside inch of a cast gun, when stretched say one-sixth as much as the inside, could, if of iron, exert a force of but one ton. The mere substitution of wrought for cast iron would give double the power, the extension being the same (and it cannot be greater unless the inside crack); but I can make the outer inch exert a force of 10 tons by altering its size. The change of metal gives an additional strength of 1 ton per inch, at most,—the change of *size* gives a further addition of 8 tons per inch.

4th. A member of the Select Committee told me after the trial at Shoeburyness that such great strength as my gun showed is not required.

5th. Wire is objected to for guns. With this objection I agree to a great extent; but it does not apply to mortars, and many cases may occur where very light guns would be so useful that the advantages of using wire would much outweigh the disadvantages. Most guns however, I think, would be better if made of concentric tubes, not wire.

The immediate use to which I should like to see my discovery put, is the manufacture of stronger 68-pounders and 10-inch and 11-inch guns. A 10-inch gun could be made weighing about 5 tons, and strong enough to fire solid shot if required. America has adopted an 11-inch pivot-gun, and I think we should keep pace with that power. A 9-inch broadside gun, and an 11-inch pivot-gun might therefore be adopted for some of our steamers; nor would the 10-inch broadside gun I mention, and a 12-inch or even 13-inch pivot-gun, weighing 7 or 8 tons, be too rapid an advance.

If any of our rivers and harbours are to be defended, I would venture to urge the use of very large shell-guns for all situations which a ship can pass rapidly; but, as I before said, I am an advocate for the employment in all cases of the smallest guns which are sufficient to perform the amount of work required.

The mode of construction I recommend is applicable to small as well as large guns. It has been adopted by Mr. Armstrong of Newcastle, who found a mere thick wrought-iron cylinder insufficient to enable him to use the full force of the gunpowder, which he does by forming the bullet larger than the general bore of his gun, so that the time necessary to force it in permits all the powder to burn. I may be wrong, but am inclined to believe some part of the wonderful accuracy Mr. Armstrong has attained may be attributed to the great velocity given to the shot by the enormous pressure which my mode of construction alone renders possible. I should mention that although Mr. Armstrong did not use the plan till some months after I had taken a patent for it, he did not learn it from me.

Mr. Whitworth, of Manchester, has been kind enough to express his faith in the great strength attainable by one method of applying the principle I advocate, viz., coiling steel or iron wire tightly round a brass tube.* Strength can thus be obtained without the slightest danger of rupture from the brittleness of the core. Mr. Whitworth intends also to make (or perhaps by this time has made) a rifle-barrel of pure iron or decarbonised steel, strengthened at the breech by means of steel wire coiled round it with the proper tension, which Mr. Longridge has calculated for him. By using the material in this form, Mr. Whitworth expects to be able to make rifles light enough to fire from the shoulder, yet strong enough to throw a bullet weighing several ounces. The

* Previously to Mr. Mallet's proposal being accepted, I had submitted one to the military authorities to make 16-inch guns at 800*l.* a piece, on precisely the same principle,—some to be delivered in three months. The Butterly Company had most liberally and patriotically offered to make these at this price, although they estimated the cost price of the first few guns at 3600*l.* each. My proposal was declined on the plea that it was unusual to entrust an individual with the spending of such a large sum as 800*l.* My impression is that the Butterly Company could have carried out the plan quite as well as any other firm or individual in Europe—probably better; for they had then already made an experimental gun for me, and tried it.

† In the beginning of this century a French company made some cannon for the Emperor Napoleon much on the same plan, though smaller. The Ordnance Select Committee has reported to the Minister of War that the plan is substantially identical with mine; this is however an error, the fact being that the outside of these welded wrought-iron guns does absolutely *less* work than the outside of a homogeneous mass, because the inside being formed of bars laid longitudinally and welded can extend in circumference much (nearly one half) less than if the so-called fibre of the metal were in the direction of the strain, so that the outside (extended one tenth as much as iron can be across the fibre) is only strained one twentieth as much as it might be, because the outer fibres are in the direction of the strain. The difference between such a plan and mine, which would make the outside do sixteen or eighteen times as much work, seems obvious. The methods may be identical, but the 13-inch wrought-iron gun cost 3000*l.*—and I can make one for 1000*l.*: the 3000*l.* one required the highest skill in the world,—but any blacksmith could make the other.

* Mr. Whitworth has since been kind enough to assure me of his faith in my method of making cannon of concentric tubes. He has himself made some experiments which prove the truth of my theory.—T. A. B.

Digitized by Google

recoil must be prodigious, but Mr. Whitworth prevents it from hurting the person firing by a most ingenious yet simple plan.

In bringing my views to your notice I would remark, that before doing so I have considered them for some years, and have subjected them to the test of careful experiment, in which I have been assisted by the advice of Mr. William Needham, late managing partner of the Butterly Company, and that of Mr. Reynolds, their talented engineer. The views of Sir Charles Fox and of Mr. James Longridge, who have both also made careful experiments, coincide very nearly, if not quite, with mine, as do likewise those of Prof. Daniel Treadwell, Vice-President of the American Academy (he read a paper on the subject to that learned body in 1856), and of Dr. Hart, of Dublin. These gentlemen all agree with me as to the remedy to be applied, as well as to the existence of the evil. With respect to the evil itself, viz., the smallness of the assistance rendered by the outer parts of a thick cylinder, I have the concurrence of opinion of all engineers who have ever cast one, and the mathematical investigations of Prof. Peter Barlow and of General Morin. In deeds, which some may think as important as words, part of my plans have also the countenance of Whitworth and of Armstrong.

Although, therefore, such an idea if based on a crude theory of my own must have been regarded as chimerical, I trust that when I now, supported to at least some extent by such competent authority, repeat my firm conviction that mortars could without difficulty be made capable of bombarding Portsmouth, Cronstadt, Cherbourg, or any other such place, from a distance of 5 miles; I trust, I say, that the reasoning on which I base this assertion may be deemed worthy of calm and sifting investigation, for, if artillery one hundred-fold more powerful than any now used can be made, we cannot without imminent danger shut our eyes to the fact.

ST. MICHAEL'S CHURCH, COVENTRY, AND ANSTEY CHURCH, WARWICKSHIRE.

A NEW contract has been entered into, which, when completed, will perfect the repairs and alterations in the north aisle of the chancel and that of the church. We can hardly designate these new works as conscientious restorations, inasmuch as sundry deviations have been made from the originals, chiefly in the replacing of parts of the window tracery which bore evidence of a debased period in architecture, by some of a purer and more consistent character. The north porch, projecting but slightly from the general face of the wall, and ceiled with stone ribs within, is included in the new work. As at present existing it is but a sorry remnant of what it once was, and what it is intended to be again,—the whole of the upper portion having been transformed, and some beautiful windows and panelling, with buttresses and crocketted gables, entirely obliterated. A very curious feature, almost unique, was an external pulpit, attached to the west side of the porch, and approached from a staircase in the angle, whose continuation led up to the roof of the aisle. The doorway out into the pulpit still remains, though of course blocked up, and the floor of the pulpit appears to have been carried on a large stone corbel, or foliated bracket. There were no upright enclosing sides, but simply an iron rail extending across, and let into the jambs of the doorway (as the holes remaining plainly show); the canopy overhead seems to have corresponded in size with the corbel beneath, and to have had rich gables and carving,—the whole terminating pyramidally. It is satisfactory to know that there are ample data for the restoration of these features; for, although they are all cleaned off to the general surface of the wall, traces may be here and there made out, and the outline of the masses is clearly discernible from the differing colour of the stonework where anything has been swept away; while, in further corroboration, an old print, of a century or more ago, is undeniable evidence.

The large east window of this aisle was filled with stained glass a year or two back (by Messrs. Heaton and Butler, of London), in memory of the late Colonel Hood, who fell in the Crimea; and a window of very similar design, in a corresponding situation on the south side of the chancel, has just been renewed, and is about to receive in like manner stained glass, as a memorial to the late General Adams, of Anstey Hall, who fell in the battle of Inkermann. The little village church of Anstey, situate a few miles from Coventry, has lately received an important addition, in consequence of the above lamented event, in the shape of an elegant steeple, 100 feet high, which has been erected at the west end, in place of an ugly and insignificant bell-turret. The new steeple has a square lower story, flanked by diagonal buttresses which terminate in pedestals surmounted by sculptured figures; there is a boldly moulded west door, above which is a niche containing a figure of a warrior in armour. The upper stages of the tower and the spire are octagonal, the former has a handsomely embattled parapet, and small belfry windows on the four principal sides. The whole is of ashlar work, and was very carefully executed by Messrs. Robinson, of Coventry, from the designs of Mr. G. G. Scott, and at a cost of about £500.

THE ARCHITECTURE OF THE THIRTEENTH CENTURY.*

By GEORGE GILBERT SCOTT, ESQ., A.R.A.

IN the two lectures I delivered during the last session, my object was to trace out the development of Pointed architecture from the Romanesque nucleus of the preceding age; to show how far this was the result of constructional necessities and the natural progression of art, and how far it was aided and furthered by external influences; and to illustrate the unity and grandeur of the artistic movement which in so short a time generated an art at once so original and so truly noble. My object on the present occasion will be to give a general sketch of that art when it had arrived at its culminating point,—or rather during that wonderful century through which it reigned triumphant, rejoicing in the full attainment of the object of its strivings, and, proceeding from strength to strength, and from beauty to beauty, filled the countries of Western Europe with creations at once new to art, and in many respects nobler than anything the world had previously seen.

Though it is convenient to classify our mediæval architecture under the heads of centuries, its points of change do not in reality coincide with such a division. It would, perhaps, be nearer to the fact if we classed the last quarter in each century with that which follows: thus, in this country the Norman style would be supposed, roughly speaking, to occupy the interval between 1075 and 1175; the Early Pointed style from thence to 1275; the Middle or Decorated periods from 1275 to 1375, and so on.

On this view of the case a great deal of what I treated of in my last lecture belongs artistically to the present one, and a portion of what I am embracing under the head of the thirteenth century would better go with the fourteenth. As, however, I should wish to be as comprehensive as possible in defining the period of the unimpaired integrity of style, I gladly extend it to the very end of the century, and will not quarrel with those who would dip a little into the succeeding one; for, though I prefer the strength and boldness of the works of the earlier part of the century, the style can hardly be regarded as complete if deprived of the more delicate productions which characterise its close.

In my last lecture I showed how, both in France and England, the last quarter of the twelfth century was occupied in bringing the earlier phase of Pointed architecture from a state of mere transition to one of full development and consistency, and how that the works of this period of especial earnestness in onward striding are characterised by a masculine vigour scarcely equalled at any other stage.

We have now to view the Early Pointed style at the period of the full attainment of its aims, and when its endeavours were rather to amplify and to extend its means than to construct a style.

The thirteenth century commenced under the most favourable auspices for the development of the newly-created architecture. In France both the secular and the ecclesiastical powers were in the highest state of prosperity; and if in England such was not the case with the crown, and we were checked by a bad and mean-spirited king, it is clear that both the barons and the Church were in a state of high prosperity; for from the very opening of the century we find works on the grandest scale to have been everywhere undertaken. Whether in the castle, the palace, the cathedral, the monastery, or the parish church, we find the newly-developed style to have been put largely into practice, so that scarcely a building of note fails to show the impress of the youthful art. Every great church must have its share of it; thus, at

Canterbury, though they had just completed the eastern half in the style of the transition, the cloisters were added in the perfected manner. At York again, the choir had been rebuilt in the last half of the preceding century; but the perfected style must have its sway, so the Norman transepts were rebuilt in it. At Lincoln, the transformation of style had commenced under St. Hugh, before the close of the twelfth century, and before 1280 but small vestiges of the Norman structure remained. At Ely, the century commenced with the building of the western porch, which was followed up by the magnificent eastern arm of the cathedral. At St. Alban's, the gigantic Norman church had not been completed much more than half a century before its western façade was demolished and recommenced in the new style, in which one-half of the nave partook; and before the thirteenth century was finished the choir had also been rebuilt. At Durham, the Norman church received the magnificent addition of the Chapel of the Nine Altars; at Fountains a similar addition was made, with an entire new choir, and many noble appendages. Wells Cathedral was almost rebuilt in the new style; indeed, it is scarcely possible to single out any great church which does not more or less evince the influence of the great architectural movement which ushered in the thirteenth century. Its most complete work is the cathedral at Salisbury; and among its later creations we may enumerate the eastern portion of Westminster Abbey, the whole of Tintern Abbey, and nearly the whole of the once sumptuous church of St. Mary's Abbey, at York; while its last decade produced some of the most exquisite gems of art, such as the Tombs of Cruchbach, of De Luda, and of Archbishop Peckham, the chapel of Ely-place, Holborn, and the Eleanor Crosses; so that, taken as a whole, the century can claim most of the noblest, as well as of the most elegant, productions of English art.

In France its pre-eminence is if possible yet more manifest. The century opened there under the fully established power of Philip Augustus, the most powerful monarch who had ruled France since the days of Charlemagne. In the days of his predecessor the English king had governed more French provinces than the King of France himself; but now the English were almost entirely expelled, and this mighty monarch reigned without a rival. In his days commenced an almost general rebuilding (wholly or in part) of the cathedrals, excepting such as were of very recent date. The west façade of Notre Dame at Paris, the greater part of Rouen, of Rheims, of Amiens, of Coutance, of Bourges, of Le Mans, and a list far too long to be enumerated, owe their grandeur to his reign, or immediately following. Towards the middle of the century the same work progressed gloriously under the auspices of St. Louis, and though slackened from actual satiety towards the close of the century, it was not really checked till the commencement of the English war.

As in England, the works thus produced evince masculine grandeur of the highest order at the commencement, and the most delicate beauty at the close of the century, while during its middle portion the two are united in the works of St. Louis.

In Germany the works of this century evince great artistic disturbance. The change from the round to the pointed arch style had been there resisted, while both in France and England it had been worked out to maturity. At the opening of the century German architecture consisted of a highly refined variety of Romanesque, with the partial use of the pointed arch, chiefly where suggested by constructional necessities. This during the first quarter, or more, of the century developed itself into an Early Pointed style, strictly German, and holding out promises of great force and originality,—promises which were frustrated by the sudden inroad of French Gothic about 1250, after which, though Germany took a course still very much her own, it was one in a great degree severed from her noble early tradition, and emanating from the French graft rather than from the original stem.

Italy received her Pointed architecture from France and Germany, and mingled it freely with her Classico-Lombardic traditions. The union produced many noble and many incongruous developments. The lessons they offer must be used with caution; but Italy being the land of ancient art, the land of sculpture, of painting, of rich marbles, of mosaic work, and of municipal and other civic edifices, the graft of northern art upon so prolific a stock has, as may readily be imagined, produced varieties which the circumstances of northern nations would have rendered impracticable in its native lands; and the suggestions they offer, if judiciously used, are well calculated to add copiousness to the style in the hands of its modern revivers. Of this I may have occasion to say more hereafter.

The thirteenth century was to the mediæval art what the Periclean and Augustan ages were to the Greek and Roman; and in each case, though war and bloodshed are in themselves hostile to art, there can be no doubt that the excitement of the human mind, resulting from great national struggles, have tended to produce that advance in art which followed, in one case the glorious assertion of national independence; in another, the conquest of the world; and in a third, the romantic and unselfish efforts of the Crusaders.

It was a period of deep-seated mental excitement, of a prodigious upstirring of the human intellect. Our learned men at the present day may smile at the quaint and imperfect erudition of these early periods of our civilisation, but they should remember that they were our days of youth, of warmth, and of rising vigour, while the more perfected literature of our own age may possibly be found to superadd to its maturity a few symptoms of old age.

This youthful energy pervaded every branch of art; everything seemed to experience a new, a generous, and a vigorous impulse. All Europe became filled with the productions of the newly generated art; every city became a repertory of noble and sublime architecture, and every town and village became possessed of productions equally beautiful, if more modest in their pretensions; while the intervening country was studded over with castles and monastic establishments, in which the same majestic art displayed itself in ever-varying forms, each suited to meet their different requirements.

Nothing is more difficult than to describe a perfected art. My last two lectures traced out the gradual construction of Pointed architecture, and its transition from the preceding style. This was comparatively easy; but to describe it when it had attained perfection is far less so.

The fact is that there is neither in France nor in England any marked difference between the styles during the later period of its transition, and when perfected beyond that unity and consistency of parts which indicate maturity. In France particularly this is the case; for neither had the style there continued long to evince its transitional state by the retention of strictly Romanesque features—unless the square abacus can be so designated—nor did it when perfected throw off, as in England, that one detail which to our eye seems a relic of transition. The later transition and the earlier perfected specimens seem in France to be the same art, a little more developed and more homogeneous, rather than to have many describable points of difference. In England the change of the abacus from the square to the round form makes the distinction more marked, so that English examples at the opening of the thirteenth century always appear later and more advanced than contemporary French ones. I instanced in my last lecture four examples of perfected Early English: the eastern transept of Lincoln, completed about 1200; the eastern chapels at Winchester, about 1204; the western portals of St. Alban's, finished about 1205; and the western porch or Galilee at Ely, finished about 1214. None of them show any remains of transitional character, and all having the English round capital in full development, appear to the English eye more advanced than such works as the western portals of Notre Dame, at Paris, which are, if anything, somewhat later in date. In this country in fact the form of the abacus is the distinguishing feature between the transition and the perfected style, while in France there is no such distinction to be found. The difference is more one of feeling, which the practical eye perceives at once without being able to define.

Though I speak of the Early Pointed as a newly generated art—as it in effect was—it must never be forgotten that it is a distinct and natural growth from the pre-existing Romanesque. The more I study old examples the more obvious does this appear. Take either France or England alone, and you may from either construct *ad libitum*, unbroken catenæ of examples, showing step by step the natural and logical growth of the new style out of the old; and that without any essential imported element (for the Byzantine capital, which was the parent of the Gothic one, was an accidental though a happy importation.)

This progressive growth was but the practical realisation of three great aims towards which the Romanesque architects were ever striving,—the perfecting of their arcuated and vaulted construction, the increase of the altitude of their proportions, and the general adding of refinement and elegance to their details. Thus, if you take the internal bay of a Norman cathedral, and simply set yourself the task of increasing its height in a given proportion,

Digitized by Google

the result will be a Gothic bay, for the arches cannot participate in the increased elevation without becoming pointed. If the details are further refined it becomes an ordinary transitional design; and if the process is carried on a little further it becomes a perfected Early Pointed work. The distinction between transition and perfected Early Pointed being merely the carrying on of the process by which the former was generated out of the Romanesque. This fact, which all who look closely into it must see, was what led a talented writer to say that Early Pointed was only Romanesque improved. He meant this as an argument against it as compared with the still succeeding styles; but I confess, for my own part, while feeling strongly the truth of the observation, and highly appreciating the importance of some of the subsequent developments, I do not the less admire the glorious productions of the early style from seeing in them the evidences of the vigorous stock from which they have sprung.

It will be seen, by enumerating the leading characteristics of Pointed architecture, that the great majority of them were already perfected, or at least brought to that reasonable and consistent state of development which stops short of excess and exaggeration at the commencement of the thirteenth century.

The pointed arch had obtained universal predominance, though without involving the rejection of the semicircular or the plain segment, where circumstances called for them; the general predominance of the vertical line was acknowledged, without running into the excess of underrating the horizontal; lofty and aspiring proportions prevailed, though not to the extent of exaggeration, and without unreasonably asserting their claims in works of a humbler class; the subdivision of arches into orders, and the clustering of the pillars, so as to satisfy the eye that each member of the arch was severally supported, had arisen during the Romanesque period, and was now carried out still more systematically and with greater elegance; and the system of making the bases and capitals face in the direction of the insisting arch-rib, which had also arisen early, was (in France at least) very generally adhered to. The distinction between constructional and decorative pillars—one of the great characteristics of the Gothic style, both round and pointed—was carried to its fullest extent; the vaulting system was perfected, though retaining its normal simplicity; and the corresponding system of buttress (solid or arched) and pinnacle, which are the necessary accompaniments of a perfect arcuated style, had been brought to perfection; the continuity of line was acknowledged sufficiently to suggest a feeling of natural growth of the parts one from another, from the bases of the shafts to the bosses of the vaulting, but without that sacrifice of force and of all salient points which became the vice of later styles.

The principle of rendering the useful features ornamental was fully developed: as an instance of it, the doorways, the only parts of the exterior which must of necessity be seen from close at hand, were rendered magnificent beyond all former precedent, and became the vehicles of noble sculpture, and the great exponents of the objects of the building, whether religious or secular. The windows now became great characteristic objects, not only from their richly painted glass within, but as leading architectural features both within and without. The bell towers became glorious structures, rendering the cities conspicuous throughout the whole surrounding district, and making every village a distinct and beautiful point in the landscape. The same principle obtained in all the secular structures. The castles of the nobility became truly noble structures, glorious for the stern grandeur of their external aspect, and for the massive beauty of their internal architecture; the gates and defences of cities partook of the same severe grandeur; while the street fronts, the town-halls, and other civic buildings displayed architectural characteristics, modest or grand, as suited their several purposes. In Italy, where municipal institutions were more developed, noble street palaces were erected; and everywhere the architecture, whether viewed in the mass or in its details, was suited, as by an unerring instinct, to the objects on which it was exercised.

The decorative system of the architecture had also been brought to great perfection. The mouldings were refined without losing boldness or strength,—in fact, were strong or delicate as suited their position; the foliated carving had arrived at very high perfection, and was of a kind perfectly new—the magnificent creation of the artistic mind; sculpture was often profusely used in connection with architecture, and if not of that perfectly studied symmetry which satisfied the academic critic, it evinces a boldness of conception, a quickness of invention, and an unaffected grandeur of sentiment, which our modern sculptors would do well to emulate, while it is eminently suited, by its rigid lines and severe force, to architectural purposes.

It would be absurd to attempt in a single lecture to give any detailed description of the architecture of this great period; nor is it necessary, as no style is so familiar to those whose attention has been at all turned to such subjects; I will, however, take a few of its leading points and call attention to some of their characteristics.

I will begin with the Column. In no feature is the difference between Classic and Gothic architecture so strongly marked as in the column. In the former one general ideal alone prevailed,—the round shaft with a capital, and with or without a base. In the latter this normal type is equally admissible and equally honoured, but in addition to it an almost endless list of forms are introduced. In the first place the round column is converted at pleasure into the octagonal or other polygonal form,—this is a mere variety of the normal type; then either the round or the polygon is flanked by four smaller shafts, attached or detached, and these subsidiary shafts may be increased in number, subordinated one to another both in size and saliance, and may be all attached, all detached, or the attached and detached shafts may be used alternately, or in any other order in the same pillar.

Then again, instead of the cylindrical pillar, we may have four cylinders united in one, and these may in their turn be made the nucleus round which detached or attached shafts may be grouped; or we may have two or more separate cylindrical main shafts carrying the load, and may group subordinate ones round them; and again we may take other forms of nucleus, as the square, the canted square, or a pier with receding orders, and place our shafts round them; and finally we may form groups in which no specific form of nucleus is to be traced, but which consist of shafts arranged with reference to the superincumbent arch alone.

The number of changes which may be rung on these varieties of pillar are absolutely endless, though it is not desirable to indulge too much in the more intricate forms of grouping; but, as a general rule, to keep to forms which are naturally suggested by the duties the pillar is designed to perform. When detached subsidiary shafts are used it is somewhat unnatural to joint them in their length without introducing some visible means of tying them to the main pillar within. This necessity gave rise to the use of the moulded band, which forms so beautiful a feature in the pillars of this period. It is sometimes made of brass, but more usually in stone or marble.

The bases of columns throughout the Romanesque period were most usually founded on some traditional variety of the attic base. The resemblance is often obscure, but in many cases very close.

Towards the end of the Romanesque period very great attention began to be paid to the sections of base mouldings, and in transitional works they are often more beautiful than at any other period. The difference between these bases and the ordinary attic base is of the same kind which distinguishes Greek from Roman moulding. It is an extreme delicacy of curve, the substitution of elliptical section for circular, and a wonderfully studious grouping of the hollows, rounds, and arrises, so as to produce a refined and delicate contrast and gradation of light and shade, without destroying the strength necessary to the main supporting feature. In this they showed a high appreciation of what is in all architecture a difficult problem,—the uniting the conflicting claims of the lower part of a building, as on the one hand demanding the greatest strength of character as supporting the whole structure, and on the other a delicate finish, as the part open to the closest inspection.

The bases have usually one more part than a Classic base, having in most cases a projecting sub-plinth, either chamfered or moulded. In earlier instances the plinth and sub-plinth are both square in plan; and here, again, we obtain a feature of great beauty, which antique architecture did not possess. I mean the beautiful leaves or bosses of foliage which spring out of the lower torus to cover the projecting angles of the plinth.

This projection is often reduced by making the torus overhang the square plinth in the centre of its sides, and a little projecting corbel is often put to carry this overhanging, as well as the leaf to cover the angles of the plinth.

At a later period the square plinth gave way to the octagonal, and in England and Normandy often to the round form.

In the early work the bases often faced about diagonally, as the caps, to indicate the direction of the arch-ribs to be supported.

Digitized by Google

In France the elliptical section of the lower torus continued much longer than in England, and the upper torus was often converted into a kind of ogee, and both in France and England the scotia was usually very narrow and deep,—so much so, indeed, as to hold water. In England another kind of base is frequent, in which a bead is substituted for the scotia. In some rich work the plinth is clothed with foliage.

I have said a good deal of the history of the capitals of the Early Pointed period in my last lecture. I particularly showed that about the period of the transition a great change took place in France in the form of the capitals, in which the old Romanesque form was almost universally abandoned in favour of one of a distinctly Byzantine origin, which I suggested came in all probability by way of Venice, at the time of the erection of the Byzantine churches in Aquitaine; and that though the domical construction of churches then brought into France does not appear to have extended northward of the Loire, the Byzantine capital of the Corinthianesque type was adopted quite into the north of France, and became the parent of the exquisite capitals and foliage which in the next generation pervaded the architecture both of France and England, and a little later of Germany. I also showed that the peculiar stalk or crocket which became so constant a feature in Early Gothic capitals, took its origin from a plain unraffled leaf frequent in the Byzantine capitals, which in their turn may have been suggested by unfinished leaves, which are of very common occurrence in the capitals of that period.

During the first half of the thirteenth century these crocket capitals were brought to very high perfection, the stalk or crocket either appearing in its most normal form, or being more or less clothed and concealed by foliage. In the latter case it forms a strong background to the leaves, giving them the apparent stiffness and strength necessary to their position. These usually turn over in a bunch of foliage, which is distinct from the leaves which clothe them; so that there is no inconsistency, but the reverse, in the clothing foliage being natural, while the terminal bunch which completes the crocket is conventional. Towards the middle of the century the natural and conventional foliage were very much used together, the former being often a light playful overlaying of stronger leading forms; but afterwards in French work, and still later in English, natural foliage became the rule, and conventional the exception.

The capitals which prevailed during this century form the most magnificent series which any style of architecture can boast. Whether the foliage is natural, conventional, or both united, the artistic power evinced is truly delightful; and when it is recollected that no two capitals are ever found exactly alike, the fertility of invention they display is perfectly wonderful.

It would be hopeless in such a lecture as this to attempt to go through, even in the most cursory manner, the endless varieties of capital,—from the stupendous masses of noble foliage which crown the apsidal columns at Rheims, whose single shafts are 6 feet in diameter, to the delicate reeds which decorate the mullions of windows. This one feature alone would form an ample subject for an entire lecture, or almost for a series of lectures. I will confine my present remarks to the great characteristic differences which distinguish French from English capitals during the thirteenth century.

This great distinction lies in the plan of the abacus: for while in France the square form of the preceding style continued, the English architects very soon substituted the circular plan. It is a curious question how and when this arose. In both countries the round abacus was in some instances used from an early period; but this was chiefly on great cylindrical columns with low capitals, such as those in the nave at Gloucester Cathedral; though even in France the round form occasionally occurs to subordinate shafts, as at St. Omer; but, as a general rule, both countries used the square or the angular form till late in the transition, when the English commenced the free adoption of the round, first alongside of the other, and afterwards to its almost entire exclusion.

So early as the erection of the crypt under the Trinity Chapel at Canterbury, by William the Englishman, about 1180, we find the round moulded capital; and in the altar recesses in the eastern transept we find the round abacus on foliated capitals, though I confess I doubt its belonging, in this last mentioned instance, to the original work.

Much difference of opinion now exists as to the comparative merits of these two forms. By some the square abacus is assumed to be the great symbol of force and vigour; while, by others, it is said to be inconsistent with the true principles of Gothic architecture. Perpaps the question might be solved by deciding that both are beautiful, both vigorous, and both consistent with Gothic architecture, and therefore that both should be admitted on equal terms as portions of our general material.

The advantages of the angular abacus are,—that it allows of the capitals indicating the direction of the arch-ribs, and assuming irregular forms suggested by them, which the round form forbids; that it allows of the use of square orders, and consequently of simpler and more effective arch mouldings than can be placed in the round abacus, on which the mouldings have to be somewhat crushed in their section, and their parts multiplied, to bring then nicely on to the round support, and that the angles indicate the direction in which the main stalks of the foliage should tend. There can be no doubt, on the whole, that it produces the most vigorous effect; and I must plead guilty to an un-English preference for it, though I also greatly admire its competitor, whose advantages are the beautiful form which the round moulding takes as seen in perspective from below, and its less disturbance of the continuity of line.

Another great characteristic of English architecture is the moulded (unfoliated) capital. This is almost wanting in French architecture, and I strongly contend that the invention of this capital, which we may almost claim for our own country, is one of extreme value, and supplies what would be otherwise a great hiatus in the style. Among its earlier instances is that I have already mentioned in the crypt at Canterbury. It is there in rather a plain and normal form, nearly resembling a capital denuded of its foliage, but with the space below the abacus and the bell somewhat increased for the sake of strength. The fully developed moulded capital differs from this in having a considerable overhanging moulding, which is the substitute for, and the representative of, the foliage of the richer capital. Though this overhanging moulding is uniform in type, the varieties it assumes in detail are endless, and the groups of mouldings in these capitals are among the most beautiful in the whole range of Gothic architecture, and the addition of this beautiful feature to our rich treasury of forms of capital is of infinite value.

The abacus of the moulded capitals is not necessarily round. There are many instances of its being square, and still more of its being octagonal,—a form in which it continued through the later periods of English architecture.

I ought to have mentioned that in its normal condition the abacus is in a separate stone from the rest of the capital, though convenience frequently suggests its being in one. When marble shafts however are used, it is far better that the same material be used also for the abacus.

Next in importance to the column, as a characteristic of the style, we must place the Window. Indeed, it has generally been made to take the precedence of it, and is no doubt that by which the date of a building is most readily ascertained, and its style defined.

The Romanesque windows were simply openings with round heads, the jambs and arches being either perfectly plain, moulded, with or without enrichment, or the jambs shafted. These windows were most usually isolated, but were here and there grouped into couplets, triplets, &c., or made to form portions of continuous arcading.

In the early days of the transition the windows remained unaltered otherwise than as to the general refinement of their details. Later on the arches were made pointed, and their proportions somewhat elongated; and even in the fully developed Early Pointed style—properly so called—the window differs little in principle from that of the Romanesque period, though in fact it assumes a widely different form, through its carrying towards their ultimate results of the principles of grouping began during the previous styles, and those of refinement and elongation incident to the transition.

It is in carrying out these principles to a still greater extent that the Early Pointed of England differs from that of France. It is really the same style, and no important feature can be pointed out in the one country which is not to be found in the other; but just as the Germans, by dwelling longer on the Romanesque style, rendered it more refined and perfect than elsewhere, the English, by the continued retention of the unmullioned window, systematised its use in a manner not equalled in other countries. I see no difference of principle in the fenestration of the Early French and the Early English Pointed styles: in both the principle was the decoration and combination of single lights.

Digitized by Google

Nor do I see that in England this was done in a manner essentially differing in any respect from what was common in France. The great difference was the far greater width of the French openings, which often rendered their windows inelegant in proportion, while it offered a noble field for stained glass. The characteristic of the English windows, on the other hand, was narrow and tall proportions, and a greater amount of enrichment of the jambs and arches, though none of these are by any means constant features. Sometimes we find in English works lightness carried to a vicious extreme, as in the beautiful but frail eastern transept at Worcester; though in the majority of instances it retains a masculine firmness and solidity, as in the east end of Whitley.

Time would fail me to illustrate the magnificent combinations of this early class of window to be found in cathedrals and monastic churches,—as the east end of Ely, the west at Llandaff, or the north transept at York; nor would it be possible to enumerate the simple and impressive village churches to which, in their humbler forms, though with equal artistic merit, they lend such a charm. The style is too well known in England to need minute description, and its merits too fully acknowledged to need enforcement from me.

I will rather proceed to consider that great invention which may be considered to complete the series of developments which constituted Pointed architecture: I mean the mullioned and traceried window; not that I consider it as in all points better than its predecessor, nor that in our own revival it should supersede it; but that, as a matter of fact, Gothic architecture would have been imperfect without it. Like almost every other feature of Pointed architecture the traceried window grew out of the Romanesque.

In all periods of Romanesque we find occasionally two or more arched openings comprised under one enclosing arch. This arrangement is more frequent in belfry windows and triforium openings than elsewhere, but occurs in ordinary windows, especially in secular buildings. The space intervening between the large arch and the two or more placed below it was, even as early as this, occasionally pierced with circles or other forms of opening. Here, then, we have the elements of the mullioned window before even the introduction of the pointed arch. In the same situations it gradually developed itself, step by step, during the Early Pointed period, so that we have in triforium arcades and in other positions a pretty full development of what is called plate tracery, before its use became frequent for ordinary windows. The case was pretty much the same both in France and England, though on the whole the love of placing two openings under one arch was greater in France; thus we see in the aisles at Chartres two plain lights under one arch with a circular opening, and above, in the clerestory, a very large circle with somewhat complex subordinate piercings. The same is the case at Bourges, where three lights are often comprised under one arch, with a single circle in the head.

The next great element which aided in producing tracery windows was the wheel, or other richly-pierced circular window. This again originated under the Romanesque style, as we may see at Barfreston and elsewhere. It is, in fact, a very close approach to tracery, and when placed in the space between comprising and comprised arches, it almost completes the change. All that is wanted is the piercing of the intervening spaces in forms whose outlines are parallel to the main piercings, so as to form what Prof. Willis calls bar tracery. This was, I fancy, commenced in France—though there are very early traces of it in England—and was done at first in a partial and clumsy manner, as in some windows at Le Mans and Tours, but soon was systematised.

I do not see that in any of the previous steps the French were in advance of the English architects, but in this last step I think they were so, and this led them to a much earlier abandonment of the single window and its combinations; so that for some time the French were using tracery windows while we were rendering more perfect the unmullioned system,—not from want of knowledge of the other, but rather preference for a system in which we were producing more beautiful combinations than our neighbours had attained.

It is not a very profitable question to inquire by how many years the French may have been in advance of us in this development, and it is so exceedingly difficult to get at positive dates of the erection of buildings in either country, that it would be impossible if desired. The fact, no doubt, is that for many years the two kinds of window were contemporaneous. Thus, traceried windows may have been in use at Rheims and Amiens, while the older kind was being used at Bourges and Chartres.

It is said that in England the fully-developed bar tracery was first used in Westminster Abbey, which was commenced in 1245; but this is merely an assumption: and it is clear that it was used in the eastern part of St. Paul's, a part of which was consecrated in 1240. The east window of Netley Abbey looks very early, but I do not know its real date, but believe it is said to have been finished in 1249, while the eastern windows at Lincoln look too thoroughly developed to be very early specimens, though known to have been erected between 1250 and 1280. In any case the change had fully established itself in England during the third quarter of the century.

There can be no doubt that whichever class of window we prefer, this invention was of immense practical utility. It rendered possible what was never obtained before,—the formation of windows of any width which might be wanted without injury to the beauty of the building. This is in fact the great use of the mullion—to enable you to use wider windows than you could use without it,—indeed, to render their width unlimited; and the consequence of the invention was the introduction of windows in some cases not less than 30 feet or more in width, and 60 or 70 in height, and that without appearing to make any unseemly gap in the walling, which would otherwise have been the case with a window of one-sixth of the size.

After the system was once introduced it seems to me to have been often more beautifully carried out in England than in France; indeed, I hardly know in France windows of equal beauty with those at Lincoln, Tintern, or St. Mary's Abbey at York.

At a later period excess of tracery became the great vice of the style, but while kept within bounds it unquestionably was a great element to its perfection; and though it must always be remembered that a building of any amount of beauty and dignity can be designed without it, it would be placing upon ourselves a very foolish restriction if, merely from an individual preference for the earlier and sterner style, we were to debar ourselves from the use of so convenient and reasonable an element.

One feature in which the English works of this period appear to me to be peculiarly excellent is the base moulds; I do not mean of columns, but of the building itself. I have never seen any in France to equal many of our own in the quality of appearing eminently fitted to support the whole structure, or in the artistic arrangement of their parts.

Against this we may balance on the other side the French cornices and foliated bands, which are one of their most beautiful characteristics. They usually consist of two courses—a hollow projecting moulding containing the foliage, capped by a weather moulding—the equivalent respectively of the bell and abacus of the capital; indeed, in many cases forming the continuation of the capitals of window jambs across the intervening piers. We have in many cases cornices equivalent to these,—as at York, Howden, and the nave of Lichfield; but they are on the whole a much less English than French feature. The foliage they contain is usually of great beauty, and eminently suited to its position.

The great glory, however, of the French churches is their doorways; and beautiful as are those of our own, they make no kind of pretension to vie with those of our neighbours in magnificence. In this respect the architects of the two nations seem to have gone on quite contrary principles; for the French, even in buildings on a secondary scale, introduced portals of prodigious size and extreme richness, while the English, even in buildings on a grand scale, often made their doorways very inconspicuous. Compare, for instance, the façades of Amiens and of Wells: in one the portals are everything, so that you can recollect little else; and in the other they are nothing, and you can scarcely recollect their existence;—while in the façade above the English example is the richer of the two; and the illustrative sculpture, which in the one case is expended on the portals, is in the other diffused over the entire front. In England a magnificent portal is of rare occurrence; in France one looks for it as a thing of course. Nothing more glorious than the great French portals can be conceived: the lofty and deeply-receding jambs are divided in their ample height into two portions, the pedestal or basement of which is richly decorated either with diaper-work or with sculptured medallions, or, as at Amiens, with both; and the upper stage contains colossal figures of apostles or other holy men of old, who appear to view with severe and solemn benignity the entering crowd, and to express, by the gravity of their counte-

Digitized by Google

nances, the caution, "Keep thy foot when thou goest to the House of God." In the tympanum are sculptured scenes from scripture history, the lives of saints, our Lord surrounded by the evangelistic symbols, or perhaps the awful scenes of the final Judgment; and the mouldings of the arch are probably filled with angelic figures, as if the guardians of the faithful worshippers; while this impressive array of imagery is placed in a setting of the noblest and most perfect architecture, and that on a scale well suited to the sublimity of the sentiments expressed.

The portals of Notre Dame at Paris, of Amiens, and of Chartres, may be instanced as among the most striking examples; but all great churches of the end of the twelfth and of the thirteenth century have the same truly glorious approaches, well calculated to solemnise the minds of those entering by them, and to prepare the way for the overwhelming dignity of the interior.

The nearest approach which we have in England to this class of doorway is the south entrance to the eastern part of Lincoln,—a truly noble portal; but on the whole, though of a different class, the most dignified approach to any English cathedral is the western part of Ely. St. Alban's has had three magnificent western entrances. The smaller ones have been wonderful works of art, though now ruined. The north porches of Salisbury and Wells are very noble; indeed, many of our great churches have portals which we should deem magnificent could we forget those of France, and what we know to be eminently beautiful, however they may be supassed in magnificence.

In almost all other parts the English cathedrals of this age are often richer than the French, as in the clustering of the columns, the richness of the arch mouldings, the beauty of their wall arcading, the importance and detail of the triforium, &c.; while, on the contra side, they have to yield greatly to the French in altitude; and in many cases in general scale, as well as in the amount of sculpture with which they are enriched.

My object in drawing these comparisons is not a wish to lay any claim to superiority for either, nor to shake the claims of our neighbours to general precedence, as I view Paris to be, in a certain sense, the centre and metropolis of mediæval art. It is rather to show that these were the arts of a great period, not of a single people; that all were labouring together in perfecting a great and glorious development of art, each knowing well what others were doing, each according to their means taking care to keep up to the standard already attained, and to add to the public treasury developments of their own; each making it his great endeavour to do his own work as well as it could possibly be done according to the means at command, and each people vieing with its neighbours—not in the spirit of petty jealous competitors for praise, but each striving with a noble and glorious emulation to do the utmost in its power to further the great art which all had contributed in generating.

Having given in this and my two preceding lectures a rough and very imperfect sketch of the rise and perfecting of Gothic architecture, it is not my intention any further to pursue the subject historically; but, assuming the thirteenth century to be the great period of the style, I should wish in any future lectures I may give to illustrate and discuss its principles, and the many sections into which it divides itself, whether geographical varieties or the leading features of the buildings themselves. I may not be able to carry out this intention, but in the one lecture I hope to give next week, I purpose—after alluding to some of the most remarkable works of the period, and with some slight description of their characteristics, and after calling attention to the all-prevailing character of the art as it bore upon secular and other buildings, upon the allied arts, and upon the ordinary arts of common life,—to found upon what we have had in review before us some general suggestions as to the practical lessons we ought to learn from what we have been considering, and the influence it ought to have upon our own artistic practice.

RICHMOND CHURCH, YORKSHIRE.

The restorations commenced a few months since at this ancient structure are proceeding satisfactorily. In the course of the work several old features, which had been either concealed or almost effaced, have been brought to light, and illustrate the history of the building in a much more complete manner than might have been expected. Portions of the chancel which have been disclosed by the removal of the vestry indicate Norman features; and, in particular, the buttress enclosing the north-east angle, which extends on both the north and east sides to a width of 3 ft. 6 in., and having a uniform projection of only 9 inches from the face of the wall. Six feet to the west of this buttress, and at the north side of the chancel, there is the lower part of another buttress of a similar character, which was entirely hidden by the vestry. This latter buttress is also 3 ft. 6 in. wide, and projects 9 inches. No doubt, like most other buttresses of that period, it would run up to the height of the side wall of the chancel with the same projection, and finish under the cornice. The string-course also that crosses the east end has run round this side of the chancel, though it must have been roughly broken off when the vestry was built. Between the buttress at the angle and this side buttress was a Norman window, and it is probable that there were at least two similar Norman windows at the east end of the chancel, before the insertion of the present Perpendicular window; and that the buttress now at the east end below the large window, not terminating at the string course, formerly ran up to the cornice upon the wall at that end of the church, with one window on each side, between it and the angular buttress. Probably there would be a similar window on the south side of the chancel, opposite to the one discovered on the north side, and this would give uniformity to the whole exterior of the chancel. These Norman remains at the east end satisfactorily prove that the first church was the full length of the one now undergoing restoration, though its aisles would not be so wide as the aisles in the present church.

ON THE PAINTING OF THE ANCIENTS.

By F. P. Cockerell.*

(*Concluded from p. 44.*)

The assumption that as art progressed colour became considered second in importance to form, and so was less used, is in a measure borne out by the experience of other schools; and though it would be a bold theory to advance that perfection of form and perfection of colour cannot coexist in a work, still we find practically that they do not except in rare instances. This is exemplified in many instances in painting, and particularly in the works of the Venetian school. There can be no doubt that in sculpture strong colour detracts from the value of form in the portions so coloured. Who can walk through a sculpture gallery without being struck with the apparent want of modelling in works executed in coloured marbles or in porphyry? Many instances of this fact will be familiar to those who are acquainted with our own and foreign galleries. We always find in well ordered museums that by the side of a gem, whether intaglio or cameo, there is a cast in plaster, without which it is extremely difficult to distinguish the beauty of execution. This subject may be further illustrated by the converse, as exhibited in the works of the school of the seventeenth century. Bernini often expressed in marble minute forms, such as the veins, &c., which in nature are scarcely noticeable except when marked by a difference of colour. In white casts from the life, of a woman's hand for instance, one is shocked by the coarseness of the skin, which appears so smooth and delicate in nature.

In architecture the disposition of lines and forms in colour of course materially affect the moulded forms, and may be in direct contradiction to them. The bird's-mouth moulding as it is usually painted, becomes a leaf moulding. Many antiquarians insist upon painting an egg-and-tongue ornament upon the echinus of the Doric cap. One of its chief charms seems to be the beautiful combination of the circle in perspective with the sectional curve of the echinus, and this is entirely disguised by the cutting of painted lines (in direction of the sectional curve) upon the horizontal circle; and a quarter-round, or any other clumsy curve, would answer the purpose almost as well.

The opinions of learned authorities upon the colouring of the Parthenon, the temple of Theseus, and other works of the best times are so opposite, and there has been so much learned argument in support of each view, that it is impossible to lay down with certainty whether they were or were not highly coloured, as many of the Sicilian temples undoubtedly were. But the opinions of some excellent authorities, and certain obvious arguments, which in their learned disquisitions are perhaps not sufficiently weighed, seem to point to a very sparing use of colour in exteriors.

* Paper read at the Architectural Museum.

For the many elaborate arguments of learned antiquaries I refer you to M. Hittorff's book, which very candidly gives both views of the question, as we have not space here to go into them. There are one or two simple arguments, however, which go a long way to prove the sparing use of colour. First, that one so constantly advanced,—that the material being white marble, very difficult to work, and obtained at a great expense, it is highly improbable that its beauty should be obscured by the general coat of paint sought to be proved by M. Semper and others. Mr. Penrose—a recent and most conscientious investigator—finds no other traces of colour than those given in this book; and he uses the apparently conclusive argument, that if it were intended to colour the Parthenon all over, the marble of Hymettus would have been used instead of that of Pentetieus, the former being much easier of access, the quarries sounder, no difficulty in obtaining large blocks; but the objection being apparently that the marble is of a grey colour. Another instance of the pains taken to procure a fine white marble is the temple of Delphi, which, being built of stone, was faced with Parian marble, brought from a great distance. It is very possible, and indeed probable, that the blazing white of the fresh marble was toned by means of a light warm dye.

Plutarch mentions a temple of Diana Orientalis, in the island of Eubœa, round which "columns or styles of marble were erected which had the smell of saffron, and assumed its colour on being rubbed with the hand."

Pliny says, "at Elis there is a temple of Minerva, in which Panœnus, brother of Phidias, covered the coating of the walls with milk and saffron, of which one perceives the smell even now when one rubs it with the wetted thumb."

Mr. Penrose in his book states that there are remains in some portions of the Parthenon of mediæval painting; and is it not perfectly possible that the embellishments of churchwardens in this, and in other monuments subsequent to the age of Pericles, may have misled those who take the extreme view of ancient polychromy?

Those ornaments of which there is no reason to doubt the authenticity are generally very small and delicate, and are sparingly used. The soffits in particular seem to have been coloured, and especially the coffers inside the portico. It is highly interesting to observe—and this is a point of vital importance in practice—that, while the architectural parts and features are marked and distinct, the ornaments painted upon them are so small and delicate that the eye has some difficulty at first in deciphering them. It is a common error to suppose that boldness and character consist in making all the parts—those which are subordinate, as well as the leading features—distinct and clear, so that the whole comes down upon the eye. But these considerations are not necessarily anti-polychromatic, for in these liberal times no one will venture to deny the advantage of colour under certain circumstances, and let us endeavour to understand what may be those circumstances.

Many of us have seen the happy results of Mr. Gibson's efforts in the application of colour to sculpture. He founds upon his persuasion of the practice of the Greeks his system of a pale warm tint (not paint) upon the flesh, a faint indication of red upon the lips, and blue in the eyes; the hair is lightly gilt, and the drapery edged or dotted over with delicate stars in colour.

But we, as architects, in admiring Mr. Gibson's works must not forget the marked difference between sculpture applied to architecture, and sculpture *per se*, or furniture, if we may venture so to call statues which have no distinct destination, but stand upon a pedestal or fill a niche as an ornament to a temple or gallery. In the former the conventional nature of architecture forbids us to raise the idea of living beings entering into its combinations. How disagreeable and absurd would be the impression of living beings perched on a pediment or built into a freize. With statues which do not form a part of the architecture, and being close to the eye, or as it were of ourselves, the case is different. Such statues would be infinitely more interesting if, instead of cold and uniform marble, they present a glorified image of the creature; not so near an imitation as to be a reality, though cold and lifeless, but so much of a suggestion as, speaking to the imagination rather than the senses, shall present an ethereal being,—such an image as one might wish to see in a dream of a beloved person. The next step trenches upon the domain of Madame Tussaud.

With regard to architecture, all the learned research to which I have referred you, though of the highest antiquarian interest, is not the most important subject for our consideration. Let us see whether it teaches us any lessons; and if so, in what respect they affect our requirements and conditions of climate, &c. If we accept the lesson which nature teaches us—as we find the Greeks did—in her geographical distribution of colour, we shall find that the exterior decoration of the ancients affects us very little. As has been before remarked, the brilliant colours which produce so good an effect in a southern climate would be staring and crude under our grey and covered skies. Any colour therefore which we apply to our buildings externally must necessarily be of a very subdued kind,—a combination of half tones; and how can we hope to produce such harmonies as nature will establish for us by a few years of exposure?

There is another very important consideration in comparing the works of the Greeks with our own,—namely, the difference of scale. The Greek temples were the merest toys compared with our great modern buildings. This does not prevent our using colour in some small objects, and in parts close to the eye, as in shop fronts, &c.

But the taste for exterior polychromy has been in a great measure rejected in the best times of northern art; indeed, so far that a large use of varied coloured materials is comparatively exceptional. The combinations of brick and stone, and the occasional introduction in stone buildings of coloured marbles in small quantities, has been canonised by the approbation of centuries, and its good effect cannot be denied.

The beautiful manufacture of Minton's tiles offers us a facility for enrichment which we should not neglect; but where they are used in exterior decoration it should be in small quantities, and so as to be considered as detail, and not as a mass of colour affecting the general aspect and tone of the building. They may indeed be of such colour as to give value to the greys established by nature, while they are themselves sparkling and interesting in detail. Other combinations may be effected by the use of different stones of slightly varied tones; but of this the ingenuity of architects of the present day has furnished too many examples to render it necessary to dwell upon it here.

The inefficiency of paint in our northern climate is sufficiently shown in some of the buildings in the Champs Elysée, Paris, as the Cirque Imperial and several café-restaurants, which, with all their pomp of classical orders, &c., are reduced by their trumpery paintings to the appearance of buildings in a fair. Our climate is not bright enough to give value and brilliancy to paint. If we use colour therefore it must be of such material as, having an intrinsic value, shall supply to the mind that interest which the eye does not feel.

Finally, if the foregoing observations should seem to be directed exclusively to buildings in the country, and which are to harmonise and enter into combination with the objects of nature, it will be found, by carrying out the principle which I have endeavoured to establish, that if strong colour cannot be brought to harmonise with our landscape, sky, &c., "*a plus forte raison*," it will appear crude and inharmonious amid the greys of London.

There is a beautiful method of exterior decoration employed in Italy, and more particularly in Florence, to which perhaps too little attention has been given,—namely, *Sgrafitto*. The mode of execution is this: upon a coating of black plaster a very thin setting of white is passed, and this is scratched through to the black with a point in patterns, figures, or arabesques, &c. There are no doubt difficulties in carrying into execution such a system of decoration in this country. First, the nature of the climate, which is so trying to plaster; then the difficulty, that we feel so much (and in which the French have such an advantage over us), of finding artists, who having the power of free and bold drawing, have not the pretension to "high art" and corresponding pay. But no doubt the first difficulty may be overcome by the various excellent cements which we possess; and this noble institution, upon which government spends so much, ought and will provide for the latter difficulty.

Having thus far considered the external colouring of the ancients, and its bearing upon our own requirements, let us survey briefly the interior decoration, which is of so much more constant application.

The foregoing observations, based as they are upon the analogy with nature, and the combination of architecture with the surrounding scenery, scarcely apply to the conditions of interiors. In an interior, with the horizon bounded by four walls, without the sky as a background to objects—the windows being as it were only pictures, without that most important element of the picturesque, sunlight,—we have to create a Paradise for ourselves,

Digitized by Google

and to supply by conventional beauties the absence of those of nature. In an interior all climates are more nearly the same; and in this country, when we take pains to shut out the outer world, we may imagine any climate we please.

If it be objected that the northern eye, being unaccustomed to brilliant colour in nature, does not require it in his interiors, it may be answered that colour is warmth, and as such is grateful to the northern senses. Besides, our analogy with nature again holds good; for being ourselves coloured in our own persons, and all our objects of use, furniture, &c. being for obvious reasons coloured, surely the receptacles for ourselves and property ought also to be coloured.

Colour in interiors has been a thing accepted in all times and countries, and I am not aware of any school having rejected or put a limit to it. All oriental nations have used colour, and do use it in their interiors. The middle ages, the Revival, and our own times, all agree in this practice. It is therefore unnecessary to bring forward any argument in its support, but only to point to a few examples of the periods more immediately under consideration, with a view not to the advocacy of a new system, but to see whether the practice of the ancients can introduce any improvement into our own system. By-the-bye, there are abundant examples in Etruscan tombs; but as the practice of the best times was of course a great improvement upon this style of art, and as Pompeii and Herculaneum no doubt nearly imitated from those best times, it is hardly worth while to dwell upon those earlier examples.

Of the Greek interior decoration we have no example extant; but we have in history allusions to many examples, and there can be little doubt that the interiors of their temples and monuments were abundantly coloured. We have record of the works of Panænus, brother to Phidias, in the Poecile* at Athens, where he painted the subject of the battle of Marathon. He also painted the temple of Minerva, at Elis. We know of the paintings of Micon and Polygnotus, in the temple of Theseus; the Propylæa, the Pinacothéca, the temple of Rhamnus, the green and red tribunals mentioned by Pausanias, and many other instances might be quoted. It is probable that the subjects formed an important part of the decoration, and occupied a large space. Of the decorative parts we know nothing; it is therefore scarcely worth while to dwell upon antiquarian speculation founded upon the dark passages from ancient authors, which are susceptible of such various interpretations.

The decorations of Herculaneum and Pompeii, of which we have such abundant examples, no doubt follow closely the Greek practice, and they are so full of beautiful motives that we cannot do better than consider a few examples, and try to mark the principles which they contain.

There is much said about polychromy in the present day, but what is new in the application of it seems to be directed chiefly to exteriors, while our interiors are still left to the traditions of the paperhanger. Some few there are who have laboured in this important field of interior colour, and we owe much to Mr. Owen Jones for the steps that he has caused us to take in the right direction. Without his assistance the Crystal Palace would have been but an overgrown greenhouse. Since that we have had other and more complete examples of colour by the same hand, such as St. James's Hall, &c.

One of the most important considerations in interior decoration is perspective,—something to give extension to our generally too small areas. Those who know Pompeii will bear witness to the extension given to the merest sentry-box by the judicious application of colour and ornament. Perspective does not necessarily imply objects represented in perspective upon the walls or ceiling, —what the French call a *trompe l'œil*. A sense of extension may be produced by receding colours thrown back by the juxtaposition of darker or more advancing colours, by the judicious disposition of pictures, looking-glass, &c. Actual perspective representations, such as those in the Church of Gesu, in Rome, and many others familiar to travellers, are no doubt meretricious, and are so directly in opposition to reason that they can hardly be defended. In Pompeii and Herculaneum perspectives are frequently used, but they are so fantastic that they can hardly be accused of an intention to deceive, and though somewhat overstepping the limits of reason, those who have seen them *in situ* will generally acknowledge their charm.

Stern virtue no doubt says, let a wall be a wall, and do not attempt by any means to give false escapes for the eye at the apparent expense of continuity of construction, &c. But the realities of life are sad and dull, and if we can by art feed ourselves with pleasant illusions without deceit, are we the worse for it? Surely the man who, living in an attic, persuades himself that it is a palace, is happier than if he obstinately recognised the neighbouring chimney-pots, and refused to forget the whitewash of his walls. All art is an illusion more or less, and the more the better, so long as it stops short of delusion. But is there no middle course, such as may satisfy both reason and folly, the stoic and the epicurean?

May we not, as before hinted, obtain extension by the use of receding colours, &c.? No doubt in a small room it is impossible to dissimulate the proximity of the wall; but by leading the eye to pictures, which convey in themselves the idea of expanse, a certain freedom is given to the imagination. The heavy picture frames which are so universal are great destroyers of this illusion. In Herculaneum and Pompeii the pictures were generally painted upon the wall; but we know that in the Roman times, and more particularly in the Greek, a large use was made of paintings upon panel; but we must suppose that they were either let into the wall or were made to appear as much as possible a part of it. No doubt there are considerable difficulties in carrying out this practice in our own times, but where practicable there can be little doubt of the advantage of it.

We may also help extension by the use of receding colours. But no colour near the eye will of itself recede or give extension without the help of a foil (in French, *repoussoir*). This is admirably understood in Pompeii. In rooms where light colours are used certain ornamental styles dividing the panels are painted either in darker colours, or, being made out with much detail, engage the eye; and the expanse of flat tint is made secondary, so as to recede from the eye. In a large space at a distance from the eye, as a church or great public hall, certain colours have in themselves receding qualities. The late professor of architecture and architect of St. Paul's, relates that some years ago, when the choir was repainted it was thought advisable to substitute for the blue pilasters, in imitation of lapis lazuli, a more reasonable colour—namely, yellow Sienna marble,—the effect of which was to bring it upon the eye, and materially to shorten the church; and the blue was restored accordingly.

Another leading requisite in interior decoration is variety and multiplicity of parts by which to obtain scale. The Pompeian decoration is full of fantastic architectural features. There is a room in a house (called of Sallust) in Pompeii, which being at the most 12 feet square, has a tiny order not two feet high reigning round the upper part of the room; the panels below being dark, and the spaces between these little columns divided into rustics of various colours. In another case there is a small lararium in the entrance of the same kind of tiny architecture. In the painting such things are constantly repeated.

In a small room where one can recede but little, each wall occupies an angle of 90, 100, or 120 degrees of the visual rays, and should therefore be so subdivided that the 50 or 60 degrees which the eye can embrace should be full of matter of interest, and more or less complete in itself. The small objects occupying that surface would be better in an exterior; but being close to the eye, in comparison only with small objects, their small dimension is forgotten, and they stand upon their merit of delicacy and not of scale and force. It is the imagination which gives them importance, as in a picture a figure 2 inches high conveys the idea of a man. The ceiling of the Sistine Chapel is a remarkable instance of the infinity produced by multiplicity of objects.

In architecture it is a constant practice to place small columns in a room upon the ground, so that half their height is constantly hidden by the people, and their proportion destroyed; but if placed upon a pedestal, and so lessened in magnitude, they may still have scale given to them by contrast. St. Peter's fails in producing upon the imagination the full effect of its vastness, from the want of subordinate architectural features to give scale to the leading ones. Panelling is a means of giving scale and at the same time proportion; but mere subdivision without ornament to give value to the broader surfaces is insufficient.

Lovers of antique decoration must regret the timidity of our decorators in the use of strong colour, and deplore the constant repetition of white and gold drawing-rooms, and indurated fog (called neutral tint) dining-rooms. Nothing but considerations of expense can excuse our whitewashed ceilings, unrelieved by a particle of colour. The light, so much required in our London

* Ποικιλος—Many coloured, adorned, of various colours.

Digitized by Google

climate, would hardly be lessened by the introduction of some ornament. In the last century there was a splendid system of putty ornaments, modelled by hand, but this has disappeared. Why should we not make use of the beautifully painted flowers which are so cheap, in bands, borders, &c. upon ceilings, care being taken that strong colours shall not be so isolated as to come down upon the eye? Much may be done to give interest—height, proportion, and colour—to a room with the materials found in a paperhanger's shop.

Having then laid before you some examples of the practice of the ancients in colouring their exteriors as well as interiors, I would conclude by reminding you that though this is the last and accessory branch of architecture, instead of the first, still the vast interest and delight that it communicates both to monumental and domestic buildings claims our attention as architects, and though we cannot pretend to follow all its practical details, we should be judges of it. The names of B. Peruzzi, Giulio, Romano, &c. &c., have come down to us as combining this with the higher functions of art; but in these times, when the distinction between architects and painters is more distinct, let us hope that painters of talent will give their attention to this subject, and this school no doubt has produced and will produce many.

INSTITUTION OF CIVIL ENGINEERS.

Jan. 11 *and* 18.—Geo. P. Bidder, Esq., Vice-President, in the Chair.
Jan. 25 *and Feb.* 1.—J. Locke, Esq., M.P., President, in the Chair.

The Discussion upon Mr. Scott's Paper, "*Description of a Breakwater at the Port of Blyth, and of certain Improvements in Breakwaters, applicable to Harbours of Refuge*," occupied four evenings.

Before proceeding with the discussion, it was remarked on behalf of the author that an error had been overlooked in the abstract of the Paper. The abstract stated that the breakwaters at Alderney, Portland, and Holyhead had sections which presented nearly, if not all, the advantages of the vertical wall; whereas they were in direct antagonism with the principle of the vertical wall. Now what it had been intended to convey was that the experience at those places had shown that the sea did not disturb rubble at a depth of 15 feet below low water; and that there was a combination of the vertical wall and slope, which was nearly equal to a vertical wall;—as when a nearly perpendicular wall was built upon a rubble mound, as near to the edge of the slope as was consistent with the safety of the foundation; the surface of the mound being 15 feet below low water, and the slope being the natural one of about 1 to 1.

In allusion to a remark, that the pier at Blyth acted like a breakwater, and at the same time as a training wall to conduct the water, it was observed that it was important to ascertain whether the prolongation for a length of 4000 feet or 5000 feet of the natural breakwater, formerly an outlaying ridge of rocks in a direction to intercept the set of the flood tide, had produced any effect on the tidal flow up the river, which had originally extended four or five miles inland. Also whether any observations had been made as to the vertical rise of the tide and the extent of the flow previous to the commencement of the works and since their completion; and whether any comparison had been instituted between the two series of observations, the average of a number of tides being taken; because it was believed that the tidal flow was perceptibly diminished. In the river Wear, prior to the construction of the north pier—that on the south having been previously erected—a wide mouth was exposed to the N.E., which allowed a large quantity of water to pass into the river, causing the tidal flow to reach two miles higher up the river than at the present time. There was likewise a difference of 4 or 5 feet in the present tidal flow at nine miles from the mouth of the river, and quays were in existence in the upper parts of the river which were at present 10 or 12 feet above the high-water mark.

It was stated that wooden piers, nearly similar in construction to one of those described in the Paper, had been adopted in the river Wear upwards of seventy years ago, by Mr. Shoot, the engineer at that period. The carcases were built on the land, in lengths of 30 feet, and launched into the river, loaded with large stones, being floated to their positions and sunk on the sand at about the level of low water. Instead, however, of the interior being filled up with rubble, as suggested in the Paper, the river and outer walls were built up with large blocks of stone, like an ordinary pier, so that when the timber became affected by the worm the wall remained tolerably perfect. The timber was not so much eaten away by the worm on the river side as on the seaward face; and, on taking down some of these old piers, the cills which had been buried in the sand were found to be quite perfect.

It was contended that breakwaters having long flat slopes were more liable to be damaged than those with nearly vertical walls, not perhaps so much by the direct action of the sea as by the recession of the waves when the efflux of the water through the open joints tended to disturb the materials, and when once they were deranged a breach was certain to occur. It was believed that in many instances a redundancy of material had been employed in the construction of breakwaters. It was well known that the violence of the sea did not extend more than 15 feet below low water, and as all that was required was still water inside a breakwater, it was worthy of consideration, whether the sections adopted had not, in many cases, been too broad and too large for effecting that purpose. Then again the materials used as *pierre perdue*, would rarely be found to take an inclination greater than 1 to 1. Thus it would appear that an unnecessarily large expenditure was frequently incurred; whilst if a cheaper and equally durable system was adopted, a greater number of these essential works could be undertaken. With reference to the pier at Dover it was remarked that before the present works were commenced it had been suggested that a simple embankment, similar to a railway work, should have been formed from the materials of the adjacent cliffs, by which means a harbour of refuge would have been obtained at a comparatively trifling cost, and in less time than had already been spent upon the new works. It was thought that as these works already afforded a quay, both for embarking and disembarking passengers, their further extension seaward should be executed in a rough manner, so as merely to prevent the sea from breaking into the harbour. An opinion was also expressed that it would have been more correct to designate the work as the "Wellington Pier," rather than the "Admiralty Pier," as but for the interest which the Great Duke took in the matter the pier would probably never have been executed. The effects of breakwaters upon the adjacent coasts ought to be narrowly watched, or else it might happen that they would cause the destruction of other ports

The piers or jetties of Calais and Boulogne, which had been constructed after Vauban's jetty at Dunkirk, and had been alluded to in the Paper as being similar to that at Blyth, might be cited as examples of the successfully constructed works, well adapted as breakwaters for a flat sandy shore, serving at the same time as conductors and protectors to a channel into and out of the harbour. It was doubted, however, whether this system could be applied to an isolated breakwater in deep water, exposed to the violent action of the waves. It should also be remembered that the western or Old Mole of Genoa, which had been formed of caissons, or chests of timber filled with stone and cement, on which a superstructure was raised to a height of 18 feet, had occupied twenty-six years in advancing 340 yards in length; and that the action of the waves on the face was such as to necessitate large stones, 15 tons in weight, being thrown down in front of it in a depth of water of 60 feet. The destruction of the celebrated cones at Cherbourg might also be mentioned, as affording another illustration of the disadvantages of that system of construction.

It was stated that the Admiralty pier at Dover was formed of a hearting of large blocks of concrete, composed of Portland cement and shingle, and faced with granite. The width of the pier was about 80 feet at the base, and it was founded 45 feet below low-water mark, up to which level it was built by divers. The blocks were continued to a little above half-tide level, and above that point ordinary concrete was filled in between the granite faces. It was intended to have a parapet of Bramley Fall stone on the sea side, but that was not yet constructed. The pier had already been useful for sheltering vessels coming into the old harbour, as well as in forming a landing and embarking place for passengers. It was thought that its extension further seaward would be attended with corresponding advantages, as large vessels would be able to come up to the pier. The estimated cost for a length of 1800 feet, including the parapet, was £650,000.

In regard to a statement in the Paper, that the cost of the works at Portland had been £150 per lineal foot, it was stated

Digitized by Google

that the most expensive part of that work, in the deepest water with the superstructure complete, and including the parapet and a wall 40 feet in width, had not exceeded £120 per foot.

It was considered that sufficient distinction had not been drawn between breakwaters intended for deep water and those designed for shallow seas; and that there was a wide practical difference between the two kinds, which require to be allowed for in their construction. Timber had been shown to be a useful material for making barriers against the sea on the east and on the south coasts of England, on the coast of Holland, at Boulogne, at Calais, and at other places; but none of these were cases of deep water piers, and it was below low water that the great difficulties were encountered. In the construction of a deep water pier at Mill Bay, near Plymouth, where the plan of dropping stone vertically from a timber stage was first put in practice, it was found that the number of pile supports and of timbers must be reduced to a minimum, so as to allow the water to pass through without resistance; the timber work thus becoming a mere accessory to the permanent structure. At the Plymouth breakwater some of the largest stones had been driven out of the top pavement and the inside slope. All experience went to show that in designing works which had to contend with deep sea waves, the greatest possible weight and solidity must be obtained that was practicable with the material at hand.

Allusion was made to a design for a breakwater combined with a landing stage or pier, constructed of iron and wood. A vertical wall of creosoted timber, with a broken or unbroken surface, was supported in its position by wrought-iron piles, with Mitchell's screws as foundations, firmly tied and braced together. It was considered that such a system of structure would greatly facilitate the construction, lessen the time occupied, and reduce the cost.

In a supplementary Paper, "*On the Form and Cost of Breakwaters applicable to Harbours of Refuge*," by J. MURRAY, M. Inst. C.E., it was remarked that a harbour of refuge did not require the enclosed water area to be as tranquil as in a wet dock where vessels loaded and discharged their cargoes alongside of quays. A little undulation in the outer harbour was not objectionable; and the protecting moles or piers would fully answer their purpose if the great force of the waves was broken, and they were thus prevented from doing injury to the vessels at anchor inside.

It appeared to be generally admitted, as to the work under low water, that rubble stone, used as *pierre perdue*, remained stationary until it attained a height of 12 or 15 feet under low water; that the slopes of the deposited mass assumed an angle of 45°, or an inclination of 1 to 1; and that this was the cheapest mode of bringing up the works to that level. In corroboration of this latter statement a comparative estimate was made of the cost of bringing up, by diving-bell work, an upright mole from the bottom, in a depth of 6 fathoms, with a spring-tide rise of 16 feet; and of a simple deposit of rubble stone of the requisite width to receive the superstructure, for which purpose a berm or bench, of 10 feet on each side, was added to the other profile. The estimated cost amounted in the former case to £296 per lineal yard, and in the latter to £37 per lineal yard, both exclusive of staging; while the time required to be bestowed in the construction of the former would be far greater than for the latter. The upright mole would also be considerably augmented in cost if the facing of the walls were of granite, and the interior filled with level courses of concrete blocks, in the manner now being pursued at Dover.

With regard to the superstructure, it was estimated that the cost would vary thus, according to the form adopted:

	Per lineal yard.
1. When constructed on a rubble stone deposit, brought up to 12 ft. under low water, and having a sectional area of 4149 superficial feet	£300
2. Of completing the upright mole, with outer and inner walls, and having an area of 3200 superficial feet ...	£558
3. With rubble-stone blocks and cement	£330
4. With concrete blocks	£303

All these systems were, however, expensive, because skilled labour was employed to a considerable extent in the construction; whereas, for the purpose of a breakwater only, this item should be reduced to a minimum.

In the construction of rubble-stone breakwaters, it was considered that the system pursued by the French engineers of not mixing any small material with the large blocks, as practised at the mole of La Joliette, at Marseilles, and to be adopted at the new mole D'Arène, was the correct principle; for there the large blocks were only used where required, and were not unnecessarily wasted by being sunk in the heart of the work. By this plan it had been found that perfect consolidation was attained with a saving of material. Acting on this principle, it was proposed that for a breakwater in the assumed depth of 6 fathoms the nucleus or core, from the bottom of 22 feet under low water, should be wholly composed of third-class rubble, or from quarry rubbish to blocks of half-a-ton in weight; that this should be coated with second-class rubble, from half-a-ton to 2 tons in weight, which it was considered would remain stationary up to 12 feet under low water; and that first-class rubble, in blocks weighing from 2 to 5 tons, should then be employed up to low water, with a berm or bench on the sea side at a depth of 12 feet under that level. It was further suggested that the upper part should be formed of béton blocks of 20 to 25 tons in weight, being of sufficient gravity to resist the force of the waves, not however as a coating, but as a mass, and terminating at the level of high water; then for 10 or 12 feet above that height two or three courses of heavy blocks, bonded and adjusted by manual labour, should be laid. It had been found at Marseilles that these béton blocks cost 5½*d.* per cubic foot, and at Algiers something more; that the interstices between the blocks amounted to one-third of the cubic contents; and that the blocks arranged themselves at an angle of 45°, or an inclination of 1 to 1. Assuming, however, the price to amount to 8*d.* per cubic foot, and that the section adopted had an inclination of 2 to 1 for the sea side, and 1 to 1 for the inner slope, then the cost per lineal yard would only amount to £200, which contrasted favourably with the estimated cost—£300 per lineal yard—of a mole founded on a rubble deposit; being a difference of £176,000 in a mile of breakwater, or if the comparison was made with an upright wall from the bottom, the saving would amount to £630,000, a sum sufficient to construct an ordinary Harbour of Refuge.

In reference to the calculated cost, £150 per foot, of the Portland breakwater, it was remarked that the basis of the calculation was in the reports laid before Parliament. From the last report it appeared that the total length already executed was 5907 feet, including the entrance, 400 feet wide; and that the cost had amounted to £715,919. In this sum was included the cost of a coal store and jetty, which might be set down at £20,000, and of a length of superstructure of about 1200 feet, irregularly constructed, which, at £35 per foot, would amount to £42,000. These being deducted from the gross cost left an amount of £653,919, which, being divided by the total length of the pier, gave £111 per lineal foot. To this must be added the price of the superstructure, bringing up the sum to £146 per foot, supposing the superstructure to be completed. But as the value of the convict labour was not allowed for in the cost of the work, the author had considered that the amount should be increased by whatever that was worth; taking convict labour as compared with free labour to be as 3 to 8 nearly, being the proportion assigned to it by the engineer of the breakwater, or equivalent to 1*s.* 1½*d.* per day, then the value of the labour of 800 convicts employed during the ten years the work had been in progress, would amount to £24 per foot run, making the total cost £170 per foot, whereas it had only been stated at £150 per foot.

In reply it was stated that the cost of the works, as given in the parliamentary returns, included all the preliminary expenses, amounting to about £80,000 or £90,000, some portion of which had been incurred for special reasons; and that these charges must in fairness be distributed over the whole of the work when it should be finished, as well as over all the contingent works. It was maintained, that in the most expensive portions the Portland breakwater had not cost £120 per foot. The convict labour had not been charged to the cost of the breakwater, and it had yet to be ascertained whether that would affect the result. There were contingencies connected with the employment of such labour which, although only subject to a mere nominal charge, would materially add to the cost in several other respects. The risk was greater, and the works would take a longer time in construction, more especially with a timber stage, and under no other system would it be possible to employ convicts with any chance of a profitable result, or with that degree of regularity and freedom from stoppages during gales which was so essential. At Portland the works had only been delayed from this cause from ten to twenty days during ten years. Then to do the same quantity of work

Digitized by Google

in the same time the "plant" must be greatly increased—say in the proportion of 8 to 3—and it must also be of a special description, suitable to unskilled labour; added to which it would be more liable to damage when used by men without skill and without experience. So that, strange as it might appear, it was much doubted whether any pecuniary saving had hitherto resulted from the employment of convict labour. Now however, by the employment of free labour in particular parts of the work, the rate of progress was being increased, and the scale was being turned in favour of the employment of convict labour.

It was remarked that when a wave reached a vertical wall it was immediately reflected back, producing the converse of itself, and this again gave rise to two reflected secondary waves,—one vertically upward and parallel to the face of the wall, and the other downwards. If the wall was situated in water of a moderate depth, and was founded in or upon sand, mud, or other soft material, a hollow trough would become excavated along the base of the wall by the reflected wave; and unless it was founded deep its base might be undermined. This actually occurred at the Commercial wharf, Kingstown Harbour, some years ago. The seas which washed over the wall, falling forward into the water of the lee side, also produced a wave by their impulse, which penetrated to the bottom, and produced at that side another but smaller trough along the base of the wall. The remedy adopted was to fill the troughs on both sides with angular shingle concrete made with Aberthaw lime.

It was observed that if timber could be rendered permanent it might be advantageously employed in the construction of breakwaters, inasmuch as by its use there would be obtained a continuity of structure, which stonework did not possess unless the materials were of very large size. The structure at Blyth had been exposed to the action of heavy seas from the N.E. for two years without accident. It was thought that an improvement might be effected in carrying out stone breakwaters by means of timber staging, by constructing a permanent stage, carefully put together for the whole length of the intended works, and loading it with rubble stone, so as to form for a time a breakwater in itself. The stage should be sufficiently strong to carry machinery capable of lifting and transporting masses of masonry, constructed on shore, of 25 or 30 tons in weight, and of depositing them on the stone face work continuously, and progressing along its whole length instead of from the end merely.

It was remarked that the estuary of Blyth was similar to that of the Mersey, admitting a large quantity of tidal or back-water. Originally, during N.E. gales, there was no protection to vessels entering the tortuous channel leading to the harbour, and numerous wrecks took place upon the sands to the eastward; while in S.E. gales vessels went upon the ridge of rocks. The breakwater had acted as a guiding-wall to the current, and a straight channel had been dredged out; an additional depth of 2 feet of water had been attained, and vessels were sheltered immediately on entering. So far therefore the structure was successful, and had answered the purposes required.

It was stated that in 1814 the late Mr. Rennie made a report upon the harbour of Blyth, in which he proposed the erection of a stone breakwater, in a similar direction to that now under construction, and also to widen and deepen the entrance channel, jetties being intended to be carried out from the south shore to preserve the channel. The estimated expense of these works was £47,079, or for the pier alone £38,015, being at the rate of £9. 5*s.* per foot; whilst the present pier was stated to have cost £10 per foot; so that no great pecuniary advantage had been gained by the adoption of the system of timber and stone combined. This mode of construction was by no means so novel as it appeared to be considered, for it would be found described in the works of Vauban, Belidor, Sganzin, and other French writers. It had also been carried into effect at Dunkirk, Calais, Boulogne, Dieppe, and other places on the French coast, where there was no means of getting other materials. It was thought that this system could not be applied with propriety to deep water sections; and it was mentioned that several extensive works had already been executed in stone at about £70 per foot. For example, at Kingstown Harbour about 9500 lineal feet of pier were executed at £73 per foot, in a depth of water of from 12 feet to 27 feet at low water spring tides, with a rise of tide of from 8 to 16 feet. Again at Howth, where in 1812 the *pierre perdue* system was first used it was believed in this country, the quay walls and parapet cost only £71 per foot. The Plymouth Breakwater, which was built in a depth of 7 fathoms of low water spring tides, cost £294 per foot, including the masonry, which was expensive; but that was an instance of an isolated breakwater, to which all the materials had to be conveyed a distance of nearly seven miles in sailing vessels, and at a time when the machinery and plant for executing works of such magnitude were not so perfect as at the present day.

It was observed that the cost of the Holyhead breakwater had been about £160 per foot, not £200 per foot as given in the Paper. It was urged that it was impossible to come to a conclusion that any one system of breakwater could be universally adopted; and indeed in no branch of engineering was there one material or one mode of construction proper to be employed under all circumstances. With regard to the particular system under discussion, it was remarked that there was nothing new in the design; for wooden piles, with or without stone thrown behind them, had been generally used where no better material could be afforded. In the United States twenty years ago, with the exception of a single graving dock at Boston, it was believed that there were no walls either of docks, quays, or piers, that were not so constructed. It was thought that loose stones requiring the support of the timber to keep them together, would not stand in such rough seas as the breakwaters at Holyhead, Portland, and other places were exposed to; and if that part of the structure was only intended as a nucleus for a permanent stone masonry structure, from which to build stone walls in water 70 feet in depth, then it was much questioned whether there would be any economy in construction.

In reference to comparisons of the cost of different breakwaters it was remarked, that the cost of a wooden structure in one place could not fairly be contrasted with the outlay incurred in another situation, under totally different circumstances, and on entirely dissimilar works. Great care was required even in contrasting the cost of stone breakwaters in different places; for the rock in one case might be much harder, more difficult to quarry, and more expensive to carry than in another.

It was contended that in the construction of breakwaters the objects for which they were required were not sufficiently kept in view; and that unnecessary labour and expense were incurred in rearing a superstructure which was not at all necessary It frequently happened that the parapet, by opposing a barrier to the waves, caused the water to fall on the platform within, and to disturb and destroy the work.

It was remarked that to execute a structure of the kind described in the Paper, in a depth of water of 60 feet, it would be necessary that the timber frames should be upwards of 80 feet in height. Judging from the difficulty of placing single piles in position in a less depth of water, it was argued that the setting up of each frame with precision in a rapid tideway, which generally prevailed round the head of a breakwater in progress, would be a matter of considerable difficulty. It was doubted whether the manœuvring of such large masses of buoyant material could be accomplished with advantage, even where it was practicable. It was thought that where there was only a small base of rubble it was preferable to float the material to the spot, as had been done at Alderney, rather than to adopt the method of depositing it from a stage. For executing the superstructure it had been proposed to introduce intermediate frames resting on rubble. Supposing the rubble to sink, which it undoubtedly would do to some extent, then either the intermediate frames would receive no support from the substratum, and they must be held in suspension by the main frames; or, on the other hand, if they were sustained by the rubble the continuity and rigid attachment of the timber framing could no longer exist. In either case a portion of the strength which seemed to be anticipated would be lost. Hence it was believed that before the superstructure could be proceeded with the main frames would have to be cut away, so as to present an equally yielding base for the superstructure to rest upon. The relative advantages of timber and stone for these works were then commented upon; and it was thought that although the first cost might be reduced by using the former material, yet it would scarcely ever be adopted where heavy seas had to be resisted. Again, if the dimensions of the timber were increased so as to withstand heavy seas, the system would be much more expensive than had been stated. It should also be remembered that although timber and rubble stone might be cheaper per cubic foot than stone alone, yet the advantages were not so great when the comparison was made by weight.

It was remarked that the subject of the Harbours of Refuge,

Digitized by Google

independently of the mechanical and engineering part of the question, was of vast importance in a national point of view, whether as relating to the necessary protection of the commercial marine, or as connected with the naval defences of the kingdom. In order to rendering clear the points to be touched upon, it had been necessary to examine those formidable and not very lively documents, the Parliamentary Blue Books, and they confirmed the opinion, that all these great works were being executed without any efficient responsible supervision or control; and that not only the public and the representatives of the nation, but also the government itself, had been utterly in the dark as to proceedings relative to them. The time had now arrived when these matters should be brought before the bar of public opinion, and as it was almost impossible to induce a dispassionate examination of the subject elsewhere, the Institution of Civil Engineers appeared to be the most fitting arena for the discussion of the question.

The mechanical portion of the subject was first briefly alluded to by reference to the reports of the several committees on Harbours of Refuge, commencing with that of 1845; which, though not absolutely the first, was that which first actually examined into the most important points. On the question of the recommendation of upright or of sloping walls, in spite of the aid given by scientific and practical men, the committee differed so widely that a supplementary report was published, exhibiting the opinions of the dissidents from the first Blue Book. Now it was submitted that this difference of opinion had chiefly arisen from not having arrived at a clear understanding of the terms used, and of the basis of the various arguments employed.

It would not be necessary now to re-open the question of the theory of the waves of oscillation and of translation. It was admitted that in the case of a pure wave of oscillation, the upright wall would receive the least amount of actual impact; and that the wave would be reflected from the surface at a corresponding angle to that at which it impinged; but when that wave became a wave of translation, the upright wall was the worst form that could be adopted, as it would be struck with the utmost accumulated force of the sea.

In applying these and other views to practical cases it must be assumed that the facts were derived from the Blue Book, which however, like the Queen's Speeches, appeared to contain everything except the specific information sought from them.

Now, in looking at the plans of the works as given in these parliamentary documents, the section of the breakwater at Alderney appeared to be of the worst possible form. There was a slope or berm below low water, then a slope of 1 in 7, and then a perpendicular wall; it was contended that upon this combination of forms the effect of the waves would be most pernicious.

When there was to be a vertical wall, the slope should be so placed as to exhaust the force of the waves before they reached the superposed upright wall: this was judicious, and it was evidence of the correctness of the doctrine, that the form of section of sea walls should depend upon local circumstances, and should be fixed by the practical judgment of the engineer. At Dover a slope would not be practicable, as there were only soft materials at command, whereas at Holyhead and at Portland there was abundance of hard material, and it was evident that in these latter positions slopes of *pierre perdue* were the proper kind of works to be executed, as they were less expensive, and required the exercise of less engineering and mechanical skill than upright walls. These latter were doubtless expensive works, and it was contended that if they could not be constructed at a less expense than the pier at Dover, which was said to be costing £415 per lineal foot, such structures must be abandoned. At the present rate of progress the projected Harbour of Refuge at Dover would scarcely be completed in less than one hundred years, and at an outlay of £5,000,000. But the actual cost would not be represented by that amount, as if the interest of that sum was spread over the hundred years consumed in the progress of the work, it would with the principal amount to £40,000,000. Supposing then that our ancestors had commenced this harbour at Dover in 1759, what would have been its utility as a work of military defence during the past continental struggles, and would not £40,000,000 be much more usefully employed in reduction of the National Debt than in a work of doubtful utility either for the commercial marine or for the navy? If such works must occupy even fifty years, they had better not be commenced at all, as by the time they were completed the perils they were intended to guard against would have passed away. The great object then must be to devise some other and simpler system of construction for works of this kind; and it was a question whether some such plan of breakwater as those of which drawings and models were exhibited by Mr. Hays, Mr. Brunlees, or Mr. Johnson, could not be adopted with advantage; those systems appeared to consist of iron piles, founded upon Mitchell's screws, and bearing a sheathing of close or open timbers, against which the waves would impinge. The system appeared to possess certain merits, and, under peculiar circumstances and in properly selected localities, could probably be made available, as a considerable length could be put down in a short space of time; and in the hands of experienced engineers such a mode of construction might be rendered available for reducing the present enormous cost of piers and works intended for the protection of shipping. With the diving-bell and helmet, and the Nautilus and other available means of securing the putting down of any kind of iron piles, it would appear easy, if these works were thrown open to the engineering skill of the country, to find the means of executing them with much greater rapidity and at considerably less cost than at present.

Reverting to the Blue Books, they would be found to reveal many things which were not generally even surmised. To the report of 1845 there was appended the signature of Mr. James Walker, past president of the Institution. That report stated, that the cost of breakwaters, whether constructed of *pierre perdue* or built as upright walls, would be nearly identical. Now, as a commentary on that statement, it must be observed, as far as a Blue Book fact could be received, that the pier at Dover had cost £415 per foot, and that at Portland less than half that sum. It was further stated that the works at Dover were to cost £2,500,000; those at Seaford, £1,250,000; at Portland, £500,000; and at Harwich, £60,000. Of these four works so recommended, three had been commenced, and two of them had been entrusted to Mr. James Walker, himself one of the commissioners.

The facts respecting Dover appeared to be, that the first contract was for 800 feet extending from the shore, at a cost of £234,000, or £290 per lineal foot; and the renewed contract in 1854 was for 1000 feet, at £415,000, or £415 per lineal foot, and to be completed in 1864. It must be assumed that Parliament sanctioned that work, ordered it to be proceeded with, and voted the money, on the report of the commissioners; yet in 1858, on some of the members of a committee of the House expressing surprise at the slow progress of the work, and asking Mr. Walker this question—"Was it known, at the time it was decided to make the works at Dover, that it would take half a century to make them?"—he replied, "I do not suppose it was. I do not think any idea was formed at the time as to the cost, or the mode in which it should be done." Hence it might be assumed that works were authorised, and the money of the country was voted away by the government, without any idea being given of the time of construction or of the cost of such works, nor even of the mode of their execution. Now mark the result at Dover: about £400,000 had already been expended, and yet it was at times nearly impracticable to effect the landing at low water of the passengers from the small steamers arriving from Calais, until the outward-bound steamer had left. This inadequate result, after such expenditure, was not creditable to the administrative skill of the government of the country.

At Portland the original approximate estimate was £500,000, which for the rough stone alone was extended to £558,000. It was however discovered subsequently that the mass of stone must be wider and deeper, and therefore the cost was increased to £932,000; and it was stated that this addition was caused by an error of 7 ft. 6 in. in the depths, which had been determined by soundings taken by one of Her Majesty's surveying ships, which had been specially deputed to make a chart of Portland Bay. Why an error of this kind—involving an expense of £95,000—had been passed over without any public notice, remained to be explained by the department of the government which was responsible for it.

Considerable discrepancy of opinion appeared to exist with respect to the value of convict labour, which it should be remarked was more extensively employed at Portland than at any other place. Nearly all the stone used in the works was quarried by convicts; it was then taken by the contractor, hauled to the top of the self-acting inclined planes (supplied by the government), and was tipped into the sea vertically from a stage erected by the contractor, who had merely to dispose of the material supplied to him by the convicts. It would at the first view have appeared easy to estimate the value of the material, and to charge it against

Digitized by Google

the works executed. This however did not appear to be done. It was averred in the Blue Books relating to the management of prisons, that the criminal establishment at Portland was self supporting, inasmuch as the labour of the convicts was profitably employed in the harbour works. On the other hand it was stated, in the Blue Book relative to the harbours of refuge, that this labour did "not save one shilling in the work." Now between these two statements there was a manifest discrepancy, which should be explained, as it was evident that the £30,000 to £50,000 annually expended on the convict establishment at Portland should produce something. The prison authorities said that the establishment cost the country next to nothing, whilst the Admiralty contended that the harbour works upon which the convicts were employed were as costly as if free labour had been employed. Now it appeared that both were a little wrong; the Inspector of Prisons might perhaps attach more value to the convict labour than properly belonged to it,—but it was absurd to say that the quarried stone, delivered on the tramway ready for deposit by the contractor, was valueless. Indeed it might be safely contended that the £930,000, representing the ultimate cost of the Portland works, would eventually be increased to £1,500,000 when the convict labour and the interest of the money was taken into calculation.

It apppeared from the Blue Books that the cost of the stone, receiving it ready quarried, and lowering it by inclined planes erected at the cost of the government, and tipping it into the sea, amounted to between three and four shillings per ton. Now this price appeared excessive as compared to the cost of similar works in other positions, and it induced the conviction that if the whole work had been opened to free and open competition, it would have been done at a less cost to the country.

Alluding to the design of the Portland breakwater it was observed that an opening of between 300 feet and 400 feet wide had been left at a certain distance from the shore, in such a position as to admit of heavy seas rolling in, to the detriment of the anchorage ground in the harbour, whilst from its position it was manifestly useless for sailing vessels either entering or leaving, and could only afford an advantage of three or four minutes even to steam vessels. Besides this opening required elaborately constructed pier-heads, which as specimens of work reflected the highest credit on all who were connected with the breakwater; but they had cost nearly £100,000, which was a heavy cost for a doubtful advantage. Moreover in any future repairs of the breakwater this opening would be found to be a source of much inconvenience as well as of extra cost.

The Harbour of Refuge of Alderney, which was estimated to cost £1,300,000, had been placed in a situation where it was nearly valueless, as all shipping carefully avoided that part of the channel.

The works of St. Katherine's Bay, Guernsey, which were shown by the Blue Books to have cost £300,000, were even if possible still less useful, as if a vessel would avoid Alderney it would certainly not go near to Guernsey. The works were now stopped, and after all the expenditure there was scarcely shelter for a few oyster boats.

The parliamentary returns were nearly silent with respect to Holyhead. It appeared, however, that the original estimate had been £600,000; but the expenditure up to the present time was £930,000. The utility of this work was undoubted; it was in the right place, and the government had at last wisely placed it under excellent and judicious management. There was, however, an unfortunate error in the original design of the work; the piers having been built concave in plan instead of convex towards the sea; thus making an angle in the construction which was very prejudicial; and it was evident that if the plan had been originally well considered nearly 200 acres more of harbour space would have been obtained at the same cost. In fine, it appeared that but little hopes could be entertained of more rational proceeding on the part of government so long as commissions were constituted as at present. The few members of acknowledged independence were swamped by other members determined by foregone conclusions, and the schemes proposed by certain parties, were by some "hocus pocus" generally recommended. It was evident that no person should be placed upon such commissions who was pledged to any system whatever; nor should the execution of any work be confined to any member of a commission by whom that work had been recommended. There were many modes of carrying out these views, and if a better and more equitable method was adopted the best professional ability and the greatest executive skill would be secured to the manifest advantage of the country.

This subject was one which well merited the attention of some independent member of the House of Commons, who might do good service to the country by pertinaciously attacking and exposing the present objectionable system of executing all government works.

It was explained that the superstructure at Portland, which was only commenced on the pier connected with the shore, was founded at the level of low water. It would have been better if the work had been commenced at 12 feet or 15 feet below low water.

As to open competition for government works, the works at Portland had been submitted to six of the most eminent contractors in the kingdom.

What had been stated in the evidence in the Blue Books was, that it was difficult to determine whether any absolute money-saving resulted from the employment of convicts upon such works as those at Portland. Now, however, from a combination of circumstances there was reason to believe that convict labour was rendered commercially advantageous. There were, however, advantages attending the useful employment of the convicts which could not be estimated commercially;—the industrial and moral training to which they were subjected during their period of forced labour tended to their reformation, and towards restoring them to society as useful men instead of outcasts. Thus if the cost per lineal foot of the Portland breakwater should be actually as great as that of another breakwater executed by free labour, there was still the advantage of the reformatory instruction and training given to the convicts.

It should be observed that in the construction of a breakwater in an exposed situation the cost would, in a great degree, depend upon the time the work was in execution, because in heavy weather the sea risk was greatly increased, when the quantity of stone tipped was limited by the want of facilities; whereas, with the extensive means afforded by a long staging, such as had been created at Portland, the quantity of material deposited could be almost unlimited, and it could be done so rapidly as to diminish the sea risk.

The opening in the breakwater which had been alluded to was decided upon by the commission on Harbours of Refuge of 1845. The object was evidently to afford facilities to ships leaving the harbour during northerly winds; and hitherto no ill effect had been felt in the harbour from the admission of any heavy seas by that opening.

With respect to the plan of the pier at Holyhead, it was explained that when the harbour was first projected a strong and successful pressure was brought to bear, by the Liverpool interest, against the formation of a port in that locality; and small area only was therefore ordered to be enclosed. It was now found that this area was too small, and further works were imperatively demanded, which could only be joined on to the old pier, by an extension in the direction that had been shown; and if there was an apparent error in the plan it must not be attributed to the late Mr. Rendel, by whom the works were designed.

It was explained that this had not been intended; but what was the use of the controlling nautical authorities, who were so active upon all commissions, if they permitted such grievous errors of design simply because an outcry was raised by interested parties from another locality? These nautical authorities were not always so impressionable by just representations; and if they could not independently determine the requisite area of a new harbour, it might with propriety be asked of what utility were they as members of commissions?

As to the employment of convict labour at Portland the discrepancy between the statements of the two departments of government had not been explained, and an annual sum of nearly £50,000 disappeared in some unaccountable way without any satisfactory reasons being rendered. Neither were the beneficial effects of the moral and industrial training admitted, as the testimony of the warders of the convict establishment showed that real reformation was very rarely induced in any of the prisoners.

It was explained, with regard to the works at Alderney, that the section of the pier was exactly that which was so strongly advocated; the vertical wall was founded at 12 feet below low water of spring tides.

As to Jersey, that place was at one time considered to be the most important of all the harbours in the Channel Islands; but some change of opinion appeared to have occurred, as the government had only authorised the construction of one arm of the

Digitized by Google

breakwater, and had neglected the other. The harbour was thus in such an unfinished and exposed condition that no vessel would go into it.

As to Dover the expenditure was given in lump sums in all the Blue Books, and the amounts now quoted as the cost per lineal foot were not correct, inasmuch as the gross sum embraced the cost of the landing jetties and other things which should not be included in making a comparative estimate of that work, and contrasting it with others.

Before the plan of the Dover works was decided upon the evidence of several eminent civil engineers was taken; the direction was then confided to Mr. Walker; and application for tenders for the execution of the work was made to six or more of the most eminent contractors, to one of whom it was let for a gross sum.

The breakwater at Dover could scarcely be contrasted with any other work, as at present it was essentially only a landing pier; although it would eventually form part of a harbour of refuge. The mode of construction was different to other works, as, owing to the absence of hard material in the neighbourhood, it had been necessary to resort to the use of concrete blocks formed of cement and shingle. The result had been perfectly successful, as not a crack appeared in the walls, although the foundation was not good. The time actually occupied in executing the present length of pier was not any criterion of what could be done; at present a certain annual amount was ordered to be expended, for which so much work was executed, but at least double that quantity could be executed if the necessary funds were voted for the purpose.

It was mentioned that the béton system had been first introduced by M. Poirel in 1838, at Algiers. It had been tried there on a large scale, and had since been adopted at the new port of La Jolliette, at Marseilles. Where no better materials could be got, it was thought worthy of the consideration of engineers; but as regarded cost, it was believed the price of béton would be found to vary from ten to twenty-two francs and upwards per cubic metre, according to the quality. This was nearly four times as costly as some of the inexpensive stone breakwaters already alluded to, where the material was at hand, and was readily obtainable—at a cost in the work of from three shillings to four shillings per cubic yard. In these cases the great expense of staging was saved by forming the breakwater like a railway embankment, and using the embankment itself as the stage from which to "tip" the material. Then as the work advanced the sea caused the materials to assume that inclination at which they would stand. This was spoken of as the simplest, the cheapest, and the best mode of forming a breakwater run out from the shore.

In reference to the remarks which had been made as to the harbour at Jersey, it was stated that by the original design it was to have been formed on the opposite side of the island, by excavating or indenting the land for the purpose, as had been done at Cherbourg. If that plan had been carried out, a useful work would have been obtained at less cost than the present harbour.

With regard to a report that it was probable parliament would be recommended to authorise the expenditure of about three millions sterling in the construction of harbours of refuge, it was remarked that that amount distributed over the coasts of the United Kingdom was so limited, that the cheapest plan of construction, combined with efficiency, must necessarily be selected. It was on this ground that a framework of carpentry filled in with rubble stone had been mainly advocated; and it had been estimated that such a structure could be executed in deep water for 70*l.* or 80*l.* per foot. But, on the other hand, it was thought a bold assertion to say that this system was a good substitute for the stonework of the old school, for in all probability the first rough sea it had to encounter would destroy it; and as far as economy was concerned, many stone breakwaters had been constructed at even less cost, where facility for obtaining materials had formed an element, as it always should do, in the determination of the site for the breakwater.

In allusion to a remark as to the probable disintegration of the béton blocks, it was stated that experiments instituted in consequence of a failure at St. Malo had proved that all rich limes mixed with sand and pozzuolano failed in salt water, though they succeeded in fresh water. Therefore, since 1852, the French engineers had used hydraulic limes exclusively in all sea works, and no failure had taken place. With reference to a statement that the works at Marseilles were not so exposed as similar works in many other places, and that therefore no fair conclusion could be arrived at as to the general applicability of béton blocks, it was mentioned that a large fort at Rochfort, in the Bay of Biscay, had been founded in 1802-3, on such blocks, 33 tons in weight, that they had remained perfectly stationary, and did not now exhibit any signs of disintegration. The breakwater at Cherbourg might be cited as an illustration of rapidity of execution in an exposed bay. The first cone was sunk in 1751, and the last in 1788—the distance between the two being 2 miles 3 furlongs. In the first seven years the whole of that length was brought up to within 4 feet of low-water mark. The cost, including the pay of the seamen and soldiers employed, was about 300*l.* per lineal yard. The additions to the superstructure, made since 1832, brought up the total cost to 433*l.* per lineal yard, and including the central battery to 658*l.* per lineal yard. This formed a striking contrast to the cost of the works at Dover, which it was found from the parliamentary returns had amounted at first to 800*l.* per lineal yard, and in a depth of 7½ fathoms to as much as 1245*l.* per lineal yard.

It was remarked that it would be interesting to ascertain the difference between the first cost of that portion of the pier at Blyth which had been built of stone alone, and that which had been constructed of timber and stone combined. In sea works the slopes should be uniform, so as not to expose a number of angles to the wash of the sea. This principle had been kept in view in the sea embankments in Morecambe Bay, where the walls throughout were at a uniform angle with the foreshore, and at such a slope, that the receding wave instead of falling directly upon the toe of the wall, as would have been the case if the wall had been vertical, was modified to such an extent that the toe was easily protected and suffered no injury.

Allusion was made to a pier which had recently been sent out to the River Plate. The piles were formed of four angle irons bolted together and fitted with Mitchell's screws. The girders were 18 feet in length, for convenience of shipping. When the materials arrived they had only to be fitted and bolted together, and the structure was complete.

A description was given of a breakwater constructed for the South Australian Government at Port Elliott, Encounter Bay, about five years back. The work was carried out from the base of a headland of granite, blocks of stone from 2 to 7 tons in weight being quarried and tipped down. As the work advanced, lines of rails were laid down on the top of the embankment, and the whole was finished at once to its full height. The blocks took their own natural slope, which was found to be about 2 horizontal to 1 vertical. About 100 lineal yards were completed in rather less than two years. The top of the breakwater was 21 feet wide, and 5 feet above high-water mark. It was carried into a depth of 2 fathoms at low water, with a rise of tide of 5 feet. This work had stood perfectly well, though exposed to the full strength of the sea from the open Southern Ocean, and to a perpendicular lift of sea of 14 or 15 feet. The principle and construction of an iron breakwater, semicircular in plan, and 240 feet in length, designed by Mr. Hays, to protect the head of a landing pier at Holdfast Bay, near Adelaide, were then described. It was observed that this form of structure was equally applicable as a breakwater for harbours of refuge. The portion designed to resist the sea extended from a height of 6 feet above high water to 12 feet below low water. It consisted of a series of parallel plates of wrought-iron, inclined at an angle towards the waves, and at distances of about 1 foot apart. These plates were firmly bolted together, and were supported upon wrought-iron (Mitchell's) screw piles. The angle of the plates was intended to be such, as to be as nearly as possible in the plane of the motion of the water, by which the structure itself would be almost entirely relieved of the shock of the sea. It was thought that such a breakwater would be cheap in construction, rapid in execution, and would permit the free flow of the tidal currents, so as to avoid the risk of setting or stopping the travel of shingle.

It was remarked that the power of the timber breakwater, described in the paper, to resist the force of a deep sea wave, depended upon two points: the absolute stability of the work, and the force of the wave which it had to withstand. A consideration of the mechanism of waves, on which depended the correctness of the form of breakwater, seemed to show that the sections for deep water had less force to resist than those for shallow water; and the opinion was advanced, that the force of the waves at

Digitized by Google

Holyhead was created by the breakwater itself, and that it would not be so much felt in deep water. The case of a solitary wave of translation, travelling along a channel of uniform section throughout, was first considered. It was shown that the facility of the propagation of the pressure increased as the square root of the depth,—that the velocity of the forward motion of the particles under the crest of the wave was to the velocity of the wave as the height of the wave was to the whole depth, measured from the crest,—and that the momenta of the several columns as regarded forward motion, was the same as if the volume of the wave was moving forwards with the velocity of the wave. It was manifest, that since the momentum in all cases was the same, and since destructive energy varied as the mass in motion multiplied by the square of the velocity, that the destructive energy of a large volume was less than that of a small one. When a wave met a sloping bottom the velocity was retarded, and the wave rose and became shorter; consequently the number of particles in motion was less, and the distance moved through and their velocity were greater. This increase in height and of motion continued until a point was attained when the motion of the particles was equal to the velocity of the wave. It then curled over and broke, when the maximum of the destructive force was attained. When there was an artificial foreshore in front of a breakwater it must cause the wave to break, and the force which was innocuous became extremely powerful. The waves of the sea were however oscillating waves, consisting of a succession of waves instead of a solitary one. If the force of a wave of translation in deep water was small compared with what it might become if converted by a sloping foreshore into a breaker, it followed that the force of an oscillating wave must be still less. It was found that a wave rose considerably above its own height against a vertical face; the total height to which it rose being the measure of the pressure exerted upon the wall. In support of the truth of these principles the breakwater at Alderney was referred to. The first wall consisted of large stones as they came from the quarry, built with a batter of 9 inches to a foot, and founded about low-water mark on a foreshore sloping downwards from that point. A length of 200 feet of that wall having been swept away, it became necessary to reconsider the design. The new work, of which a length of from 600 to 700 feet had been constructed prior to the storm of November 1850, was founded 12 feet below low water. The foreshore was carried down from that point to a distance of upwards of 100 feet, at a slope of 7 to 1; and having then reached 15 feet below low water, it dropped at the natural slope of 1 to 1. The rise of the tide was 17 feet, and the wall was 25 feet above high water. In the great storm the waves were observed to curl over above the parapet, and to break upon the wall with considerable force. The stone was hard quartz grit, that in the foreshore being sharp and angular, and so great was the action of the sea, that the stones became rounded and smooth, and the face of the wall was polished. From these remarks, it was concluded that the perpendicular wall from the bottom was the true form for breakwaters, and that the forms proposed in the paper were based upon correct principles.

In reply to the remarks of the different speakers, it was observed that the proposed system of construction differed materially from the wooden piers described as having been erected in the river Wear seventy years ago. The carcases, in the latter case, were said to be loaded with large stones, whereas the Blyth section was not a box, but a framework entirely open at the ends and bottom, and partly at the sides; it had, therefore, no power to float stones. It was also submitted, that in deep water or even in shallow water, with an irregular rocky bottom, it would be impossible to carry out the system of carcases. All however that was claimed in the proposed system, was an improvement in the mode of construction, although it was believed that a similar work had never been described nor constructed before; certainly it was quite different from the caissons carried out at Genoa. With regard to the cones at Cherbourg being identical, it was impossible to imagine anything more dissimilar, for the cones were entirely isolated at intervals of several hundred feet; whereas one leading advantage of the proposed system was the continuity of face, whereby every part of the work received support from the neighbouring portions. No doubt wooden piles, with or without stone thrown behind them, had been used in this country and elsewhere, but that system was only applicable to moderate depths. But piles were not intended to be used, for they were inapplicable in a hard rocky bottom and for great depths. As to the assumed difficulty of erecting the frames, it was stated that when set up on end they were not like a mass of timber floating loosely, as they rested on the bottom by their own weight and had no floating power, a great part of the mass being above the water. Attention was then directed to the difference between the action of the sea in shallow and in deep water. In the former the waves necessarily broke on the work, whereas in deep water, and with nearly vertical faces, the waves did not break. If therefore any given work would resist the impact of the waves in shallow water, it would be much more likely to do so in deep water. At Blyth a comparatively fragile work had withstood the full force of the waves of the German Ocean; and to show the power of the sea there, it had been known to move a stone 9 tons in weight, and to lift a stone 3½ tons in weight up a perpendicular face 4 feet high.

As to the objection that the stability of the intermediate frames might be affected by the settlement of the rubble bank, it was remarked that the bank was deposited and allowed to settle before the frames were erected. When the frames were placed, the stonework was only carried up to the under side of the cross ties; and even should any settlement take place afterwards, the lower tie being a chain was not affected by it, and it could not affect the uprights. When this hearting had become consolidated, the upper part of the work was filled with stone, and dry walls were built along each cross tie, so as to prevent any settlement of the superincumbent stone from injuring them. With reference to the proposed plan of breakwaters with upright walls to be constructed of large masses of concrete, it was remarked that the parapet had been altogether omitted. The parapet might be dispensed with in such a case as Plymouth, where the sea was broken by the long sloping foreshore, and therefore entered the harbour as broken water; but with such a section as that described, the mass of the wave would go right over the supposed breakwater into the harbour. In regard to the cost of the Portland breakwater, if the preliminary expense of 80,000*l.* or 90,000*l.* were distributed over the whole intended work, being a length of 8000 feet, instead of over the 5907 feet already completed, that would only reduce the cost given in the paper by 4*l.* per foot run. As to the employment of convicts involving a larger plant, it was observed that the only part of the plant affected would be that used in the quarries, being but a small part of the whole, and the cost of which would not amount to above a few pounds per foot of the work.

The proposed system had been explained generally, and the principles upon which it was based stated, without those details being entered into which might require to be modified to suit particular localities. It appeared to have been overlooked that the timber system had been advocated as the backbone of a permanent stone structure. Viewed in this light, a comparison was instituted between two breakwaters, identical in form, in external dimensions, in material, and in prices; the one constructed under the most improved of the existing systems, and the other under the new system. It was found, that for a length of 2000 yards in a depth of 52 feet of water, the former would cost 718,934*l.*, and occupy twenty-one years in construction: whilst the latter would only cost 538,622*l.*, supposing the creosoted timber to last twenty years, or 600,585*l.* if the timber only endured ten years, and would afford the same amount and kind of shelter in five years. The progress of the ordinary stone breakwaters was limited by the time required for the erection of the superstructure, as the rubble bank could always be formed with sufficient rapidity. Under the new system a harbour would be enclosed in five years, instead of in twenty or twenty-one years on the old system; and the timber breakwater would afford great facilities for the construction of the faces, as there would be no current to contend with, and the work might be proceeded with at many different points at the same time, instead of being confined to one spot.

JOSEPH LOCKE, Esq., M.P., President, in the chair.

Feb. 8.—The Paper read was "*On the Performance of the Screw Steamship Sahel, fitted with Du Trembley's Combined Vapour Engine; and of the sister-ship Oasis, with Steam Engines worked Expansively, and provided with Partial Surface Condensation.*" By JAMES W. JAMESON.

Before proceeding with the main object of the Paper, which was to record the results obtained during twelve voyages of each

Digitized by Google

ship, made for the purpose of testing the comparative value of the two systems, the author gave a brief description of the Combined Vapour Engine. The principle of this engine was based upon the fact that the condensation of a liquid, such as water boiling at a high temperature, might be effected by surrounding an external condenser with a liquid such as ether boiling at a low temperature. Thus the condensation of the vapour of the one might be made the means of generating the vapour of the other; and a useful effect might be obtained from the heat given out in condensation. The engine up to a certain point resembles an ordinary steam engine with surface condensation, except that the surface of the vessel called the vapouriser, which was also the condenser of the steam, was surrounded by ether instead of water. The heat evolved by the condensing steam generated ether vapour. This vapour accumulated in the upper part of the vapouriser, and was conveyed from thence to a cylinder fitted with a piston, &c. precisely like an ordinary steam cylinder, in which the ether vapour exerted its force. From this it was conveyed to another external condenser, where it was condensed by means of cold water, and was then returned to an air-vessel, in which any air that might have entered was separated from the ether. From this vessel it again passed to the vapouriser, in which it condensed fresh volumes of steam, and was once more turned into vapour. In a steam-boat with a pair of engines, one would be worked with steam in the ordinary way, and the other with the vapour of ether. The vapourisers and condensers were composed of a number of elliptical copper tubes fixed into brass tube-plates. The tubes were generally 5 feet in length, $\frac{1}{25}$th of an inch in thickness, and the bore was a flat ellipse, measuring 1 inch by $\frac{1}{4}$ of an inch. These tubes M. Du Trembley preferred to have drawn solid, without any brazed joint or other seam. The tubes, after having had their ends tinned, were placed in the mould for the tube plate, and the molten metal was then run round them, by which a very tight joint was made between the ends of the tubes and the plates. Groups of these tubes, properly fastened together, were placed vertically in a cast-iron case, in which the exhaust steam was introduced, so as to surround the outside of the tubes. The liquid ether to be boiled off and to condense the steam was placed within the tubes, arrangements being made above the top tube-plate to collect the vapour, and prevent its mixing with the steam that surrounded the exterior of the tubes. The condenser was nearly similar to the vapouriser, except that the tubes were placed horizontally, and were curved slightly upwards in the middle, so that the ether obtained from the condensation of the vapour might readily escape from the tubes.

The author then succinctly alluded to the experiments made by Mr. Rennie, on board the ship Du Trembley, in the year 1853, which led to the application of the system in two new ships, the France and the Brésil, of 300 nominal horse power, belonging to the Compagnie de Navigation Mixte, of the port of Marseilles. These vessels performed an uninterrupted service for upwards of eighteen months between Marseilles and Kamiesh, during the Crimean war; and were so favourably reported upon by M. Meissonier, Ingénieur des Mines, and M. Gouin, Ingénieur des Ponts et Chaussées, that it was determined to apply the system to seven new ships. Ultimately however, in consequence of the burning of the ship France in the port of Bahia, and owing to the failure of the Brazilian line of steamers, after three voyages, the system was only applied to three ships on the African line. These vessels were the Sahel, Zouave, and Kabyle, of 825 tons displacement, and 180 nominal horse-power. About the same time the Compagnie Franco-Americaine having made some incomplete and unsuccessful trials of ether engines, in the ships Jacquard and Francois Arago, gave up the system. These two engines were then arranged to work by steam alone, the tubular apparatus being made use of for surface condensers. It was said that by this arrangement such favourable results were obtained, as to compensate for the suppression of the ether. All these circumstances combined, induced the two companies to engage the services of M. Moreau to conduct a series of experiments to determine the relative economy of the two systems. In his report he endeavoured to prove, that although in the combined engine a consumption of 880 lbs. of ordinary Cardiff coal and 2·16 pints of ether per hour had produced 439·6 indicated horse-power, or 2 lbs. per I.H.P. per hour, yet a result almost equal to this might be obtained from engines of the same dimensions by employing steam of the same pressure as in the combined engines, and by using a diminished introduction, a greater expansion, and surface condensers. Subsequent experiments corroborated the results arrived at by M. Moreau, as to the consumption of fuel; but in a reply to that report, the accuracy of his reasoning and calculations was disputed. The directors of the Compagnie de Navigation Mixte, however, determined that the plan proposed by M. Moreau should be carried out in the ships Oasis and Marabout, also belonging to the African line; and this had enabled the present comparison to be made.

The engines and boilers of the two ships, Sahel and Oasis, as well as the hulls, were identical, except that the boilers of the latter had about one-third more heating surface. The voyages, twelve in number, were perfectly similar in all respects, and occupied eight months, during which time about 14,000 miles were run by each ship. During the experiments the mean indicated power was found to be 405 H.P. in the Sahel, and 273 H.P. in the Oasis and the Marabout. In the former the total consumption of coal taken on board was 3·1 lb. per I.H.P. per hour, and in the latter 7·12 lb. per I.H.P. per hour—that of the Oasis being 7·5 lb., and of the Marabout 6·75 lb. These rates of consumption were obtained by dividing the total amount of coal used on board for all purposes by the actual number of hours under way. They, therefore, include the quantity consumed in getting up the steam, as well as that used for cooking, &c. The rate of consumption was also affected by the inferior quality of the fuel frequently used, by the considerable waste, and by the great number of hours under steam compared to the hours under way. These rates, though high, did not exceed the usual rates for ships in the port of Marseilles, fitted with direct acting engines of the same power. The most economical results obtained in any of that class were those of the ship Avenir, belonging to the same company, in which the consumption of fuel, measured in the same way, was 5·4 lb. per I.H.P. per hour. This agreed very nearly with the account given of the Scotia, Anglia, and Cambria mail boats running between Kingstown and Holyhead, in which the consumption was stated to be 5·3 lb. per I.H.P. per hour. Reference was also made to Professor Rankine's experiments on board the Admiral, fitted with double cylinder engines, in which the consumption was said to be $2\frac{1}{2}\frac{8}{0}$ lb. per I.H.P. per hour, or nearly fifty per cent. more than that of the Kabyle, as determined by M. Moreau. Also, to some experiments on board the Algesiras, a French ship of the line, of 2414 I.H.P., when it was found that with the full pressure of the steam the consumption was 3·74 lb. per I.H.P. per hour, and with the steam cut off at one-third of the stroke 3·6 lb. per I.H.P. per hour. The author believed that the ordinary consumption of fuel in marine engines was above 6 lb. per I.H.P. per hour; that comparatively few worked so low as 5 lb., and none under $4\frac{1}{2}$ lb., taking the gross consumption for a whole year.

An examination of the tabular records of the experiments made with the two ships Sahel and Oasis, gave the following results in favour of the combined vapour engines. First, a weight and space available for 50 additional tons of cargo, or an increase of one-sixth; secondly, a diminution in the consumption of fuel of 40 per cent.; and thirdly, an increase of one-ninth in the speed of the ship. The attendant disadvantages were, the first cost of the apparatus, the difficulty of condensing the ether during very hot weather, the losses arising from leaks which occurred from time to time in the vapouriser, and the expense and danger of the liquid employed necessitating constant care and a more efficient engineer than an ordinary steam-engine. Still, notwithstanding all these inconveniences, the actual saving was such as to merit attention. The additional expense required to fit the Sahel with a combined engine instead of a common steam-engine would not exceed £4000. Such a ship on the African line could accomplish from twenty to twenty-four voyages per annum, or run from 20,000 to 24,000 miles, and economise, as compared to the Oasis, 1000 tons of coal, of the value of £1600. From this would have to be deducted the value of the ether consumed, say £409, and £400 as a sinking fund to pay off the extra expenses incurred, or together £809, leaving a net economy of £791. But to this must be added the profits arising from the additional cargo capable of being carried; this could not be estimated at less than £700, so that there resulted a net economy of £1491, a sum more than sufficient to pay an interest of 6 per cent. per annum on the capital required to purchase such a ship.

The number of accidents which had occurred during five years' experience had been but three. The first happened on board the ship France, when lying in the port of Messina. This arose from an escape of ether, caused by a workman having trodden upon and broken a weak copper pipe under the bilge water, and

Digitized by Google

which was therefore out of sight. The ether having accumulated in the engine-room, was accidentally ignited, when a great flame filled the engine-room and extinguished itself in a few moments without producing any disorder, or leaving any trace of the fire. The second accident, which caused one death, occurred on board the ship Brésil, when in the dry dock at Marseilles. This accident was also occasioned by a workman entering the engine-room with a naked light, against express orders, and setting fire to the gases of the ether floating in the room, the vapouriser being open at the time for cleaning. The third accident was the most serious, and the most fatal to the development of the system. This was the burning of the ship France, in the port of Bahia, before alluded to. It was now well known that this had been caused by discharging at night a number of cases containing ether, not belonging to the provision of the ship. One of the cases was broken, the liquid spread, and ignited at one of the lanterns, setting fire to the hold, at some distance from the engine-room. Thus, these accidents all occurred when the engines were not at work, when the fires were extinguished, and the ships were in port. No accident had happened to the ships while at sea, and no extra insurance had ever been paid on the ships on account of their containing ether, even after the burning of the ship France.

In conclusion it was remarked, that the difficulty of condensing the ether would not take place in latitudes where there was not an excessively high temperature, nor if a liquid with a higher point of ebullition was employed. The occasional leakage of the vapouriser was a purely practical defect, which would, no doubt, be easily remedied. As therefore a great economy of fuel had been shown to result from the combined system, it remained to be seen whether the inconveniences mentioned were such as to limit its general extension. It was thought possible that a cheap, non-inflammable liquid might be discovered, and that the cost of the apparatus might be still further reduced; as experiments made by Mr. Bramwell seemed to lead to the belief, that the surface of the vapouriser might be considerably decreased. The extensive scale on which the system had already been employed, and the favourable manner in which it had been reported upon by different engineers, was the author's reason for bringing the subject under the notice of the members. M. Du Trembley was most anxious that his invention should be better known to English engineers, in the hope that they would co-operate in removing the existing defects, and in rendering its application more certain and practicable.

THE PALACE OF THE PEOPLE, MUSWELL HILL, HORNSEY.

A project is on foot, having the sanction of many influential names, for erecting, in the most elevated and beautiful suburb of the metropolis north of the Thames, a building akin to that which adorns its southern vicinity, at Sydenham, and with a similar purpose in view,—the instruction and amusement of the masses. It is proposed to be placed within a short distance of the Hornsey railway station, on the Great Northern line; it will thus be easily accessible from all parts of London, while from its position it will command an extensive and beautiful prospect in every direction, as well as forming in itself an ornamental object in the landscape, The estate at Muswell Hill, comprising more than 450 acres of land, has been secured, and, after reserving all the land required for the palace and grounds, about 300 acres it is calculated will remain, to be available in other ways.

The designs for the building itself are at present on private view, but will doubtless shortly be made more public. They have been prepared by Mr. Owen Jones, the architect who was engaged, among others, on the Exhibition building of 1851; as well as on the palace at Sydenham. The drawings are complete in every respect, and, including the general plans and that of the site, occupy eighteen large sheets. Of the prevailing character it will be sufficient to explain that it resembles that of the building last mentioned, modified of course to suit avowedly the present requirements. In the centre of the building is a dome of 200 feet internal and 210 feet external diameter, springing at a level of 36 feet from the floor below, which is 12 feet above the general level of the building: it rises between four towers, and its parts are connected by galleries. The square block thus formed is 276 feet on each side, and is flanked by two naves, each with a clear area of 336 feet by 120, with side-aisles 72 feet wide. The ends of the building are 264 feet by 48; and, in continuation, are two semicircular colonnades, 120 feet in diameter within and 296 feet without: these it is intended to devote as refreshment courts. The extreme length of the building is 1296 feet; its greatest width, 492; the total area covered is—

	Feet.
On the ground floor	511,038
On the gallery floor	138,816
On the upper floor	91,008
	740,862

Galleries, 48 feet wide, run round the dome and naves; also across the ends: with upper galleries round the dome and at the two extremities of the building. The fall of the ground allows of an additional story, 48 feet wide, being contrived in the basement of the south side, which corresponds with the level of the railway station on the north side.

The central dome is intended to be appropriated to a winter garden, and the two naves are to be devoted respectively to a permanent exhibition of the works of industry and objects of commerce, and to those arts and sciences which direct and embellish the productions of industry. The area of each nave is divided by two main arteries, each 24 feet wide. In the centre of the industrial nave may be placed machinery in motion, and, on either side, fixed machinery, agricultural implements, and raw products; whilst in the galleries may be arranged the varied results of machinery aiding man in converting these products to his use.

In the fine art nave the various schools of art may be fully illustrated; and, in the galleries, divisions allotted to illustrations of mathematics, astronomy, physics, biology, &c.

To carry out more fully the plan of instruction, a lecture room has been provided, near the centre of the building. Its diameter is 216 feet; it is surrounded by corridors 24 feet wide, communicating with three sides of the building, and is calculated to hold 10,000 persons. Beneath the platform on which the lecture theatre stands is a railway station, in which passengers would arrive under cover, and ascend to the ground floor of the building.

The carrying out of this desirable scheme is proposed to be undertaken by a company, and in its aid the sympathy of the public is invited; the projectors, in their preliminary announcement, expressing their confidence "that an institution of so comprehensive and useful a nature, and accessible to so large a portion of the population of the United Kingdom, cannot fail to enlist the support of all those who are friendly to the cause of national education, and the healthful recreation of the people."

REVIEW.

The Year-Book of Facts in Science and Art. By JOHN TIMBS, F.S.A.—London: Kent & Co.

It is seldom one meets with so matter-of-fact a man as Mr. Timbs, or one who has the rare skill of detaching from the commonplace occurrences of life such portions as are of solid and permanent interest. His long connection with the literary world renders him a mine of information in himself, and one every way fitted to expatiate to others on "things not generally known." 'The Year Book of Facts,' edited by him, and which has now attained its twenty-first volume, is an additional proof of his researches and zeal in his favourite pursuit. It is replete with information gleaned from a variety of sources, and collated with great care, so that in a little book of less than 300 pages may be traced a useful epitome of all that has transpired during the past twelvemonths in the arena of science and art. The general heads under which these particulars are classified are:—Mechanical and Useful Arts, Natural Philosophy, Electrical Science, Chemical Science, Natural History (subdivided into Zoology and Botany), Geology and Mineralogy, Astronomical and Meteorological Phenomena. To these is appended a brief obituary list, with which the volume concludes.

On dipping into its pages we of course recognise many subjects which, either *in extenso* or in the quoted form in which they here meet our eye, have already found a place in our own volume in the mechanical and engineering section—this is particularly noticeable; we are induced, however, to copy the example, and, for the

Digitized by Google

benefit of our readers, borrow in return. The nature of the work does not admit, of course, the introduction of discussional subjects in general, and the articles themselves are necessarily varied and brief:

NEW BRIDGE, CHELSEA.

"This new bridge, connecting Chelsea with Battersea, was designed by Mr. Page, and is on the suspension principle. At the site chosen the Thames is 737 feet in width. The river is spanned by three spaces, the central being 352 feet between the piers, and the side ones 173 ft. 6 in. each; the two piers in the river are 19 feet wide each by a length of 86 ft. 6 in. The height of the caissons of the piers above Trinity high-water level is 7 ft. 6 in. Above the level of the top of the caissons the piers are surmounted by towers, constructed principally of iron. They diminish in plan to 9 ft. 8 in. by 4 ft. 2 in. at top, the whole being surrounded by a cradlework of cast-iron, upon which the rollers of the saddles work that carry the suspensory chains. Below the caissons the ironwork spreads out at the bottom on bed-plates, that rest upon York stone landings, below which are piles and concrete supports. Externally the whole of the piers are covered with an ornamental casing of ironwork. The point of contact of the suspensory chains on the towers is at an altitude of 51 ft. 8 in. above high-water mark; and the top of the finials that terminate the towers is 88 ft. 6 in. from the same level. The abutments of the bridge, both on the Chelsea and Battersea sides of the river, have each 'a relieving arch' in the centre, which serves the purpose of distributing the weight uniformly, the space between the arch and abutment being filled with concrete. The abutments as well as the piers rest firmly upon piles, which have been driven 20 feet beyond low-water mark. There are also piles driven at an angle in front of the mooring chamber as an extra security. The roadway and overhanging footways of the bridge are embedded in asphalte on a ground or foundation of cork and bitumen asphalte. On each side of the carriage-way is placed a tram for the heavy traffic. A very large amount of additional strength is obtained over the ordinary mode of construction that has hitherto been adopted in the formation of suspension-bridges, by the introduction of two longitudinal lattice girders of wrought-iron, one of which is inserted on each side, and separate the roadway from the foot-paths. At each end of the bridge are picturesque lodges, octangular in plan, the roofs covered with Portland cement, and their angles and summits adorned with appropriate terminations in terra-cotta. The four towers that rise over the caissons and piers in the river are highly picturesque in form, and are entirely constructed of iron, except 18 feet of their upper portions at top, which are of moulded copper, which is gilded and painted to resemble light-coloured bronze. The summits of the towers are crowned with globular lamps."

VICTORIA BRIDGE, CANADA.

"Although the Britannia-bridge represented the most scientific distribution of material which could be devised at the date of its construction, it has since been improved upon by the same engineer in the Victoria-bridge, now in the course of construction across the river St. Lawrence, near Montreal. The Victoria-bridge is, without exception, the greatest work of the kind in the world. For gigantic proportions and vast length and strength there is nothing to compare with it in ancient or modern times. The entire bridge, with its approaches, is only about 60 yards short of 2 miles. It is five times longer than the Britannia-bridge across the Menai Straits, seven-and-a-half times longer than Waterloo-bridge, and more than ten time longer than the new Chelsea-bridge across the Thames! The Victoria has not less than 24 spans of 242 feet each, and one great central span—itself an immense bridge—of 330 feet. The road is carried within iron tubes 60 feet above the level of the St. Lawrence, which runs beneath at a speed of about 10 miles an hour, and in winter brings down the ice of some 2000 miles of lakes and upper rivers, with their numerous tributaries. The weight of iron in the tubes will be upwards of 10,000 tons, supported on massive stone piers each of solid masonry. So gigantic a work, involving so heavy an expenditure, has not been projected without sufficient cause. The Grand Trunk Railway of Canada—one of the greatest national enterprises ever entered on—is upwards of 1100 miles in length, opening up a vast extent of fertile territory for the purposes of future immigration, and by connecting the settled provinces of Western Canada with the seaboard states of the American Union, calculated to afford full scope for the development of the industrial resources of that magnificent colony. Without the Victoria-bridge the system of communication would have been manifestly incomplete; the extensive series of Canadian railways on the north side of the St. Lawrence, terminating opposite Montreal, would, for all purposes of through traffic, be virtually sealed up during the six months of the year that the St. Lawrence is closed against navigation by the ice, and the Grand Trunk system must necessarily have remained to a great extent nugatory, in consequence of the province being cut off from the coast, to which the commerce of Canada naturally tends."

GRAND TRUNK RAILWAY OF CANADA.

"Messrs. Peto, Brassey, and Betts, the contractors for the Victoria-bridge at Montreal, belonging to this company, have progressed during the past summer at a rate that gives hope they may be able to open it for traffic in October 1859, instead of on the 1st of January 1860, in accordance with the terms of their last contract. It is estimated that if these two or three months can be gained, they will probably make a difference in the receipts of the company for the second half-year of 1859 of from 70,000*l.* to 80,000*l.* The number of hands at the work on the 1st of October 1858, was 3231, apportioned as follows:—fitters and smiths, 153; riveters and platers, 121; carpenters, 280; masons and stonecutters, 326; painters, 19; labourers, 1331; raftsmen, 49; boys, 75; crews of steamers and barges, 450; men employed at the Canada works, Birkenhead, in the construction of tubes, 477. There were also employed on the bridge 142 horses. The bridge consists of twenty-four spans of 242 feet each, and one in the centre of the river of 330 feet. The spans are approached on each side of the river by a causeway, each terminating in an abutment of solid masonry 240 feet long and 90 feet wide. The causeway from the north bank is 1400 feet long, that from the south bank is 700 feet long."

BRITISH RAILWAYS.

"At the present moment we learn, from returns recently published, that we have in this country alone 9500 miles of railway executed and in actual operation; and taking, at a rough calculation, one locomotive engine with a force of 200-horse power to every 3 miles of railway, and assuming each to run 120 miles a day, we thence calculate the distance travelled over by railway trains to be equal to 380,000 miles per diem, or the enormous distance of 138 millions of miles per annum, a space measuring the distance of the planets, and beyond the conception of those unacquainted with figures. To transport engines and trains this distance requires a force equivalent to that of upwards of 200,000 horses in constant operation throughout the year."

PREVENTING DOWN DRAUGHTS IN CHIMNEYS.

"Mr. H. Wetherell, of Upper Chapman-street, St. George's East, has patented a singular but very efficient apparatus for the above purpose. It consists of a valve and valve-seat made and acting as hereafter described. He fits a seat in metal or other suitable material at any desired height in a chimney or flue, and above the seat suspends a ball filled with some gas lighter than the atmospheric air. The ball offers no impediment to the passage upwards of smoke, vitiated air, or any other ascending current; but any descending current is effectually stopped by the valve, which is thereby forced down on to its seat."

HYDRAULIC CEMENTS.

"A Paper on this subject has been submitted to the Paris Academy of Sciences by M. F. Kuhlmann, showing the advantages to be derived from the combination of silicates with mortars and cements in general, and especially with those that are intended to resist the action of sea-water. It is well known that the first effect of water on cements is that of forming hydrates; after which a gradual contraction takes place, producing a degree of hardness, which increases in proportion as the contraction is slower, and there is more silex or alumina in the cement. Now, M. Kuhlmann has observed that if alumina or its silicate, or else magnesia, whether caustic or carbonated, be kneaded into a paste with a solution of silicate of potash or soda, the compounds resulting therefrom will bear a perfect resemblance to the natural silicates, such as feldspar, talcous slate, magnesite, &c., and will by repose and slow contraction become hard and semi-transparent, resisting in a high degree the corrosive effects of water. If slaked lime be added to the said compounds they acquire the properties of hydraulic cements. M. Vicat, jun., having shown that calcined magnesia added to a cement would resist the action of

Gt James St Bedford Row

Digitized by Google

sulphate of magnesia, M. Kuhlmann has endeavoured to turn this observation to account by mixing calcined dolomites (which contain magnesia) with mortar, with the addition of alkaline silicates. This composition he finds very advantageous, since most of the salts contained in sea water must contribute towards the preservation of such cements. In fact the chloride of magnesium, as well as the sulphate of magnesia, will be decomposed and form a layer of silicate of magnesia on the surface of the cement; in the same manner the sulphate of lime must, being in contact with the silicate of potash or soda, form a silicate of lime; and all these silicates strongly resist the action of sea-water. As for sea-salt, which is a chloride of sodium, M. Kuhlmann proves that in the proportion in which it exists in sea-water it will slowly decompose the silicate of potash contained in the cement, and leave the silex free. The compositions proposed have therefore the singular property, not only of resisting the corrosive qualities of sea-water, but of actually becoming more insoluble the longer they are in contact with it. A cement composed of 30 parts of rich lime, 50 of sand, 15 of uncalcined clay, and 5 of powdered silicate of potash is recommended by M. Kuhlmann as having all the requisite hydraulic properties, especially for cisterns intended for spring-water. In marine constructions care should be taken to add an excess of silicate to those portions of cement which are exposed to the immediate contact of the sea."

Among subjects less within our own province, we may direct attention to those upon the Atlantic Telegraph, the Electric Telegraph Improvements, the great Solar Eclipse of last March, and Donati's Comet.

BUILDING AND SCULPTURE MATERIALS IN NEW SOUTH WALES.

There was a time when, judging merely from the barren soil and the brittle sandstone about Sydney, even the geologists of England thought that there was not a particle of any useful mineral in the whole of the Australian continent. Still, marble has been worked in New South Wales ever since the year 1832, by Mr. Clewitt. The red, black, white, and yellow varieties were especially praised by Mr. Clewitt, but they formed merely subordinate strata in the slate and wacke formation of the Razor-back Mountain, about thirty miles south of Sydney. As we proceed further south primitive formations make their appearance, and there are mountains of primitive (crystallised) limestone on Mereno Downs, near an acidulated cold spring, discovered in 1834. Here slabs of every size of this Australian Carrara marble will be ready for the statuary and architect as soon as a railway will connect these fertile downs with Twofold Bay, and as soon as that bay will have the necessary commodities for shipping. White Houses and Capitols may then be built, which will astonish the traveller—not to be matched, probably, in any other part of the world.

In some of the mountain tiers which stretch into the Downs of Mereno (being extensive plains of various shapes), and which bear vestiges of volcanic action, materials for high architectural ornamentation and statuary of surprising beauty and extent are to be met with. Here the finest syenite, serpentine, and porphyry cheer the sight of the traveller, and remind him of the fact that even in these hitherto unwrought and neglected wilds the germs of a future high civilization and a high pitch of art are laid. Speaking commercially, a huge slab or column of serpentine, porphyry, or syenite will change what might have been ballast hitherto into a rather valuable cargo.

Plunging further south into the heights of the Australian Alps, granites of all colours and granulation are to be met with, some flesh-red ones, resembling those of Egypt; and it may be soon the case that the hitherto log huts of the wealthier squatters and sheepowners may be changed into cottages built of granite—a very economical building material when labour is not too dear, as many of the houses, even in the outskirts of Rio de Janeiro, are built of that material.

There has been purchased, some years ago, a collection of Australian rocks by the trustees of the British Museum, where all the before-mentioned rocks are to be met with.

CHURCH OF ST. MARY TOLMERS, HERTFORDSHIRE.

(With an Engraving.)

This church is situated near the village of Newgate-street, and stands on the estate of Thomas Mills, Esq., M.P., by whom it was first erected, and has recently been greatly enlarged and improved. The west front, tower, transepts, and vestry are entirely new, and the old portions of the church have been faced with stone, and made in other respects to correspond with the new portions.

The ceiling has been removed, and diagonal boarding on the back of the rafters substituted. The roof is stained and varnished. The benches are all of wainscot, and of good design, and the pulpit of stone, elaborately carved. The effect of the interior is greatly heightened by the windows, which are filled with stained glass, by Messrs. Gibbs, of London, consisting for the most part of subjects from Scripture history. There is also a fine organ, built by Mr. Walker, in a case appropriately designed and executed in wainscot. The tower doorway forms the main entrance to the church, the floor being composed of Maw's tesselated pavement, specially designed for this purpose. In the upper portion of tower there is one bell. The boundary wall is of stone, surmounted by an iron cresting, relieved by gilding, the gates being of oak.

So complete is the restoration that the church has the appearance of being an entirely new building. It is in the Early English style, and gives additional attraction to a locality which naturally has many charms.

The outlay has been about £2800, and the works have been admirably executed by Messrs. Dove, Brothers, of Islington, under the superintendence of the architects, Messrs. Lander and Bedells, who have also carried out the works in connection with the schools, mansion, and buildings adjoining.

ON DESIGN IN INTERIOR ARCHITECTURE.*

By Sydney Smirke, A.R.A.

Last year I had the honour of addressing to you some remarks on the subject of form as it affects design in exterior architecture. I propose now to submit to you the result of my experience and reflections on design in interior architecture. These two subjects readily admit of separate consideration, and, indeed, almost demand it; for the aim and purposes, as well as the means, of the designer in each case are widely different. In determining the external features of a building, we have to consider, besides the character of the building itself, various collateral circumstances, such as the nature of the site, the character of the surrounding scenery, and the aspect of the architecture with which our work may be associated; and it is the contours or bounding out lines of the building we design that in great measure determine its effect. It is far otherwise with internal architecture: there we may disregard any collateral circumstances, and are enabled to limit attention to the individual character of our subject.

In designing the interior architecture of a building, there arises, however, a new and peculiar source of difficulty. Considerations of convenience come in to embarrass our pencil and to complicate our difficulties. Architectural effect and fitness of arrangement will often militate most inopportunely against each other. We must needs have a door, perhaps, exactly where we would fain have had solid masonry; and light, perhaps, can only be obtained from the east, whilst æsthetic considerations urge us to prefer the west. In fact, to reconcile these two important yet often incongruous objects, forms one of the severest trials of architectural skill.

The art of conveniently arranging the various parts of a plan so as to fully adapt them to their special purpose, is truly one of primary importance to the architect. It is indeed an obvious truth, that unless our plan be such as to afford a convenient collocation of its several compartments, and unless these compartments themselves are well adapted to their respective purposes, all the rest of our labour and our art will be idly and wastefully expended. To lay down a good plan, therefore, becomes the first duty of an architect, and demands his first and most earnest attention.

* Lecture delivered at the Royal Academy.

Digitized by Google

It is not, however, on an occasion like the present that this subject of a convenient arrangement of a plan can be entered upon with advantage. Such a consideration is too technical for our present purpose, and comprehends too wide a range of subject for the time at our disposal. I will, therefore, on this point confine myself to the general observation, that simplicity and directness are cardinal virtues in all architectural arrangements. Avenues should be as straight, as short, and as obvious in their course as possible. The rules for the moral conduct of a man are very applicable to this branch of our art: his ways should be clear and obvious; free from ambiguity and uncertainty,—without tortuous or dark places. When a turn is necessary, let it be one which cannot be mistaken. There should be no seeking for the way in or out.

The first impression on entering any building should be such as is becoming its special purpose. The temenos of a Greek temple was well calculated to give an impressive air of sanctity to the temple itself, by excluding from view all incongruous and mean objects; enhancing, too, the architectural effect of the façade by surrounding it with suitable accessories.

A similar feeling, perhaps, led the early architects of Christendom to form that peculiar forecourt or atrium in front of the haos, of which but few examples now remain, although probably this atrium was an essential part of every Early Christian church. The basilicas of San Ambrogio, at Milan, and of S. Clemente, at Rome, are very interesting and nearly complete examples. There can be little doubt that the builders of that devote age were influenced by subjective considerations of this kind, although the ritual appropriation of this portion of the building was to receive the catechumens of the church, and to afford a suitable and becoming place wherein the candidates for baptism might present themselves. At all events, a very powerful effect must have been produced upon the eye and mind by thus shutting off from view the outer world, and concentrating attention on the more sacred structure about to be entered.

It was, perhaps, a similar motive—a legitimate artifice for the purpose of strongly impressing the mind of the worshipper—that led our old church builders usually to form their doorways of very moderate dimensions. Great emphasis was ordinarily given to the western, and often to the lateral doors, by exterior decorations, and by recessed and gabled porches, often rising to a height of great grandeur; but the actual opening of the doorway will generally be found comparatively low. The natural effect of this is to produce, as it were, a surprise, and by the contrast to make more impressive the extent and loftiness of the structure within.

Turning to domestic architecture, we shall not fail to recognise the efforts made by the early Italian architects, in designing the entrance-halls of their noble palazzi, to secure the benefit of a favourable first impression. At Venice, especially, these halls are of large dimensions, and are treated in a broad and grandiose style, sparing of mere surface ornament, but usually embellished with ancestral statues and warlike trophies; of which one of the most striking, as well as the most frequent, are the gigantic bronze lanterns taken from an enemy's galley.

Beyond the entrance-hall of domestic buildings in Italy we sometimes meet with those inner halls, which, perhaps, owe their origin to the example set by Palladio in his well-known Villa Capri, where a central hall of large size and graceful proportions gives means of communication with all the principal apartments, itself sufficiently removed from the exterior to admit of being used as a saloon of general domestic resort; a happy idea, that was alike productive of beauty and convenience, not only in the land of its birth, but in the interior arrangement of many of our own country residences.

On turning to the ground plans of some of our own princely structures, we shall perceive how largely English architects availed themselves of this feature of Palladian art. Somewhat analogous to these inner halls are the cortili, which form so usual and so graceful a feature in Italian palazzi. These cortili may probably be regarded as lineally descended from the central peristyle of the Romans, which, as we see at Pompeii, formed the ordinary place of resort for the residents and visitors, as well as being a means of general communication with the adjacent apartments. The cloisters of conventual buildings were also, apparently, an amplification of the same idea, and may claim a similar descent, although used not as a forecourt like the atrium of a basilica, but rather as a collateral adjunct, well adapted alike for exercise and for contemplation. Whatever the phase of art, whatever the mode of treatment—whether arcaded, whether columnar, or both—these enclosures afforded occasions for most picturesque and pleasing designs. At those interesting remains of Roman magnificence, called the Villa of Mecænas, at Tivoli, we find a remarkable instance of the union of an arcade and colonnade, forming a cloistered ambulatory; and examples such as this became the parent of a host of beautiful arrangements in after times, by which the greatest possible amount of variety of outline and *chiaroscuro* was obtained.

We must proceed now to an important feature in the plan of every structure of moderate height destined for man's occupation,—I mean the staircase.

In the design of this often very picturesque feature, it must be admitted that we owe but little to any examples of antiquity. In temples, staircases of ample size were obviously not required; but I am unable to cite any instances of an internal staircase of striking effect or dimensions in even any Classical remains. Magnificent flights of steps no doubt occur in exterior architecture, and in Belli's 'Description of the Greek Theatres of Crete,' translated by my able friend Mr. Falkener, as well as in other examples, we see evidences of the existence of double returning flights of stairs, similar to those in frequent use in modern architecture, having each flight enclosed within solid walls, and setting us an example of sound and solid construction, well worthy of careful study in the execution of our own public buildings. The newel stair, so characteristic a feature in the plans of a subsequent age, was certainly of purely Greek origin.

A perfect example exists, in good preservation, among the ruined temples at Selimentum. Its dimensions, however, are small; the diameter of the circle which contains it being but 6 ft. 4 in.,—dimensions which were subsequently greatly exceeded in the similar spiral stairs within the monumental columns of ancient Rome. The domestic architecture of Rome seems to have required little aid from interior stairs; and even in so sumptuous a building as the Coliseum, where many thousands of spectators had to be provided with ready means of access to very high levels—a building, too, erected when Roman power and art were in their zenith, expressly to gratify the extravagant love of splendour and display which characterised the Roman people—we find no indication of any fine staircase. Among the buildings which remain to us of the earlier middle ages, it is still difficult to point to any notably fine stairs. Highly effective flights, no doubt, occur; striking examples occur at Assisi and at the cathedral in Lucca, where flights of stairs 7 or 8 feet wide occur, with marble balustrading, sufficing to show that mediæval builders were, to some extent, alive to the fine effects attainable by the artistic treatment of this portion of their plan.

Still, these examples are of rare occurrence. It will be difficult to refer to any case in this country of equal importance to that in the cathedral close at Canterbury. The newel stairs, of which so many examples remain, as at Dover Castle and Tamworth church—the latter presenting, I believe, an almost singular example of a double spiral stair round one newel—were certainly the most usual form of stairs in buildings, even of the most important character, during the whole middle age period; so much so, indeed, that the detached turrets which contained these newel stairs became one among the most prominent features of domestic architecture throughout Europe during that period. It is needless to point out the numerous examples that everywhere remain, but I would say that perhaps no city contains more remarkable ones than that so rich in scenic effects, viz., Nuremberg. Wherever this turretted staircase occurs, it always constitutes a pleasing and striking object, imparting an agreeable variety of outline to the architectural composition. As peaceful arts advanced and men ceased to look for security in embattled buildings, the artistic eye of the builder soon perceived the opportunities that were afforded by interior flights of stairs for pleasing and pictorial effects. Nor could he be insensible to the extreme inconvenience of a newel staircase which, whatever its width, can necessarily offer but one place where the treads and risers are of proportions at all convenient to persons ascending or descending. In the quiet times of the later Tudors, staircases in this country began to assume their proper position and character; and there is no part of our old Elizabethan mansions on which the builders seemed to have dwelt with more pleasure, or on which they were more wont to exercise their fancy, than the staircase.

But whilst those fantastic works were in course of erection which we see at Crew Hall, Hatfield, and many other places, the

Digitized by Google

more polished artists of Italy were erecting staircases of magnificent proportions and bold character, although of a totally different aspect. This is a phenomenon of art well worthy of observation. At the very time when those rude and sometimes grotesque works were being executed here, to which I have been alluding, there existed in that land of art staircases designed by the great Italian masters which were consummate models of grace and refinement, like that at St. Georgia, in Venice, by our great master Palladio. From these our Elizabethan and Jacobean works differed as widely as these latter did from the works of their English predecessors. The genius of each people is well typified in this diversity. Broad, bold, irregular, and unrefined, —such were the characteristics of the one school; whilst the staircases contemporaneously erected by the other school were grave, symmetrical, and extremely simple, although of much bolder dimensions.

I am well aware that the study of this contrast may lead different minds to very different conclusions. The picturesque and quaint exuberance of our own old manner of desiguing the balustrading, for example, seems calculated to win the admiration of the mere painter more readily, perhaps, than the plainer and more sober balustrades of the Italians; while a different feeling may prevail in the colder temperament, which is forced, as it were, on the architect by the very nature of his profession, working as he does not on canvas, but in solid masonry.

That this more simple and less ambitious character of balustrading was affected by mediæval architects of the best period, as well as by the architects of the Palladian age, is a fact that may lead us to the conclusion that, much as we may admire, we must as architects be slow to imitate the pictorial wantonness of design prevalent in the sixteenth and seventeenth centuries in this country.

As time advanced, the sobriety of manner which distinguished Italian architecture in the fifteenth and earlier part of the sixteenth century gave way, and staircases began to be designed in a capricious and fantastic manner. An excess of freedom and a wonderful power of execution led to the erection of staircases that are fit rather for the study of the scene-painter than for that of the architect. Greatness of dimensions, however, was a merit to which all were alive, and we accordingly find in Italy staircases of a size sometimes almost extravagant. The staircase in the Albergo dei Poveri, at Genoa, is 115 ft. by 63 ft.; and that in the Royal Palace at Naples is no less than 163 ft. by 85 ft.

The Renaissance school, of which we are treating, employed two very different types of staircases, each perhaps equally susceptible of beauty. One wherein both ends of the steps are inserted into and supported between two walls, as at the Cretan theatres already named; the other, where only one end of the steps was inserted into the walls, the opposite end simply resting on a wall or other sufficient support. As notable and familiar examples of the first type, I might point to the principal staircases at Versailles, Fontainebleau, and the Louvre, and to a host of Italian examples which it would be superfluous to enumerate. This form of stairs is capable of great dignity, as well as of great beauty, but it has some inherent inconveniences. The raking soffit of each flight is a source of difficulty in design, and gives rise to some unpleasing appearances: it is wanting in lightness and freedom of effect, and is open to this practical objection— that persons ascending and descending do not see each other until they abruptly meet on the landing. The staircases of the second type are, on the other hand, far more free and open, and the eye expatiates over the whole area of the staircase at once. It is needless to multiply examples of this latter familiar form. The elegant work of Palladio at Venice, already named, and the stupendous staircase already referred to at Naples, are well known illustrations of this type.

I might add perhaps, as a third variety of staircase, those wherein there is no turn, and where the stairs extend in a continuous straight line,—a form of plan by no means to be recommended, except where the height to be attained is very moderate, or where the width of the staircase is of the most ample kind, as at the Royal Library at Munich. The Scala Regia, in the Papal Palace at Rome must however be admitted to be an example presenting an extremely striking architectural scene. The proportions are colossal, and the flight is flanked on either side by a stately colonnade. The effect of this staircase is artfully heightened by a very peculiar expedient, which, as far as I know, is without a precedent. The flanking walls of this staircase are not parallel, but gradually and imperceptibly approach each other, the width at one (the lower) end being 10 feet more than at the other. The result of this is, by an illusion, to prolong the perspective, and to increase the apparent length of the colonnade to the view of a person approaching the state apartments—an architectural fraud, ingenious it may be admitted, but which I cannot recommend to your imitation.

It is, I think, to the second type of staircase that I would point as that which most deserves your attention. Schenkel's great work, the museum at Berlin, affords a favourable illustration of it; and a still more colossal staircase at the same museum has been recently executed by Stüler. The dimensions on the plan are about 140 ft. by 70 ft.; the walls affording, of course, a vast expanse of surface for the frescoes of Kaulbach and others. Munich also furnishes various fine examples, which the architectural student will do well to observe.

The principal error to avoid in these great open staircases is any appearance of tediousness in mounting. It should never be overlooked that the great, indeed the sole, object of a staircase is to facilitate our way upwards or downwards, and no display of architecture will reconcile us to any unreasonable amount of manifest indirectness in our upward or downward course. Those large, straggling, tedious stairs, up which we are occasionally obliged to travel, interrupted by perpetual landings,—and which, by following in their turnings all the four sides of the staircase, seem to lead us in any direction rather than that we desire to take,—are at once unsightly and inconvenient.

Before I quit the subject of staircases, I desire to commend to your observation and study the opportunities that a simple flight of even a few steps afford of producing an agreeable effect. It would be easy to multiply illustrations, but I will confine myself to two or three very simple instances occurring in that land of art—Italy. At the entrance into the Ospedale dei Incurabili, at Genoa, some local circumstances imposed on the architect the adoption of a very indirect line, the public street not being at right angles with the direct line of access to the interior of the hospital. So far from submitting to this awkwardness as a necessary evil with ignominious resignation, the architect struggled successfully to overcome the difficulty, and to give an apparent, although he was unable to give a real, symmetry to the plan, by the somewhat picturesque arrangement shown in the drawing.

To descend to a still humbler illustration, I would adduce an instance which I chanced to observe in a small and very unpretending house at Bologna. In a straight passage of moderate width it was necessary to rise 4 or 5 feet. The most convenient place for the steps required for this purpose was in the middle of the passage. The natural course for an uninventive mind would have been to adopt the very plain and prosaic course of placing so many parallel steps in a row, and so to get the passenger up and onwards in the simplest and most inartificial way. But such a mode of proceeding would ill accord with the æsthetic views of an Italian artist of the sixteenth or seventeenth century. He broke his flight of ten steps into two flights of five steps by a landing, with a short piece of ornamental parapet on either side, and thus not only gave these few steps a positively ornamental effect, but really assisted the passer both up and down, by affording a means of intermediate support.

I cannot refrain from pointing to a third example of a like nature, which attracted my notice at a convent in Rome. Bernini, who was its author, belonged no doubt to a debased school, but he was an artist of excessive boldness, and indeed vigour; his principal aim seemed to be to avoid insipidity at any cost. In this little work he entailed, it is true, upon all succeeding ages, as long as his staircase may be used, a constant and never-failing source of inconvenience. But he achieved his great object of avoiding the abhorred simplicity of a straight flight, and produced a highly pictorial effect with very small means and within a small compass. Do not imagine that, in pointing out to you this example, I am advising you to follow it: but such instances are suggestive, and we may frequently observe that in contrivances of this nature, insignificant and unobtrusive though they be, a really inventive talent displays itself.

(To be concluded in our next.)

The Royal Albert Bridge, Saltash.—Mr. Brunel's bridge crossing the Tamar is completed, and the first locomotive passed over it on the 26th ult. It is anticipated that the Cornwall Railway will be open for traffic by the end of April next.

THE MEDALS OF THE ROYAL INSTITUTE OF BRITISH ARCHITECTS.

At a special meeting of the Institute, held on the 14th ult., the royal medal for the year 1858 was awarded to Mr. G. G. Scott, subject to her Majesty's sanction.

The silver medal of the Institute was awarded to a critical essay on the Architecture and Genius of Sir Christopher Wren, under the motto "*In Memoriam.*" This is at present anonymous.

The Institute medal, with five guineas, for the best illustrations of a Mediæval building in Ireland, Scotland, or Wales, was awarded to Mr. Edward Hughes, of Chester,—motto, "Caer Lleon,"—for a restoration of Kilmallock Abbey. To Mr. D. Paton Low, for restoration of Torphichin Queer, Linlithgowshire, honourable mention.

The Soane medallion, for a design for a circus for equestrian performances, to Mr. Thomas Vaughan, junior,—motto, "Hope for the future gave energy to the past."

The student's prize (books) to Mr. W. T. Sams, for design for a riding-house.

NOTES OF THE MONTH.

Dry Dock, Port Louis, Mauritius.—'The Overland Commercial Gazette,' Port Louis, Mauritius, 27th Dec. 1858, contains the following, which we extract:—We have the satisfaction of announcing that to facilitate the recently established mail service between this Port, Australia, and the mother country, the Mauritius Dock Company, have commenced the excavations for a vast dry dock, to afford every facility for repairing such noble vessels as we shall have calling shortly at our port (Port Louis). The size of the dock is to be 350 feet long, 80 feet extreme breadth, 60 mean and 40 feet minimum breadth, depth 22 feet: in fact, capable of easily taking in such magnificent vessels as the Duke of Wellington, of 3756 tons, length 278 feet, length of keel for tonnage 202 feet, depth of hold 24 feet, breadth 62 feet. H.M. steam frigate Mersey, length 336½ feet, length of keel for tonnage 254 feet, breadth 52 feet, burthen 3726 tons. H.M.S. "Boscawen," which was lately here, is 2212 tons, length 213 feet; such a vessel would appear like a longboat in the new dock. The most important fact is, that merchant ships of all sizes can be taken into dock and immediately repaired. The pumping machinery is being constructed by Messrs. Gwynne and Co., engineers, London, whose names stand so favourably before the public. Engines of 100 horse power will work three centrifugal pumps, *each* discharging 12,000 gallons of water per minute; and the dock when full containing 13,000 tons of water, will be emptied in 2½ hours. Besides these pumps, a smaller one worked by a separate engine will keep the dock dry during repairs to vessels. The company have in addition, a forge and every appliance for the repairs of iron vessels,—this fact cannot be too widely known. The contractors have engaged to finish the excavations in a year, but nine months will probably suffice for the reception of vessels.

New Theatre Scribe, Turin.—This new theatre has been built after the plan of M. Bollot, and is said to be a model in its way. The building consists of four tiers of boxes, all furnished with a saloon, to the number of 100. The theatre thus forms a semicircle, topped by a gallery, which, like the pit, can contain 400 persons, the whole theatre accommodating 1600 persons. The fine decorations of the interior, white and gold, are by M. Aliberti, and the ceiling is painted by M. Sereno, presenting a fine allegory of the Muses and the Olymp.

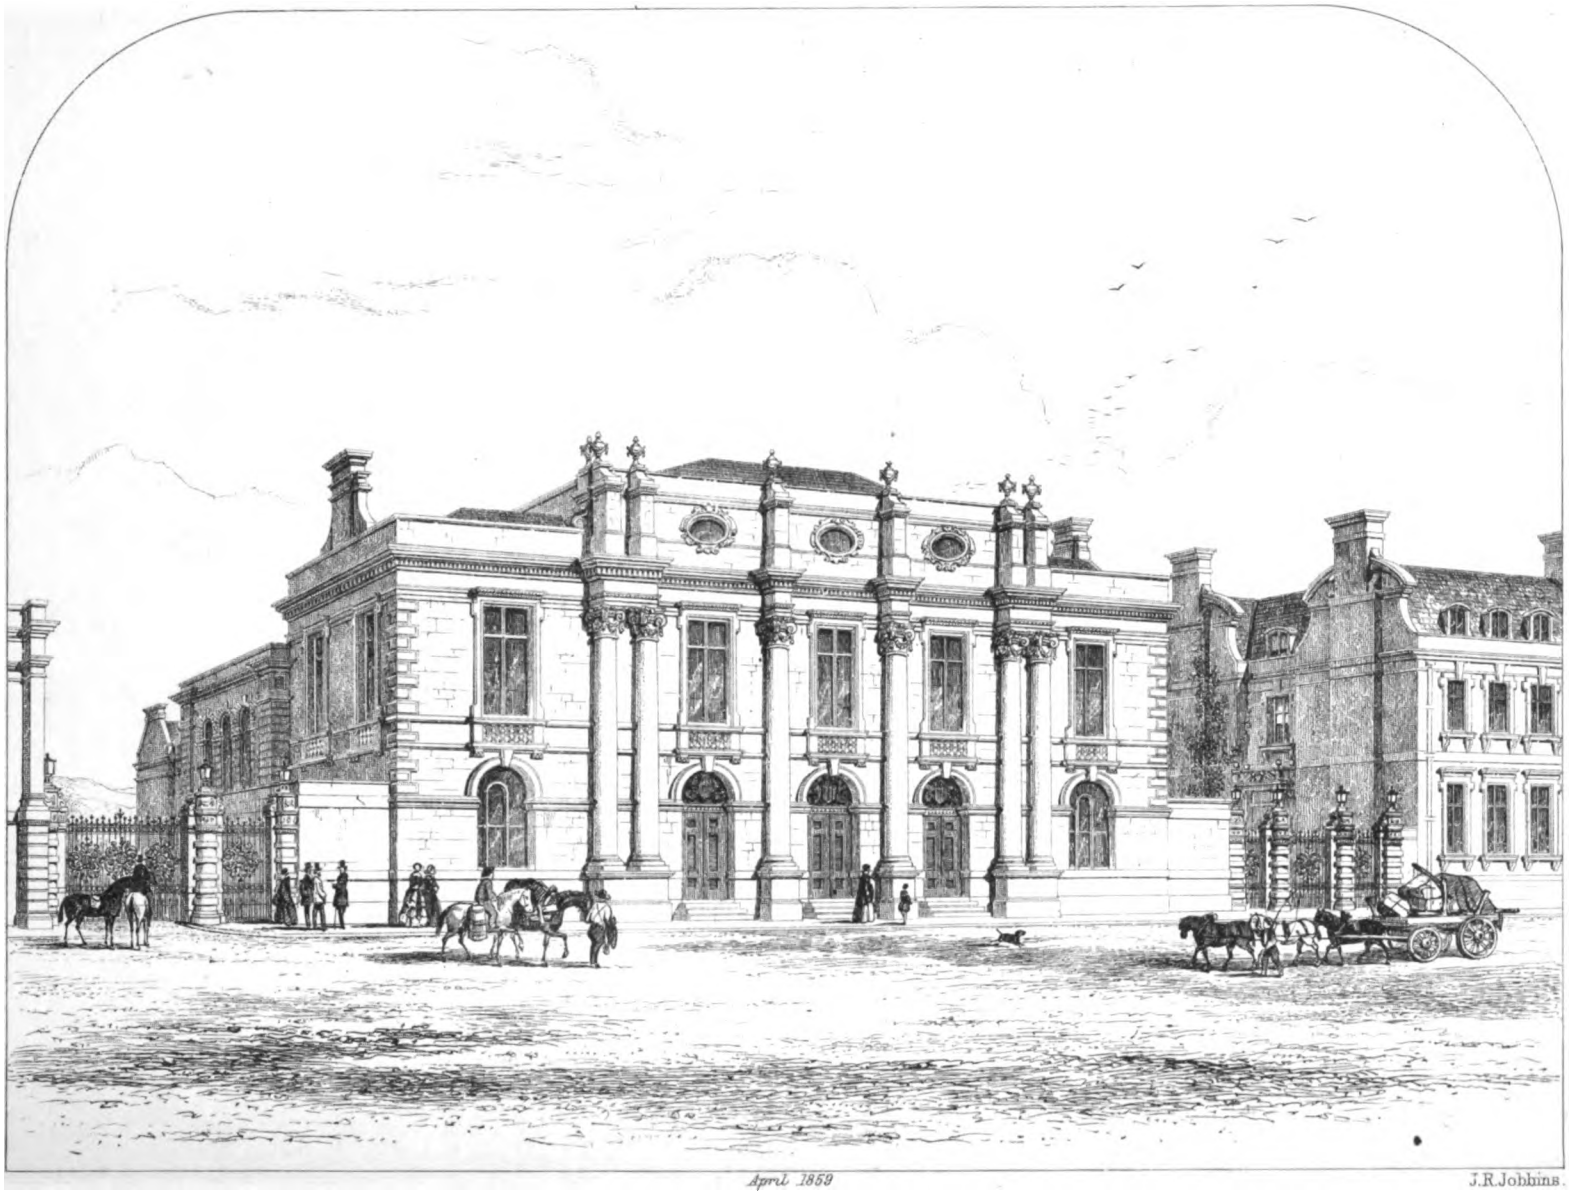
Denbigh.—A fine specimen of stained glass has been inserted in the east window of St. David's Church, Denbigh, in memory of the late Mrs. Henry Tatlock, who resided in the neighbourhood, and whose liberality among those who needed it will long be remembered. The window is about 24 feet high and 12 feet broad, and has been painted by Mr. Ballantine, of Edinburgh. It is of three lights, with tracery in the head. Each light is divided into two compartments; the three upper of the series represent the subjects of Faith, Hope, and Charity; the lower divisions illustrate three of the acts of mercy—"Thirsty," "Naked," "Sick." In the tracery above are figures of angels holding scrolls, on which are inscribed appropriate texts.

Monument to Mozart.—As the exact place where this great composer has been buried is not known, a strange expedient has been resorted to for giving his mausoleum an approximative locality. It is that the monument will have such a broad base as to cover a number of contiguous graves. A pedestal of granite 8 feet high will support the mourning statue of Polyhymnia, made of bronze. The four sides of the pedestal will receive the bronze medallion of Mozart and suitable inscriptions. The plan has been made by Hans Gasser, and the monument is in course of construction.

Railway over the St. Gothard.—The engineer, M. Luchini, has completed plans for a railway through this alpine pass. According to two lines proposed, there would be either 2000 or 7000 metres of tunnelling required, the expenses being from 46 to 60 millions of francs.

Unwholesomeness of Lights.—Recent experiments have proved that lights of equal intensity obtained from different materials require very different lengths of time to generate the same quantity of carbonic acid. The following is the relative time required by the common materials: olive oil 72 minutes, Russian tallow 75, common (French) tallow 76, whale oil 76, stearic acid 77, wax candles 79, spermaceti 83, gas from the common coal 98, gas from fat or cannel coal 152 minutes. Coal gas therefore, and especially gas from the cannel coal, is the least unhealthy of all ordinary lights; which is contrary to the usual opinion.—*Cosmos.*

Florence.—New Building.—The progress of the arrangements for the new front of the Cathedral (Duomo) is satisfactory, and it is expected that the particulars of the competition will appear shortly. The front of the Santa Croce is proceeded with according to the plans of Cavaliere Matas. The materials are mostly taken from Prato and the Marenime, and this minor work is a good prelude to that of the cathedral. Other restorations also are in progress—as that of Or San Michele, which, together with the restoration of the Tabernacle, is nearly completed. But it is especially the Palazzo Pretorio or del Podesta that is most carefully restored; and the Cavaliere Passeini has of late published a history of this most important law court of Florence.



Enamelling Iron.—A very simple method of coating iron with an enamel of glass is a desideratum. In the following process the iron articles are first thoroughly scoured with sand and dilute acid, then washed and dried. Their surfaces are then covered with a thin coat of gum arabic laid on with a brush, and over this the enamel powder is sifted, until all the surface is covered to a certain depth, according to the thickness of glaze desired. The articles are now put into an oven heated to 212 degrees, and completely dried; after this they are put into a furnace and raised to a red heat, which melts the powder, and it forms the glazed surface. They are now removed to a closed chamber, when they are allowed to cool slowly, and are then annealed. The glazing powder for white enamel is composed of 130 parts of powdered flint glass, 20 of carbonate of soda, and 12 of borax. These substances are fused in a crucible and reduced to powder. Some glazes contain oxide of lead: they are dangerous to employ for culinary vessels.

Holland.—Great Engineering Works.—A stupendous work is going on in Holland—the embankment of two inlets of the sea,—and this converted into a canal navigable for the heaviest craft. By this operation 12,000 hectares of the finest soil will be obtained on the coast of the Scheldt. This canal will transect the Sud-Beveland island, between Hanswerd and Wemendinge. It will have a length of ten kilometres (6½ miles), with a tramroad on each side, aqueducts for taking off the superabundant water, &c. At both ends of the canal will be sluices, and a wet dock of 1000 metres surface. The dams will be four metres above high-water mark. A double line of rails will reach from Vliepingen to Bergen-op-Zoom, built on a *pilotis* ten metres broad. This work will place Vliepingen in immediate communication with all the railroads of Germany.

The new Railway Station of the Chemin du Nord, Paris.—The changes proposed in this huge structure are to the effect that the new entrance, instead of opening in front of the Rue de St. Quintin, will open into the Rue de Dinan, which will be converted into a large boulevard of 50 metres, and ending in a square formed by the Boulevard du Nord and De la Fayette. Every opportunity will be seized for improving the adjacent localities of this part of the French capital.

CARDIFF TOWN HALL AND LAW COURTS.

(With Engravings.)

THIS building is situate on the west side of St. Mary-street, Cardiff. It is of the Italian style of architecture, the front is Caen stone, the gate piers of Portland stone, the remainder of the work in rear and flanks is executed in Newbridge stone with cement dressings. The accommodation internally is as follows:—The entrance hall 50 by 37 feet, merchants' or reading room 36 by 19 feet, police court 36 by 19 feet. On the upper floor over these three rooms are the corporation room and ante room, respectively 70 by 36 feet, and 36 by 19 feet. The crown court is 45 by 40 feet, the nisi prius court 43 by 40 feet.

The acoustic arrangements of the courts are such as to have given general satisfaction. The ventilation is simple and natural, and without occasioning draughts. With reference to this particular, the courts have been favourably spoken of from the Bench, as well as by the general frequenters. A reference to the plan will give a clear idea of the general arrangements of the building, as well as of the minor accommodation.

The cost of the building was 12,500*l.*, exclusive of warming apparatus and gas fittings. The works were executed in three separate contracts, two of which were taken and carried out by Messrs. James and Price, and one by Messrs. Harris and David; all of Cardiff.

This edifice was designed by and executed under the superintendence of Mr. Horace Jones, architect, Furnival's-inn, London.

THE ARCHITECTURAL UNION COMPANY'S NEW GALLERIES.

THE desideratum of a *locale* for the meetings of the principal architectural societies of London is at last accomplished, and we have the satisfaction of pointing to premises which, in their remodelled form, promise to be admirably suited to their purpose. They are situate (as most of our readers know) in Conduit-street, Regent-street, and were used previously as a dwelling-house by the Earl of Macclesfield. The frontage is not great, nor is there anything very distinctive in the external appearance, even under present circumstances, but there is a quiet substantial look, which is ten times better than unmeaning and expensive ornament. The area occupied by the several galleries is however by no means small, the principal rooms running behind and transversely to the Conduit-street building, while, in addition to these, there is a narrow strip, called the "north gallery," extending still further back, and communicating with Maddox-street. The plan may be described as follows:—approaching from Conduit-street we enter a spacious hall, at the end of which are the principal staircases. Descending a few steps we arrive at the large exhibition gallery, 60 feet long and 26 feet wide, beyond which, in continuation to the left, is the west gallery, 38 feet by 23 feet, and to the right is the east gallery, 50 feet long by 19 ft. 6 in. wide. The north gallery, before mentioned, is attached to the principal room, and measures 45 feet by 12 ft. 3 in. In adapting these apartments for their intended purpose it is evident that no pains have been spared, and we are happy in congratulating the architects, Messrs. Edmeston and Gray, on the successful termination of their labours. In the all-important matter of *lighting*, the favourable results we augured on our previous survey have been fully realised; it is everything that could be desired, both by exhibitors and visitors, which is saying a great deal. The proportions of the galleries are also well-disposed, and the ceilings effective, though as yet comparatively plain. In the principal rooms the ceiling is strictly elliptical—it would perhaps have been better a little *stilted*, as the line is partially hidden by the projection of the wall cornice—the transverse axis being rather more than a third of the conjugate (or span). Enriched ribs following this form divide the length into seven compartments, which are again subdivided longitudinally into corresponding panels, which are ultimately, we understand, to be decorated in colour. The light is wholly admitted from above, in a long narrow strip on each side of the constructive ridge of the roof, and immediately below it; the space between this glazed roof and the elliptical curved ribs being filled in with perforated scroll work in iron, very tastefully executed by Messrs. Hart and Son, and a like running enrichment separates the upper junction of the glazing, serving also for the purpose of ventilation. The principal and the west galleries are each 14 feet high to the springing of the ellipse; the east gallery measures 19 feet to the ceiling, and the north 12 feet. A committee-room, 20 feet square, and conveniently planned, completes the list of apartments on this floor.

This suite of galleries was opened for the Architectural Exhibition on the 15th ult., and will be occupied by the same till the end of June. From the middle of July till December there will also be a special exhibition of building materials, patents, and inventions; and from December till March the exhibition of the Architectural Photographic Association will be held here. The west gallery is engaged from the present time on the Friday evenings for the meetings of the Architectural Association, who are removing from Lyon's-inn hall, and it is also available on one evening each week for meetings of other societies.

Re-ascending the steps into the hall, we come immediately to the upper flight,—also of stone, and spaciously wide,—leading to the first-floor rooms; these are wholly devoted to the use of the Royal Institute of British Architects. The principal or lecture-room is 17 feet high, measuring 37 ft. 6 in. from east to west, and a foot less in the other direction. Its north wall is entirely new, and on this side is obtained nearly all the light for the room through a series of windows in a handsome arcade below the cornice. The general aspect is at present rather bare, owing to the poverty of the architectural adornments, and in particular of the ceiling and cornice, the style of which date perhaps about a century back. Something will probably be done by way of improvement. South of this room, and lighted by the first-floor windows of the Conduit-street front, are the libraries, measuring together 37 ft. 6 in. long, by 19 ft. 6 in. wide; while at the other extremity of the lecture-room is one appropriated for the council meetings, and measuring 24 ft. 6 in. by 20 ft. A second flight of stairs, also two or three small but convenient rooms, complete the general arrangements. The floor above it is intended to let as chambers or offices, while the third will be occupied by messengers and other officials of the establishment.

The alterations have been carried out by Messrs. Hack & Sons, of Poplar; the metal-work (as before mentioned) is by Messrs. Hart & Sons, of Wych-street; the heating—by hot-water pipes laid under an open grating in the floors—by Mr. Potter, of South Molton-street; the plastering by Mr. Parsons; the gas-fittings, which are simple but tasteful, by Messrs. Johnston, of Holborn; and the hall and approaches by Messrs. Minton, Hollins & Co., Messrs. Maw & Co., and the Poole Company respectively. There are also specimens of embossed glass from the establishment of Messrs. Rees and Baker, of Hatton-garden, introduced into some of the windows; while Moore's patent ventilators are fixed in the principal room of the Institute.

THE ARCHITECTURAL EXHIBITION.

ALL well-wishers to this exhibition will rejoice that it has at length taken such a position as to enable it to occupy galleries of its own, built for the purpose, suitable and commodious, and that thus it can be open annually, in the London "season," for the space of three successive months,—advantages which have long been a desideratum, and which will prove, if we mistake not, of signal service in furthering the interests, not only of our own profession, but those of the art-world at large. The fact, too, that His Royal Highness the Prince Consort has been pleased to allow his name to be added as patron of the exhibition, is a proof of the hold it has taken among influential circles, and may be accepted as an omen of still greater success.

Though compared with the previous exhibition the number of drawings this year is somewhat fewer, the apparent loss is

Digitized by Google

more than compensated by the improved facilities of lighting and hanging, which are at once evident on entering the new galleries. Yet that in the latter particular there is room for further improvement is manifest as we follow the pictures, catalogue in hand. Making every allowance for the pleasure which the eye derives from seeing an ingeniously-packed series of frames, containing an agreeable interchange in the pictures they enshrine of light and shade, colour and outline, this should not be indulged at the expense of that integrity of purpose and beneficial influence which an architectural exhibition ought to realise. One of the great features of a periodical display such as this, should be the careful arrangement of its subjects. It may be well supposed that each successive season will bring its quota from the competitive and other sources which have interested the professional world during the year. These it should be the especial endeavour of the committee in the first place to procure from their authors, and next to show their appreciation of the loan by so disposing of them as that they shall be readily examined, each with each. The services which might thus be rendered both to the practitioners of our art and their clients, are more than may at first be supposed, but as we have on a former occasion pointed out these more at length, we shall not go over the ground here. It must, however, be acknowledged, that the past year-and-half have not called forth so many productions of this kind as usual, and hence, probably, their comparative rarity on the exhibition walls. The great Public Offices Competition yet presents a solitary reminder or two, and we are glad to perceive among these the drawings prepared by Mr. Pennethorne, independently of, and previously to, the competition itself, and which have occasioned so much discussion. Of these we shall speak more at length presently.

The Lille Cathedral affair appears to have altogether subsided, the same with the Constantinople,—and Crimean memorials are giving place to others; the designs for the Ellesmere Monument, by-the-bye, here present a formidable array. A few also for Mr. Spurgeon's chapel, for the Chelsea Vestry-hall, for the Free Church, Edinburgh, for Heigham and Tottenham churches, and others, will be found also; but they are, for the most part, too scattered about to be practically valuable for comparative reference. To take an illustration. Almost the first number in the catalogue introduces us to an interior view of the successful design for the Folkestone Town-hall (lately decided); this is however too small and sketchy a drawing to convey much real information, and we are consequently but little enlightened on the subject, till we come to (150), where we find, misplaced, the corresponding exterior view. A little foresight and classification would surely have prevented this!

If the exhibition, taken as a whole, may not be characterised as a decided advance upon its antecedents, it is unquestionably up to the average standard, and can boast of not a few peculiarly interesting and valuable contributions. That important key to perspective views—a little block-plan in the corner of the frame —may now not unfrequently be discerned; these answer every ordinary purpose, while those to a larger scale are not so readily comprehended in general, and therefore not so explicit, besides taking up so much more room. Though there are not so many *outré* productions on the walls as we have sometimes seen, the number of designs existing as yet in imagination only appears decidedly to predominate over works executed or in progress; but while each of these is highly useful in its way, there can be no question as to which is of the greater practical service, and therefore have the preference of selection, if there be a choice.

The collection opens with a series of "Sketches made in France and Italy," by Mr. Nesfield, who in (31, 32) continues the same subject. These sketches are well chosen, and carefully as well as artistically handled. The plan of thus arranging kindred subjects is a useful one, and there are several other contributions of a like nature in the present exhibition.

(2) Illustrates the decoration of a portion of the roof of the Duomo at Monreale, near Palermo, Sicily, and embraces also a plan and section of part of the building itself. Like the majority of the ancient buildings in this island, this appears to possess considerable merit.

In (3), the same delineator, Mr. Lightly, presents a capital drawing of the Ambo, or pulpit, in the church at Ravello, with details of the mosaics. The elaboration bestowed on the latter is something marvellous, as travellers well know, and the whole is here minutely delineated. With regard to the coloured decorations, the patterns do not strike us as by any means equal to many we have seen in that country; red, blue, and white are the prevailing colours, mostly employed in stripes, and in the picking out of the geometrical forms which constitute generally the surface ornament. An ingenious kind of guilloche, and some interlacing borders, are deserving of examination.

(4). Mr. Dawson's, Photographs of a villa at Reigate are not altogether satisfactory. The architecture is of the mixed kind, partaking both of the Elizabethan and French-château character, —a combination which seldom works in happily.

(5). Design, by Ward and Hughes, for a seven-light window at Glenalmond College, Perth, is of the Flowing Decorated period, founded apparently on some well-known examples. The leading lines are not particularly graceful.

A slight sketch of the interior of Folkestone New Town-hall, by Mr. Messenger (6), shows a very plain-looking apartment, of Italian character, with an elliptical ceiling divided into bays by broad bands. In another room is the corresponding exterior view.

(7) Is a choice impression of the lithograph of Mr. Scott's "Dockyard Chapel, Woolwich," which appeared in the February number of our *Journal*, and which we have already described.

(8) Is a Mural Monument, designed by Mr. Truefitt, which, like all that gentleman's productions, bears the stamp of clever originality. The design before us does not however commend itself to us as one of his happiest efforts, notwithstanding that sculpture and inlay-work are introduced in addition to architectural forms.

(10), By Mr. T. H. Watson, may very well answer its purpose as an "Artist's Studio," but has no pretensions whatever to architectural distinction.

(11) Is one of the numerous drawings which exhibit "alterations" to mansions. In the present case these appear to be of an extensive character, especially in the outbuildings. The effect is more attributable to grouping and outline than to ornamental detail.

(12) Is one of several contributions by Messrs. Walton and Robson, being a free pen-and-ink sketch of the "Schools and master's residence now erecting at Redcar." In this, as well as in some other works exhibited by the same authors, architectural embellishment is almost wholly avoided; effect being sought by means of good general proportions and picturesque outlines, presenting a variety of groupings from different points of view.

(13) Is a valuable and elaborately drawn elevation of the west elevation of Winchester Cathedral, now undergoing restoration at the hands of Mr. J. Colson, of that city.

(14), (99), and a few more pictures, have their origin in dreamland. It may be entertaining, but surely is not very profitable, to indulge in such pleasures of the imagination.

Mr. T. W. Knightly's pretty vignette sketches (15), though most minutely rendered, are not sufficiently defined to investigate their architectural merits. The frame includes seven subjects, consisting of chapels, schools, and houses, "now in course of erection," in the Italian and Gothic styles. In 3 and 5 the round forms occur in the plan with good effect.

(16)—A selection from the illustrations accompanying the *Dictionary of Architecture*, now being issued,—makes a very interesting sheet. Among them will be observed the elaborate ceiling of Bishop West's Chapel, at Ely, also sketches of San Zenone, at Verona, and Amalfi Cathedral, which have been particularly well reproduced by Mr. Bedford. We learn that the Dictionary is now only about one-third finished, so that, at the rate at which it drags its slow length along, years must elapse ere the undertaking is fully accomplished.

(17). "Design for the church of SS. Peter and Paul, Berne; to which a gold medal was awarded" (G. Goldie). This is really so unsatisfactory a design, taken as a whole, that one is at a loss to perceive its peculiar charm in the eyes of the judges. The author appears to have culled from his foreign sketch-book a few choice details, and strung them together, regardless of general symmetry and harmony.

A brown ink-drawing by W. Smith (18), shows the nave arches (Norman) of Walsoken Church, Norfolk, and also the curious ancient seating, of Perpendicular date, and so elaborately adorned with figures in niches, buttresses, and complicated mouldings. Some additional seats have been introduced, to complete the restoration, but we are under the impression that these are by no means equally rich with the old ones: the details have possibly been tampered with to suit economical funds.

Mr. Tucker's "Villa residence, New Zealand" (19), does not

Digitized by Google

deserve the room it takes up; it is hung moreover in a place where its architectural barrenness is, by contrast, eminently conspicuous.

We own to an aversion to those emanations in which a vast amount of detail is crammed into a given space, without any specific object, except to gratify the fancy of the author by seeing his ideas upon paper dignified by the appellation of "a design." There are a few of this class in the present exhibition, but the one which comes under the title of a "study of a Palace Façade" (20), by Mr. Horton, is really a meritorious work, and nicely drawn: the style is Palladian, well composed, and the proportioning of the whole exceedingly good.

Mr. Ellis's proposed Bank, at Norwich (21), is Italian, and has a good substantial look, but otherwise is not very noticeable. The upper stories are in red brick with rusticated dressings in freestone (or cement?) The ground-floor is rusticated throughout.

(22), Barwick-house, near Yeovil, is Jacobœan of the worst kind. It is a pity that Mr. Shout should have perpetuated such abominations in remodelling this mansion, even if the old part were in this "pestilent" taste.

In (23)—Decorations for the Princess' Theatre, and for the Surrey Gardens Music-hall,—Mr. Kuckuck gives the reins to imagination in combining the real and the fanciful with something beyond artistic license. The result therefore will not bear scrutiny, but the colouring *per se* is judicious, and in the blending and diversifying of the hues there is nothing to complain of.

(24). Mr. I'Anson's buildings are among the best of their kind, and have contributed much toward "London improvements." In the drawing before us is a series of these, including the Fenchurch-street Chambers, and the Corn Exchange Chambers, Seething-lane: but they are represented on too small a scale to convey more than a general impression.

Mr. Roger Smith, in the "Independent Chapel and Schools" now erecting at Highgate (25), does not rise even to mediocrity in his Gothic notions.

Brickendon Grange, Hertfordshire (26), G. F. Jones, is a curious amalgamation of Gothic, Italian, and Elizabethan; the structure is apparently mostly in red brick, and the outline is picturesquely broken.

The "Warehouses recently erected in Montague-close, Southwark" (27), T. C. Clark, are among the best and most characteristic we have seen. There is no attempt at extravagant display or inappropriate features: all is simple and truthful, and therefore satisfactory. A slight relief in colour is gained by the use of red brick in the arches, &c.

The next drawing (28) is a sort of burlesque on a most interesting ancient subject—Holy Cross Abbey,—and should unquestionably have been rejected.

(29). "Stephenson Memorial Schools, Willington, near Newcastle-on-Tyne," are erected on the site of the cottage where he once lived, and are very fair specimens of Gothic, though perhaps rather too ambitious. The materials are red brick with white dressings.

In (30), Mr. R. H. Shout exhibits a good architectural drawing, of the genuine kind. It shows the "Schoolhouse now erecting at Abbotsbury, Dorsetshire." There is some originality in the design, although marred by the disproportionate size of the windows.

(33). "New Printing Offices, Bread-street-hill," by Mr. Dawson, are built of yellow malms and red bricks with stone weatherings; while extensive portions of the building in the rear are constructed in cast-iron. The design itself is very poor.

(34) Is an enlarged view of the Seething-lane Chambers, which we have before mentioned (see No. 24). The drawing does not do justice to the subject, it being, like the colouring, far too heavy and laboured.

The "Roman Catholic Church now erecting at Bandon" (35), is designed in better keeping than some others of Messrs. Hadfield and Goldie's works, but it is not free from mannerism. The apsidal end tells well in the grouping, but the best effect is acquired in the belfry stage, and the short spire by which it is surmounted.

(36) Presents "Christian Memorials" in a variety of forms, but nothing new. They consist of crosses, altar-tombs, headstones, and brasses, tastefully selected, and neatly drawn.

Mr. Clayton's "Station at Tynan, on the Ulster Railway" (37) is nothing short of being absolutely ugly; but that at Glasslough, on the same line, is a happier conception. Some timber construction is well devised, also the bell turret.

(39), A "Design for a Façade," may be supposed to be in the Louis Quatorze style, and will exist, we hope, only on paper.

Twelve large coloured views, explaining Mr. Owen Jones' design for the "Palace of the People," Muswell-hill, form a very handsome termination to the end wall of the gallery. As we have, in a previous Number, called attention to the leading features of this vast project, and described its architectural contrivances, it will be sufficient to say, that, by the fortunate acquisition of these drawings for the exhibition, every facility is afforded for a thorough acquaintance with the attractions presented by this noble scheme.

Mr. J. W. Papworth's "Albert Institution, Blackfriars-road" (50, 51), is utterly tasteless in point of design. It is exhibited under two different arrangements, the second having the addition of an upper story. This is the better-looking front of the two.

The only contribution by Mr. St. Aubyn is a small lithograph (52), of the Church at Kilmaloada, Ireland, which seems to possess, like that gentleman's works in general, some happily designed though unobtrusive features.

The Branch Banks at East and West Hartlepool, by Messrs. Pritchett and Son (53, 54), are very tame-looking; indeed, scarcely beyond ordinary street buildings.

Binstead Church, is a well-known early specimen of architecture, one of the few of that date tolerably perfect in the Isle of Wight. Mr. Hellyer's interior view (55) shows the building itself intact, but the whole polychromed to an intense degree. For all this there is doubtless the authority of precedent, but it is a question how far it is advisable so fully to mask all architectural features as to inevitably disguise their real details.

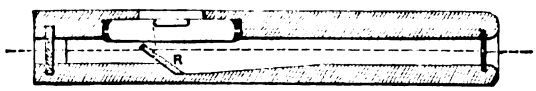
(56) Is one of the cleverest pictures in the rooms, whether we look at the pleasing novelty of the ideas, or the telling power with which they are expressed. Imbued with continental ideas, Mr. Blomfield has managed to engraft some tasteful notions on what might be deemed a very common-place subject—Drinking Fountains. The combinations of stone and metal are effectively brought to bear, and have evidently been well considered.

Placed wilfully in contrast, one might almost be led to suppose, is Messrs. Driver and Webber's "Memorial Fountain" (57),—a specimen of pseudo-Gothic about as much below the average as those we have just quitted are above.

In (59) we have an elaborate pencil drawing, by Mr. T. Vaughan, of the South Transept and Tower of York Minster, while in (92) the same artist treats us to the Towers of Lincoln,—in (119) to sundry other bits from York,—in (140) to a "classical" subject, a "Design for a Circus," which gained the Soane Medallion of the Institute of British Architects in February last;—in (142) we return to "Gothic," in the shape of a vista down the South-east Transept of Beverley Minster;—in (345) to a view of the Western Towers of Durham;—and, in (346), to a final peep into the Presbytery at Lincoln Cathedral. This collection supplies, in itself, almost enough data for tracing the successive phases of mediæval architecture, and though not rendered with a particularly free touch, are so carefully detailed as to make them highly serviceable for comparative study.

Want of space forbids us to pursue our examination further this month, but in the next Number we purpose resuming this subject; and we shall finally devote considerable attention to that important feature of the exhibition,—the "Department of Materials, Inventions, and Manufactures."

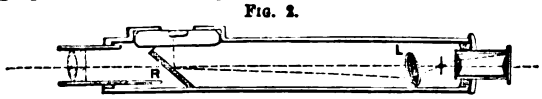
Several interesting lectures connected with art are announced to be delivered on successive Tuesday evenings; and to-night the Architectural Association holds an inaugural *conversazione*, when the whole of the rooms will be thrown open to the visitors.



ROYAL SCOTTISH SOCIETY OF ARTS.

At the meeting of this society held at Edinburgh on the 14th February, the vice-president, Mr. R. H. Bow, C.E., read a Paper on "*Several forms of Spirit Levels that may be used without tripod or other fixed stands.*" The principle on which Mr. Bow's levels are planned consists in such an arrangement that the observer may note at the same instant the height of the cross-hair as projected against the levelling staff, and the momentary central position of the bubble in the spirit-level. The simplest form of the instrument, shown by fig. 1, differs but little in external appearance from the common pocket or workman's spirit-level, and can be put to the same uses in addition to its particular duty of affording observations by being simply held in the hand while

Digitized by Google



looking through it. For more accurate observations various forms of the instrument were exhibited, in which a telescope with cross-

Fig. 1.

hairs was incorporated with the spirit-level: the most perfect of these is that shown by fig. 2, in which by means of the very narrow reflector R, and the thin slice of a lens L, an image of the bubble is formed near the cross hairs, and consequently seen as though part of the landscape.

Fig. 2.

Mr. Bow explained at considerable length the beautiful principles employed in the construction of Prof. Piazzi Smyth's "Spontaneous horizon points," and summed up with remarks upon the merits and defects of levels to be used without fixed supports, or at sea, showing that though they could not be depended upon for very accurate work, they yet deserved to be considered instruments of considerable practical importance, from the expedition with which results could be obtained by them, and the valuable aid they could afford to the exploring traveller, or to the engineer in search of the best general route for a road, railway, or canal. For the latter purpose the simpler form of the instrument may be made still more complete by having a series or scale of cross-hairs, so that the general gradient of a plane or valley may at once be perceived.

GREVILLE PLACE CHURCH, EDGEWARE ROAD, KILBURN.

(With an Engraving.)

The church in Greville-place, Edgeware-road, now in course of erection, is being constructed of brickwork, the walls being faced with yellow malm bricks, in which many elaborate patterns of red and purple Staffordshire bricks are worked. Great relief and boldness are given to the arches by the introduction of ornamental designs in the brickwork, as indicated on the elevations. Most of the arches are gauged. In the interior the whole of the arches and uprights are of wood, resting on cast-iron twisted columns. The spandrels of the arches are filled in with tracery, pierced only. The clerestory is of cast-iron, fitted into the woodwork.

The vestry communicates with the church, but can be screened off for evening services when required: the large arch is for the reception of an organ. The spire is of stone. The contract for the erection of the church (including the spire, but exclusive of seats) has been taken by Mr. Simpson, builder, of Goodge-street, for the sum of 1711*l.* 16*s.* 2*d.*

The church is designed to accommodate 416 persons on the ground plan, and 146 in the gallery, making a total of 592 persons.

The architect is Mr. Edward Habershon, of 37, Bedford-place, Russell-square, London.

FLOATING DOCK GATE, DUNDEE HARBOUR.

Designed by Mr. Ower, C.E.

The Engineer to the Dundee Harbour Board, Mr. Charles Ower, who is superintending the extensive new works now in progress at the harbour, in order to meet certain local requirements, has invented a floating dock-gate of very skilful construction, opening and shutting in a novel manner, and capable of answering as a bridge both for foot-passengers and carriages. The opinion of Mr. Fairbairn upon the subject was invited, and that gentleman's report, recently made to the Trustees, which we append, is highly satisfactory.

"Manchester, Jan. 10, 1859.

"Gentlemen,—Mr. Ower having submitted to me a model and drawings of a revolving floating gate, proposed to be erected for closing the entrance into the Victoria Dock, I have, in compliance with the resolution of your board, given the subject my best consideration. The structure, as shown on the drawings, is composed entirely of iron, and so constructed with interior cells or floors as to enable the gate to float a few inches above the bottom, when it may be opened and closed with facility and despatch. To effect these objects, and in order to afford the necessary powers of resistance to the pressure of the water during all states of tide, it will be necessary to make certain modifications in the construction. This is the more essential as the gate should open with the same facility at the lowest neap as at the highest spring tides. To meet all these requirements, and at the same time to make it answer as a bridge of communication between each side of the dock, I would recommend as follows:—

"1st. That the caisson or floating gate be made of the rectangular form, 64 feet long, 10 feet wide, and 29 feet deep, and to be composed of plates varying in thickness from eight-sixteenths to five-sixteenths, according to position.

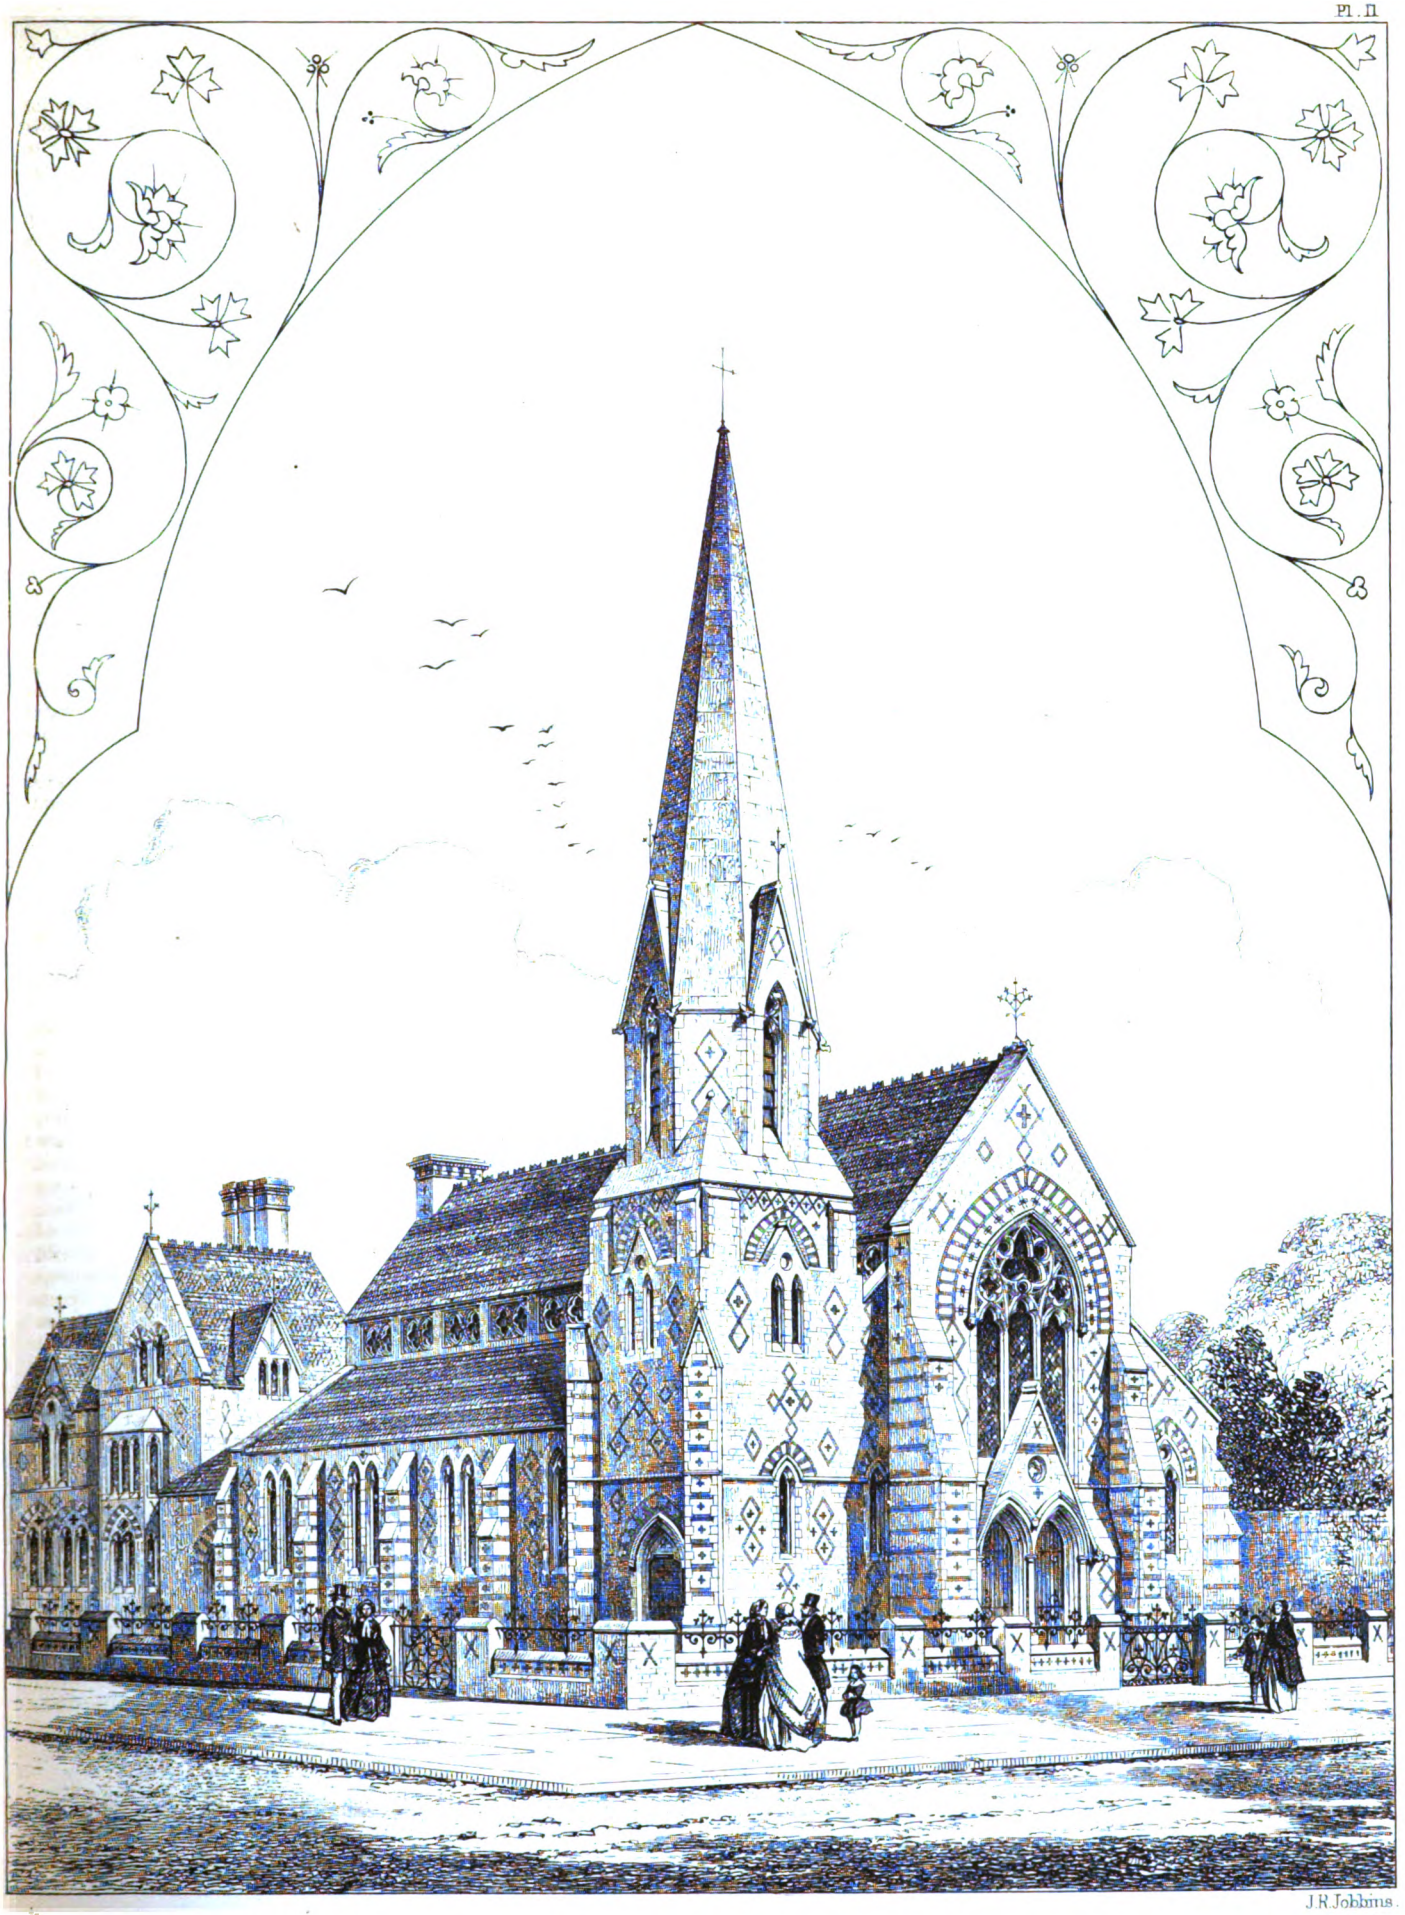
"2nd. That the weight of the gate will be about 150 tons, equivalent to its displacement at a depth of 8 feet; or, in other words, it will rest upon the bottom of the dock with a pressure at low water of about 2 tons at neap tides.

"3rd. As the gate is not intended to be opened but at high water, it will require about 200 tons of ballast, either of water or ashlar stone, in the bottom, to prevent floatage until the height of neap tide or 10 feet from low-water mark is attained. In this position I would recommend, in addition, that up to the highest spring tides the floatage of the gate be regulated by sluices, to admit the water from the dock into the water chamber below, and *vice versâ*, to run it out again at low water when the gate is sunk in its place. In addition to these arrangements I would recommend, in order to give increased facility for regulating the floatage, that the upper division be formed into a water tank for sinking or raising, under any circumstances that may occur in the opening or shutting of the gate.

"By this arrangement it will be seen that the rollers shown on Mr. Ower's drawings may be entirely dispensed with, as by the discharge of a small quantity of water from the proposed tank the gate may be floated, if required, at an earlier period than high water at neap tides.

"As regards the strength of the gate, I calculate its powers of resistance, at 10 feet wide, to be 3560 tons equally distributed over the surface; and the greatest pressure that it can ever be subjected to will be about 600 tons, thus giving a ratio of strength nearly as 6 to 1. Looking at this large margin of strength which we have in a gate thus constructed, I would recommend that the breadth of 11 feet, as shown by Mr. Ower, be reduced to 10 feet, which will be quite sufficient for that purpose, and that the roadway be formed with T iron covered with 3-inch red pine, as shown in the annexed sketch. Under these circumstances, only one water-tight floor will be required; the others may be formed of open work for the purpose of stiffening the sides of the gate. In this construction I would further recommend that Mr. Ower's circular plates be dispensed with, and in lieu of them, plates, 2 feet wide, and varying from three-eighths to five-sixteenths, be rivetted to the floor, beams, or angle irons. This would prevent flexure, and give increased rigidity and strength to both sides of the gate.

"Having thus discussed the mode of working, strength, and other proportions of this new method of closing and opening the entrance into docks, I may shortly advert to the old plan of gates usually adopted for this purpose. In these it will be seen that much time is lost in opening and shutting; and a much greater number of men is required than is necessary in the present case, where the whole can be done from one side, thus affording increased facility in working vessels in and out of the dock.



"In the sliding caisson which I constructed for the Government steam docks at Keyham, Devonport, it can be opened and shut in eight minutes, and that simply by floating it into a recess instead of causing it to revolve on a centre as proposed by Mr. Ower, which, I think, in your case is an improvement. Again, this construction answers the double purpose of a bridge as well as that of closing the entrance into the docks, and thus saving the expense of a separate structure, and all the cost of attendance to open and shut the bridge at the same time the docks are opened.

"I have, &c.,

"Wm. Fairbairn."

Mr. Ower's floating dock-gate is now in course of construction, and as soon as completed we propose returning to the subject.

ON METROPOLITAN IMPROVEMENTS AS AFFECTED BY THE BILLS NOW BEFORE PARLIAMENT.*

By T. M. Rickman.

One of the most systematic examinations of the principles of metropolitan improvements was conducted by the Metropolis Improvement Commission, which made its first report in 1844. Two sentences from the opening pages are of great importance. Respecting the plans submitted it is said: "The utmost attention will be required in selecting such of them as may appear to possess the highest claims, and at the same time to be within the limits of practical and not too expensive execution." The other refers to Sir Christopher Wren's proposed recast of the metropolis: "His attempts were thwarted by public bodies and individual interests;" and it is added, the consequences of the Fire of London as regarded the disposition of the city were but to accelerate the westward movement of the nobility.....The extension of the town is the work of private enterprise, but the openings of internal communication must be effected by public aid."

For a long time improvements to a small extent in the city had been conducted by the corporation. The necessity for a bridge at Westminster was considered local, and not metropolitan. It was completed in 1750, with funds partly raised by a lottery. About 1795 the same means were adopted for throwing open Snow-hill and the site west of Temple-bar. Blackfriars-bridge, or "Pitt's bridge," finished in 1769, was paid for by a toll, continued for a number of years. Waterloo, originally "Strand" bridge, was erected by a private company, and opened in 1817: Southwark-bridge by similar means in 1819; in connection with it was the opening of King and Queen streets. Hungerford-bridge was opened in 1845. The great improvements at the west-end were carried out at the ultimate expense, in great part, of the land revenues of the crown, with a large aid from the consolidated fund. London-bridge was opened in 1831, and the present coal tax assisted in a great measure in the completion of the approaches. The tax has since been expended in the formation of other streets, and has hitherto been considered the sole pecuniary means of effecting "metropolitan improvements." The City Corporation Commission, which aided in the introduction of the Metropolitan Management Act, reported against that tax, and in favour of one to be levied on the whole metropolitan district for the purpose of improvements. The coal tax lasts till 1862: it is entirely hypothecated. Till other funds are forthcoming, or the new tax established no extensive improvements can be carried out.

In the year 1813 the "Commissioners of Woods, Forests, and Land Revenues of the Crown" made their first triennial report after their connection with the "Board of Works," on the state of the property confided to them, with a statement of their proceedings. One of the first points to which their attention had been directed was the improvement of the Marylebone Park Farm. The offer of a premium of £1000 not having produced any design calculated to effect the desired result, Messrs. Leverton and Chawner, surveyors to the Office of Woods, and Mr. Nash, one of the architects to the Board of Works, were requested to furnish plans. The former sent in a design for laying out the larger part for building purposes; the latter one, which gave a much more extensive area to the public, and combined the erection of terraces, villas, markets, and streets on the eastern side, with a new street to Pall-mall in a line with Portland-place. This, or Regent street, as at first planned, terminated in a square inclosing a public building. This arrangement, principally from want of means, was changed into the present Quadrant, after the execution of the main sewer, which consequently in some places runs under the houses. Regent-street was opened in 1819. The total cost in 1826 was £1,315,000, of which £515,000 was paid from the crown revenues, and £800,000 from the consolidated fund. The annual income was £36,000, but ultimately it will be £160,000. The net cost of laying out the Regent's-park, which was defrayed out of the crown revenue, was stated in 1823 to be £20,000.

This great artery having been opened, and the lung formed—the Regent's-park—the commissioners proceeded in their labours eastward. Mr. Nash's plans for continuing Pall-mall to St. Martin's-lane gradually grew into the formation of Trafalgar-square, and the buildings on its east, north, and west sides, with the district between the Strand, Agar-street, and the south side of Chandos-street. Some progress was made in the continuation of Pall-mall in 1823: and shortly afterwards the growing attraction of the British Museum was adduced as a reason for widening St. Martin's-lane; but this improvement was only carried out as far as the corner of Chandos-street. The report of 1826 describes the passing of an act to widen the Strand, the new works in connection with the Charing-cross improvements having rendered the northern side of that thoroughfare an eyesore. An act passed in 1826 (the Charing-cross Act) included powers for improvements in Downing-street and King-street, Westminster. In 1835 the whole of the purchases had been completed, the land revenue having paid the cost (which was ultimately £1,196,000), except £600,000 still due to the consolidated fund. Of the above sum £1,058,000 may be set down to the improvements at Charing-cross.

Two results ensued from the lavish expenditure on these great works. It was desired to extend the improvements, but it was not thought fit to continue the unlimited system of borrowing from the consolidated fund to supply the land revenues of the crown. The widening of the lower part of St. Martin's-lane, with the view of opening up a communication from Charing-cross northwards, pointed to Long-acre as an intermediate westerly route, and its continuation westward through Leicester-square to Piccadilly was seen to be of importance. The opening of Waterloo-bridge in 1817 pointed out the improvement of Bow-street, and the formation of Endell-street. The straightening of the Oxford-street and Holborn route, by cutting New Oxford-street, seemed most desirable to improve the northern east-west route; and the opening of Bloomsbury-street to connect Endell-street with St. Martin's-lane, and the clearing away the middle row and projecting buildings at the head of St. Andrew-street in Broad-street, St. Giles's, followed as the result; and while so much was proposed to improve the east-west routes on the Middlesex side, it seemed but proper that a new parallel route on the Surrey side should be projected to connect Westminster-bridge with Southwark. Mr. Nash had prepared plans for Cranbourne-street and New Oxford-street, but the state of the crown revenues, in consequence of other large operations, prevented any works of importance in this direction from being carried out for some years, except those connected with Wellington-street and Bow-street, which were effected to a great extent by arrangements with the adjoining owners; but in 1839 the commissioners reported that all the new streets authorised by parliament had been completed, and the debts paid; that the growing produce of the crown estates would be paid to the Ways and Means, and the produce of sales invested.

In 1836 and 1838 committees of the House of Commons were engaged in examining the plans which had been brought forward, and in ascertaining the funds available, and the expense likely to be incurred. The last committee reported in favour of three routes: (1) Cranbourne-street and Endell-street; (2) New Oxford-street; (3) Spitalfields;—consequently in 1839 an act was passed authorising the construction of these streets, and granting for that purpose a charge upon the London-bridge Approaches Fund of £200,000. In the following year, the commissioners finding the amount voted far too small, came to parliament, and requested either to be restricted to one of the plans, or to be allowed more money; and in conformity with the recommendations of the select committee of 1840 on this subject, an act of the same session was passed continuing the coal tax for four more years for this purpose. In 1844 Cranbourne-street, and in 1845 New Oxford-street, Endell-street, and the new street in Spitalfields were opened, at a total expense of £841,000, though on a reduced scale.

In 1842 a commission was appointed to inquire into the most effectual means of improving the metropolis. The first report appeared in January 1844, and others from time to time till 1851, when the seventh and last was issued. The completion of the Spitalfields line through Whitechapel to Christ Church, and the important vegetable market, had rendered it still more desirable to continue the line of street to the Eastern Counties station and on to the City-road. An act was therefore passed in 1846 enabling the Commissioners of Woods to complete the first portion of the work. The funds were to be supplied from the penny duty on coals. This duty had been first levied to pay the expenses of the new Coal Act, the erection of the Coal Exchange, &c., but as those objects had been accomplished, and the execution of this work was pressing, its application to this purpose was guaranteed by the act of 1846, but it was not till 1849 that the commissioners

could raise money upon this duty to carry out their undertaking: the whole was formed by the Commissioners of Woods, with the aid of mortgages on the spare land, and the street was opened in 1858. The continuation to Old-street and City-road now lies with the Metropolitan Board of Works. In 1844 the opening of Albert-gate was completed, partly at the expense of the land revenues of the crown, and partly by arrangement with Mr. Thos. Cubitt. In 1851 the opening in front of Buckingham Palace, and the removal of the Marble Arch were effected; and from that time to the present the entrance to St. James's-park from the Victoria-road and Belgrave-place has been progressively enlarged.

Victoria-street, Westminster, was opened in 1852 with the aid of considerable grants from the coal duties, &c. The difficulties which the crown did not feel have fallen heavily on the Westminster Improvement Commissioners. The lessees who undertook Park-crescent failed, but the crown obtained others; whereas the Westminster Commissioners advanced heavily on the buildings in Victoria-street (it is said to the extent of £400,000). Their administration has been questioned, both as to the withholding of accounts, and the issue of bonds without security; and their affairs have become food for the lawyers. The creditors refused two years ago the bill proposed by the commissioners, and there are now two rival bills for effecting similar objects; one for authorising sales through the medium of the Court of Chancery, the other for a reconstruction of the commission on an equitable basis.

The construction of Victoria-park and Battersea-park illustrates another phase of public improvements. On the death of the Duke of York, the lease of the house which he had built, being heavily mortgaged, was bought by the crown. In 1827 it was sold to the Marquis of Stafford for £72,000, but as an assignment could not then be made the money was vested in trustees, and remained out at interest till 1841, when it amounted to £115,683. An act having been passed to enable the Commissioners of Woods and Forests to purchase and form the Victoria-park, this sum was applied to the purpose, and the remaining expense, about £14,000, was defrayed out of the revenues of the crown. The area purchased was 266 acres, of which 45 are retained as building land, and let by the crown. The purchase of Battersea-park was authorised by an act of parliament in 1846. The funds were to be advanced by the Exchequer Bill Loan Commissioners, to the extent of £200,000; it was calculated that this sum would be sufficient, and that the return from the building land purchased at the same time would eventually repay the whole cost. It was a good time for purchasing land in that district, but from the irregularity and long delay in the advance of the requisite funds, the land increased in value; and in 1853, when the purchases were completed, the cost, including formation and expenses, amounted to £316,000. The total area of land purchased was 319 acres, of which 125 are building ground. The whole of the park is made ground, the bed of the ornamental water being about the level of the original ground. Closely connected with Battersea-park is the erection of the new Chelsea-bridge. The design, like that of many of our bridges, has undergone numerous changes—wood, stone, iron, suspension. The act empowering the Commissioners of Woods, &c. to carry out the embankment of the river connected with this work dates 1846. The Improvement Commissioners made their sixth and last report in 1847, and devoted it to this subject. Great endeavours were made to effect the embankment by private arrangement; but up to the present time the conflicting interests of private individuals have succeeded in thwarting the extension beyond Chelsea College, and the powers of the act have expired. The bridge was long delayed through the failure of a contractor, but was opened in the spring of 1858.

The first subject on which the Improvement Commissioners reported was the embankment of the Thames. In 1844 they referred to the change which the river had undergone from the removal of Old London-bridge, authorised by an act of 1823, and to the irregular curves with the projections and recesses of the banks. An act of 1678 had regulated embankments for a long time; but, gradually falling into disuse, it was repealed in 1821. Messrs. Walker and Burges laid down certain lines, which have been theoretically the limits of projection; but they have been practically followed only to an insignificant extent, if at all. The authority in these matters now rests with the conservators of the river Thames. It was not thought till 1840 that the Thames had found the limits of alteration from the change in London-bridge. Since then many have been the schemes for utilising the banks of the river. Since 1824 Sir F. French had been ventilating this subject. In 1844 Mr. Walker, on behalf of the corporation, was pressing his scheme, but at that time insuperable obstacles prevented its execution. The two plans then considered the most feasible were Mr. Walker's for a broad embankment into the river, and Mr. Page's for a wall with a roadway, retaining in many places large tidal reservoirs up to the present banks. The first would require the wharves of each proprietor to be brought forward and changed, while it would reduce the mooring ground for coal barges, which is of continually increasing extent. Mr. Page's plan, while it filled up the frontage where no trade was carried on, left openings for the vessels and the tide at many points. The conclusion of the commission was in favour of an embankment for improving the navigation, while the importance of combining this object with the conveniences of additional land communication was considered great: the space to be thus treated most recommended by the commission extended from Westminster to Blackfriars, and for that purpose an increase of 5*d.* per ton on the coal duty was suggested. We have now the Metropolitan Management Act, the institution of the Metropolitan Board of Works, armed with a rating power, and the reconstitution of the conservators of the Thames,—measures following in conformity with the recommendations of the Corporation Commission of 1853-4. The abolition of the privileges of the Thames watermen and lightermen (not a city company proper, but dating from the time of Henry VIII.) also urged by the report, is now the subject of a smart agitation in the city.

The corporation have always been engaged in improving the city; for since the passing of the act after the great fire, which required a 40-feet way from the Temple to London-bridge, the streets have never been wide enough. New London-bridge and the Exchange have been connected by a series of fine open streets which have ramified. The Post Office and the Bank have been likewise centres for considerable openings under different authorities; but in both of these cases the plan has not been carried out on a scale sufficiently complete to afford all the advantages which might have accrued to the public. The uselessness of Gresham-street, and the difficulty of now improving it, are instances of the want of system from which the labours of the several authorities have sprung. The noble opening of Cannon-street, at the cost of £500,000, is also waiting for a more convenient access at the west end to accomplish the purposes for which it was designed. This street and the greater part of the last-mentioned improvements have been the work of the corporation, aided by the coal tax. The opening of the district round the Post Office was to a great extent a government affair, and with the administration of that day rests the charge of having put off the purchase of the property between that building and Cheapside, and of so placing the building itself as to prevent convenient access to St. Martin's-le-grand from the east. A valuable site for opening up this building is now being built upon. The improvements in opening Farringdon-street, forming the market, purchasing the site of the Fleet prison, and forming the Victoria-street, have been the result of disjointed action. The commissioners appointed to execute the latter were unable to complete their task with the means at their disposal, and it merged at last into the hands of the Corporation.

The improvements now authorised, for which sums have been provided, are: the communication between St. Martin's-lane and Covent-garden, for which purchases are being made; a short street exclusively in the Bedford estate, from Burleigh-street to Tavistock-street, aiming at the south-east angle of Covent-garden; the new street from Stamford-street to the Town-hall in the Borough; New Earl-street, to lead from Cannon-street to the west end of Upper Thames-street; and the approach from Limehouse, at the junction of the East India Dock-road and the Commercial-road to the south end of Grove road, and thence to Victoria-park. The rebuilding of Westminster-bridge, with the removal of the houses on the south side of Bridge-street, and the widening of Newgate-street, are gradually progressing.

Let us here take a cursory view of the requirements of London as our metropolis. Its position is on the main river of the country; upon a bend of that river, as in old times the military views of the founder dictated. The low grounds on the south side held the out-posts, the "tête du pont," Southwark. The Tower was adjacent to the walls of the city, at a short distance from the bridge. Away to the west the Isle of Thorney, with its monastery; opposite to it Lambeth. This concrete has become

Digitized by Google

one nucleus, and the London of the present day has arisen. Thus we have routes east and west as the main metropolitan thoroughfares. London is a town of commerce—a great depôt: commerce is conducted by shipping and by railways—hence the connection between the docks and the town and railways is of primary importance. The Thames is the great highway for London, and it bears its proportion of local traffic both for passengers and for articles of consumption. The docks require immediate connection with railways, especially for imports: they require for their export trade connection with the whole of London, by wide roads and easy gradients. All the railways therefore require to be linked together, and connected with the docks and river for their goods traffic, so as to avoid trans-shipment and unloading. Then as to passengers—the railway termini and the main streets must be laid out with reference to each other. In every metropolis there are two centres of interest and importance; one, the civic and commercial, where the local government has its seat among the marts of industry, the sources of its individual power and position; the other that of the government and of all connected with the throne, the aristocracy and the administration of the country. The original relative position of London and Westminster has been the key to the class division of the metropolis. Centered at Charing-cross are the streets of the west-end, and at the Bank those of the east-end; in the immediate neighbourhood of each of these centres the value of property is immense; between them lies a district of secondary value, and towards the extremes the value gradually diminishes. Property is valuable in these spots because vast masses of people engaged in their proper callings congregate there. Therefore, for the passenger traffic, the railways should have termini of great capacity as near these two centres as possible, while the less valuable ground in the intermediate district points out that locality as for occupation by the main arteries of the empire. Then these main stations, with abundance of minor stations and convenient loop-lines for the use of the outskirts, ought to put the passenger traffic of the metropolis on a sound and practicable footing. This is the end towards which the efforts of the railway companies now tend. The North London line, with the Blackwall and Greenwich lines, and the West London Railway, are links in the chain of loop-lines; the Eastern Counties find their account in adopting the Fenchurch-street terminus. The Thames separates the South Eastern lines from the city at present, and the London-bridge and Fenchurch-street stations must be considered as grouped together. The greatest efforts are now making on the part of the southern, western, and northern lines to obtain a station at Charing-cross, and if the Duke of Northumberland can be prevailed on to give up his mansion and grounds (not now what they were), the noblest site in Europe may be turned to proper use, and London no longer be beaten by Liverpool in the position of her central terminus. The Victoria station for Belgravia will group with the last mentioned centre. But neither the Bank nor Charing-cross can be reached by the Great Northern, North Western, or Great Western railways, except by long detours. Their interests are the same, their power of attracting passenger traffic greater than any others. The land lies vacant in Farringdon-street, or poorly built on in Moorfields, for their stations; and yet session after session passes without their securing a position, the key to the whole metropolis.

To return to the political distinction between the east and the west centres of London, between the city and the court, between commerce and legislature: as there is in reality a medium, so there should be in fact a locality devoted to their mutual action. The administration of justice and the law, while it gives the poor the advantages of the executive government, is the means of returning to the commercial classes great advantages, such as can only be purchased by the steadfast maintenance of the authority of government and by respect to the laws of the realm. The judges of the land are the representatives of the crown. The justice they mete is the test of the honour of the nation. The courts of law should therefore be so situated that the commerce and the executive legislature of the country should have equal access to its halls.

For improving the eastern central stations there are no propositions. The increase of traffic is proceeding; but the divided interest in the London-bridge railways has produced its effect in the great endeavour on the part of the South Eastern line to obtain a better footing at the west-end than its twin brother, the Brighton line, has already obtained through the West-end and Crystal Palace lines, leading into the Victoria station. The East Kent, or direct Dover line, has arranged to run into the Victoria station; and for that reason the South Eastern must come westwards to Charing-cross or elsewhere. There are several schemes for taking the South Eastern to the Victoria station, by southern loop lines; but the scheme which seems to promise most result is that called the London-bridge and Charing-cross Railway. This line starting from the north side of the London-bridge station, crosses over the stream of people at the south side of the bridge, bears south of St. Saviour's, and adopting nearly the line of the originally proposed new street, is connected with the Waterloo station, and crosses the Thames at Hungerford, using the market and adjuncts for its terminus. Any one of the lines proposed to connect the West London Railway with the South Western line would in effect give all the lines north-west and south-west of London opportunity of entering either at Charing-cross or the new Victoria station. Besides the last mentioned line, as affecting the West central stations, there is the South Metropolitan Railway proposing a high level line from the South Eastern, through the southern parts of Lambeth, across the South Western and the river to the side of Victoria-street, Westminster, where a new station was proposed. But the scheme has given way before others having more influential support. The Victoria station and Pimlico line are now constructing: these will give as good a station for Belgravia as the Great Western has for Tyburnia. Hence the schemes having for object the connection of this railway with the western lines by a line from Kensington, either through Chelsea or through Battersea. These western lines rest upon the West London Railway, "*Punch's* line," and each scheme for adapting this railway, and its possession the Kensington canal, also proposes to improve its connection with the Great Western and North Western lines, and to connect it with the Hampstead Junction line. So much for the eastern and western group of stations,—for Paddington station cannot be considered as fulfilling the conditions of a first-rate position. We come then to the central stations which should serve those lines that carry the passengers to the manufacturing districts of the North and Midland counties, to Scotland, and to Ireland. The Metropolitan Railway and Regent's Canal Railway are schemes for this purpose. The enormous traffic conducted at the Fenchurch-street station shows that good management will prevent any confusion; and the advantages to be derived from a station so accessible to business men from all parts of the town, as is the bottom of Holborn-hill, if the law courts settle down near Temple-bar, or as the neighbourhood of Finsbury for city men, especially for long journeys, in place of the present Euston, Paddington, and King's-cross stations, needs no argument; nor would the advantages be less perceptible for local traffic. The decision of this conflict will decide the position of the New Post-office.

Before leaving the railways one further scheme deserves attention, that of the Thames Embankment and Railway. It combines the points recommended in the report of the Improvement Commissioners in 1844, and though urged year after year, is still fighting its way; now with Walker's lines, now with the wharfingers and the hay barges, and in its railway department with the Victoria station and Pimlico, and the King's Scholars' Pond sewer.

In conclusion a few remarks on the various streets proposed to give passage to the traffic of the metropolis. Southwark-bridge requires a new Middlesex approach, and to be made toll free; New Earl-street requires to be continued till it reaches the embankment of the Thames and the "Quai de la Grande Bretagne," or else to be stopped by St. Paul's Bridge-road. The routes to the docks by Tower-hill and Commercial-street require opening; the Spital-fields-street requires extension to Old-street, and in connection with this a continuation of Hart-street and the Oxford-street thoroughfares through the northern confines of the Charter-house; the declivity of Holborn-hill must be overcome; the Mall requires opening into Charing-cross; and a road should be formed across Hyde-park and Kensington-gardens; these and many other improvements are urgently required, and have been suggested by many persons, from Gwynn downwards. The success of either the "Regent's Canal" or the "Metropolitan" Railway will greatly influence the amount of traffic at the east; and the effect of the Charing-cross or Victoria station, or both, as western centres will also be greatly felt; all must admit that this conflict, waging at both ends of London, is a subject of the utmost interest to the profession. We cannot have a straight street from St. Paul's to the Queen's palace in the centre of Hyde-park; that was the dream of Colonel Trench and Philip Wyatt, in 1827; but we can have such a central thoroughfare as shall carry the traffic from

Digitized by Google

Piccadilly direct to the eastern focus, opening up the only fit district for the Law Courts, in such a manner that Cannon-street shall be no longer a pudding-bag, and St. Paul's an obstruction to the traffic. Take down the block of buildings between St. Paul's-churchyard and Old Change; give St. Paul's School a site in Doctor's Commons, in exchange for a thorough opening of the churchyard; and let the hallowing influence of the place upon the living, when they have some chance of admiring its beauties, atone for the utilisation of the sacred precincts. Whatever is done, let it be considered with reference "Usui civium decori urbium," and not be apportioned to the clamour of a metropolitan constituency.

In the Discussion which followed, Mr. RICKMAN said that one of the most interesting points connected with the subject was the junction of the railways on the north side of London with those on the south. This it was proposed to effect by a line promoted by the West London Railway, and approved by the North Western and Great Western companies. Continuing the line of the West London Railway by means of the Kensington canal, which belonged to that line, and then crossing the river, it would be connected with the South Western and the West-end and Crystal Palace line, and thus with the Victoria station at Pimlico. With respect to the improvement of the metropolitan communications, at present a divided authority exists in the Board of Works, the Commissioners of Sewers, and the railway department of the Board of Trade. The arrangements for new streets were governed by the lines of sewers, and were affected by the lines of the railways and the position of the termini. London therefore could not be properly treated as a metropolis, unless the three boards now controlling these important subjects were combined.

M. HECTOR HOREAU considered the subject before the meeting to be not only of the greatest importance to the reputation of the profession, but of much social interest, as tending to afford employment to the working classes. In no city was the circulation of traffic more broken or more encumbered than in London, whilst its amount was increasing more rapidly than that of any other place. The streets and bridges were narrow and insufficient. The latter generally had bad approaches, and encumbered the river by the smallness of their arches. A grand general plan should be prepared, showing all the improvements required; and this would render their accomplishment more easy and economical. It could not be the work of one man; but if the work of many it might be brought into proper shape by the Institute, which could not have a more fitting task. M. Horeau urged the expediency of abattoirs outside the metropolis, and prohibiting the nuisance of live cattle in the streets, and advocated the embankment of the river, in order to gain for profitable use the present mud banks, especially between Somerset-house and Westminster-bridge. A well managed municipal loan, or an *octroi*, might produce funds, which would be increased by opening (without crowding) some of the parks, which at present diverted much traffic from its direct route. This might be termed encroachment, but it would really benefit the working classes by supplying the means of improving their streets and dwellings, still leaving them spacious boulevards through the existing parks for air, exercise, and recreation. By some means or other the bad streets and narrow bridges of the metropolis must be improved, and more imposing public edifices erected than those at present standing.

Mr. HEYWOOD said the subject under discussion was so large that no one could give any consideration to it without finding its enormous difficulty. Mr. Rickman's map proved the utter want of forethought on the part of those who had hitherto been allowed to rule our municipal improvements. The lines upon it were exactly such as might have been traced by a spider escaped from an inkstand. He was no advocate for the American system. Square blocks of streets were no doubt somewhat convenient, economical, and conducive to health; but he preferred "London as it is" to living in a town with streets told off by A, B, C, or first, second, third, &c. A medium however might be devised between the rectangular system and the miserable net-work of modern London. Within the present century only two really great improvements had been carried out; Regent-street, and the New London-bridge, with its approaches. These were great works (effected before railways had taught recklessness in hacking and cutting down), and their projectors deserved the greatest credit. In spite of the now crowded traffic, the approaches to London-bridge must still be considered a great metropolitan improvement. Cannon-street he considered only a local improvement. The west-end centre line of communication and the city central line having been thus provided for, it appeared to him that the next great fundamental want had been entirely lost sight of,—namely, a line to connect the one of these with the other. He was not sure that even this great want was not subordinate to that of throwing open the whole of the toll bridges. At present no one could say what the traffic would do for itself if unimpeded by these obstructions. This measure he had no doubt would immediately relieve London-bridge of one-third of its traffic, and in a very little time even more, thus avoiding the expenditure of £40,000 in spoiling the bridge as had been proposed, and rendering the approaches more crowded than at present. All the small measures that had been projected would only add to the difficulty and expense that must at last be met, and rather than adopt them he would let London-bridge become impassable, in the hope of having Southwark-bridge thrown open, as it might be for £250,000. Of the new streets required, the first as already intimated was one which should commence about the Bank, proceeding between Oxford-street and the Strand towards Hyde-park; and then, the bridges being opened, time might be allowed to see what course the traffic would take for itself, and what might be required next. With regard to the railways as connected with the metropolis, he thought that this branch of the subject had been too long deferred. The late John Martin, the painter, a man of extraordinary power of mind, had long ago projected a system of railways round London, very much like that which was being carrried out. But Martin lived half a century before his time. His great schemes had been deferred till they were far more costly than they would have been when he proposed them, and were now being carried out much less efficiently; because, instead of being accomplished as parts of one system, the lines were formed to suit the particular views of different companies, and the public lost the benefit both of cheapness and time in transit, from the disadvantageous positions of the respective stations. He would not advocate concentration. Two bridges of 50 feet wide would be better than one of 100 feet. Those who were officially compelled to stop the traffic of the street knew, as he did, that such stoppages were not at present likely to be avoidable; and they also knew the inconvenience of stopping a huge traffic without the means of diverting it into another channel. The plan of bringing the northern railways to a station in the valley of the Fleet was admirable in many respects, but he should prefer three termini to one. The width of Farringdon-street, great as it was, would not be sufficient for the continual collecting and discharge of traffic all day, and another more eastern terminus was desirable. He thought there could not be a better plan than that of taking the line of the Regent's Canal and continuing it to as near the Bank as possible. New streets rather than wide ones—in order to give alternative lines of communication—were the first requisite; railway communication across the Thames and the improvement of Holborn-hill were secondary points. He hoped the Board of Works would not spend upon the latter object the quarter of a million proposed, which would be much better employed in opening Southwark-bridge. The Thames embankment would give to London that grand feature of embellishment which it so much required, but at the same time it would be more splendid than useful, and would not render any of the improvements he had referred to unnecessary. The Board of Works should contemplate the question in a broad spirit, and not make streets now which in a quarter of a century would be useless. The subject should be dealt with irrespective of cost. The metropolis was rich enough to find the necessary funds. Excepting the improvements defrayed from the crown revenues, all the great modern works had been done by the corporation of London. He believed that the Metropolitan Board of Works, embodying as it did from its constitution the spirit of parochial economy, as commonly understood, would never be able by the system of direct taxation to carry out the great streets that were necessary, in the way the work should be done to supply the necessities of the population. The Main Drainage must be accomplished, and there were at least two spots shown in the map which were fairly entitled to their parks. Considering these, in addition to opening the bridges, new streets, and increased railway accommodation, he was quite certain that ten millions of money would not accomplish all that was required. The widening of Cannon-street, and the rebuilding of one side only, had cost the corporation three quarters of a million, after allowing for the improved ground rents. This however left them

Digitized by Google

the vacant ground at St. Paul's. The cost of metropolitan improvements should only be spoken of in millions, for the streets he suggested, from the Bank to Hyde-park-corner, must cost nearly or quite a million a mile. The great continental improvements, he believed, were never the result of direct taxation. In France they had the *octroi* duty; and the much abused coal-tax in our own metropolis (which he hoped would not be abolished) bore upon an article consumed by every one, and was collected at a very little cost by a body which had been in organised existence for a couple of centuries. It bore a direct proportion to the means of all; for the coals a man burnt was as fair a measure as possible of his expenditure. Its amount was only 1*s.* 3*d.* per ton, but it produced, without unpleasantness in collection, £240,000 a year. By doubling or trebling this an enormous fund could be provided; but if the coal-tax were taken off, as proposed, in 1860, no persons but brewers and other large consumers—the only classes who at present opposed it—would be materially benefited by the change, and the fund from which the great modern improvements had been made would be lost. To a serious thinking mind the growth of London was becoming fearful! They had not the ignorance of their forefathers as an excuse,—they well knew from the calculations of the last half century, including periods of war and pestilence, that the population of London doubled itself in 37 years. The enormous surface to be covered by the future population was a very serious matter for consideration; for, as the distance of the suburbs from the centre increased, so must the use of carriages increase, until the present London streets would be in one huge state of stricture. No police regulations for traffic, nor any expedient for widening existing bridges by overhanging footways, could do any real good; and whilst the value of property required for new streets was daily rising in value, procrastination must increase their cost enormously. In addition to the coal-tax he thought the tax on carriages might be equitably and fairly given to the improvement of the metropolis. There might be a great struggle for it, but it could not be resisted even by the House of Commons. He believed the time was coming when the enormously increasing population of London must find other centres: but if so, it must be from the impossibility of getting to the large centres in the network of alleys shown on the map, for, in relation to the wants of the population, the streets of the metropolis were really nothing but alleys.

Mr. Pocock agreed with Mr. Heywood's principle of distributing rather than concentrating the traffic; and he had the acknowledgment of Mr. Lambert Jones, that in the approaches to London-bridge that principle had been too much overlooked. About the Mansion-house especially all the streets converged to one point, leading necessarily to great confusion. He differed with Mr. Heywood as to the improvement of Holborn-hill. The heavy van traffic from London-bridge station to the Great Western Railway and north and north-western parts of the metropolis, now passed from Fleet-street through Fetter-lane or Chancery-lane, instead of taking its legitimate course from Cheapside to Holborn-hill; and the formation of a level from Skinner-street to Holborn-hill would keep this traffic in its natural route, and prevent the blocking up of Fleet-street and the Strand. Mr. Marrable's plan for the Holborn viaduct had the advantage over the other scheme of enabling the cross traffic to pass under the viaduct; and if Blackfriars-bridge were to be improved in its gradients, and the declivity of Holborn-hill done away with, the present confusion at the foot of Ludgate-hill would be very materially diminished. The street from east to west proposed by Mr. Heywood was of great importance; but in the city itself another vast improvement might be made by widening the line of Gresham-street, at present almost impassable, and extending it westward by removing the Blue-coat School to the fresh air of the country. Money should not be spent in widening streets, but in making entirely new lines with double instead of single frontages, which rendered it practicable to deal with much less valuable property; and this applied to the line from Skinner-street to Gresham-street, which if carried out would relieve Newgate-street. The line from Liquorpond-street to Old-street, or some other line, was necessary to relieve Holborn. The Bank would always be a focus of traffic, and also Charing-cross; but a great deal of traffic which had no business there went to those places simply because no other routes were open to them. London-bridge was not merely a great metropolitan thoroughfare, but it was the main line connecting Kent and Essex. Much traffic passed over it which need not go into the city at all, or at least might as well go over Southwark or Blackfriars bridges.

Mr. Richard Bell advocated the improvement of the quays of the river; but this was a question of cost. For thirty years past nearly three millions a year had been expended on metropolitan improvements, which, comparatively speaking, had been invaluable; but in order to carry out the improvement of the quays of London the best method would appear to be the adoption of a sort of sliding scale; and to purchase the reversionary interest of the freehold property along the sides of the river to the necessary extent. If a well digested plan of this kind were laid down, money might be judiciously invested so as to secure the possession of part of the property in 40 years, and another part in 80 years. At the same time he should deprecate any encroachment on the water way: he would indeed hardly allow a walking stick to be placed in the bed of the river, nor any new bridges on piers to be erected. The obstruction of a bridge on piers affected the tides a mile and a half down the river. This had been proved by the observations made and recorded twice every day for 18 years by the Dock-master of the London Docks. Money however could not be more judiciously expended than in making a good wide quay along the river, by which, amongst other advantages, the passenger traffic from Westminster to the city would be accommodated. Mr. Bell then explained (referring to the map) his proposal for a railway station on the site bounded by Little Moorfields, Milton-street, Fore-street, and Chiswell-street, to be reached by adopting and extending the line of the Regent's canal. This, he observed, would relieve the Holborn line of the traffic from Notting-hill and the north-western suburbs, which at present took that route in preference to the nine miles circuit of the North London Railway, as it would bring it much nearer the Bank. He then proceeded to explain his proposed adoption of the line of the Regent's Canal to Limehouse, and thence by a tunnel, with a gradient of 1 in 150, under the London Docks, using the Thames Tunnel, and joining the southern railways at New-cross. He described the advantages of this plan in relieving London-bridge; and urged the superiority of Fore-street to Farringdon-street as a city railway terminus, in reference to the levels and other circumstances, particularly the narrowness of Newgate-street, and its inadequacy for large traffic from a Farringdon-street terminus.

Mr. C. H. Smith strongly urged the great importance of improving rather than injuring the river, and advocated the embankment of the stream throughout. At present, whilst the narrowness of the river in some parts gave force and rapidity to the current there, carrying onwards the matters in solution, —in the wider parts, as at Hungerford, not only was the mud deposited on the banks, but the stream became so shallow as to be almost useless for purposes of traffic. The Thames being made more available for goods traffic, the streets of London would in consequence be greatly relieved. In any future act of parliament unlimited power should not be placed in the hands of any one individual. This had however been done in the case of the Regent-street improvements, and the consequence was that at the junction of Regent-street and Portland-place there had been a divergence from the straight line originally contemplated.

Mr. O. Hansard urged the advantage of a street from the Quadrant, taking the line of Leicester-square, and so—by a widening of Drury-lane—to the Strand, at St. Clement's Church. This would relieve the Holborn line, and render Blackfriars-bridge, instead of London-bridge, the leading thoroughfare for traffic going to the south side of the river. He also referred to Gwyn's plans for London improvements, published 100 years ago, in which a bridge next Somerset house, and many of the plans now carried out, were anticipated.

Mr. Cates referred to and explained Mr. Pennethorne's plan for a line from New Coventry-street, by Long-acre, crossing Drury-lane, by Carey-street, the new Record Office, Farringdon-market, over Farringdon-street by a bridge, and terminating at the General Post Office. This would save the expense of altering Holborn-hill. He illustrated, by reference to the same plan, the extreme difficulty of laying out a line in this direction without interfering with the numerous public institutions which stood in the way of an absolutely straight line.

Mr. Godwin begged to say one word in fairness, to emphasise the importance of the projected extension of the West London Railway. This would give the Great Western and North Western railways the important advantage of access to the Pimlico station; and, if an act were obtained (for which strong interest was being made), to Charing-cross, the project would join the whole of the

Digitized by Google

lines north of the Thames with those on the south, and remove the absurdity of the present railway system of the metropolis. London was the only town in the United Kingdom in which a person wishing to pass through it from one railway to another was compelled either to stop at an hotel or take a cab from one station to another. The West London Railway had been exposed to the greatest obloquy, yet now no less than five projects had been submitted to Parliament this session in order to render it available, and three of them had passed the standing orders committee. This should serve as an encouragement to all who conceived a good idea, to submit even for years to the scoffs and ridicule of a large majority against them. The West London line thus extended, must one day be a good line. The North Western Railway Company, he believed, had agreed to subscribe £100,000 to the scheme, which would unquestionably materially relieve the traffic of the streets of London.

ELY CATHEDRAL.

It is proposed to restore the central octagon and lantern of this cathedral as a memorial of the late Dean Peacock, from a twofold motive, it being the portion of the fabric which appears naturally next to claim attention, and also that to which the energies of the late Dean had been for some time directed, and which he was so anxious to see completed, as may be gathered from a statement he drew up and issued in 1853, respecting the works already finished in Ely Cathedral, and those which then remained to be carried out. In this statement the following passage occurs:

"Of all the works which remain to be undertaken, the most considerable and the most important is the restoration of the lantern, including the decoration of the vault, the substitution of windows of an appropriate character for those which now disfigure it so seriously, and the addition of the outer corona of turrets and pinnacles as originally designed by Alan de Walsingham."

In the course of last summer the late Dean was engaged in preparing another account for the public, enumerating in detail the works executed since 1853, from which it will be seen that the restoration of the octagon and lantern was still, in his view, the chief undertaking to be accomplished for the completion of the great work of improvement. The eight windows of the upper octagon, which are now examples of the meanest description of "carpenter's gothic," were reduced (probably by Essex) from four lights to three, and shortened more than three feet; the footings of the mullions and jambs of the windows are still in existence, so as to leave no doubt about the possibility of their correct restoration, though there exist no corresponding means of restoring the tracery. No difficulty would, however, present itself in the restoration of the painting of the vault, as the traces of the ancient decorations, both in outline and colour, are too manifest to be mistaken.

The case is very different with respect to the outside of the octagon (the whole of which, it may be observed, is constructed of wood), the upper timbers of which are in a ruinous state, and which has undergone so many changes from the repeated patchings rendered necessary by the decay of the materials (so little calculated to resist the action of the weather) that it would be impossible to reproduce with certainty its original form. In some ancient prints representing the cathedral, flying buttresses are indicated, and the forms of the upper tier of windows are altogether different from the present; but such representations are generally so vague and unfaithful that they are of little or no use in aiding the restoration even of the ancient features, much less the details of the architecture. If the design of the great architect Alan de Walsingham had been perfected, eight lofty turrets at the angles of the greater octagon, and four lofty pinnacles in the middle of its four larger sides, connected by a double range of open parapets of an enriched character, would present a corona of singular beauty and boldness, concealing altogether, or nearly so, the smaller octagon within, and rendering the architectural details comparatively unimportant.

A resolution has been lately passed by the Dean and Chapter authorising Mr. Scott, the architect to the cathedral, to prepare a plan for the restoration of the octagon and lantern, in order that this work may be undertaken forthwith as the most fitting public memorial of the zeal, energy, and liberality displayed by the late Dean in the great improvements executed under his superintendence in the eastern and western portions of the fabric. A committee has also been formed for the purpose of promoting the work.

ON THE RELATIVE POWER OF METALS AND ALLOYS TO CONDUCT HEAT.—*Part I.**

By F. Crace Calvert, F.C.S., and Richard Johnson, F.C.S.

Metals and their alloys being now so extensively employed in arts and manufactures, and for instruments of precision, we have thought that it would be interesting, in a scientific or commercial point of view, if we were to examine their conductibility carefully and completely.

To enable us to determine with accuracy the conducting power of all the ordinary metals, and of seventy of their alloys and thirty of their amalgams, we had to find out a new method of determining the conducting power of metals; for the process followed by M. Despretz could only give results to be relied upon for a few of the best conductors, such as silver, gold, and copper. Further, his process, which consists in having a long and thick bar of metal, so as to allow holes to be drilled, in which mercury and the bulb of a thermometer are inserted, would have required a large quantity of each metal in a state of purity, the labour of obtaining which, even comparatively pure, is well known. Also from the fact of mercury being employed, we should have been unable to ascertain the conducting power of such important alloys as brass and bronzes, and could not have applied to the process of amalgams.

The method which we have followed gives such consistent results, that we have not only been able to determine the influence exercised on the conducting power of metals by the addition of one or two per cent. of another metal, but also to appreciate the difference of conductibility of two alloys made of the same metals, and only differing by a few per cent. in the relative proportions of the metals composing them. At the same time the conditions theoretically required in order to obtain results independent of everything but the nature of the substances, are not very rigorously fulfilled, so that the term "conducting power" as used by us must be understood in a somewhat qualified sense, and as having relation to our method of determining it. We believe, however, that the ratios of the conducting powers as determined by our method do not differ from those of the real conducting powers.

The apparatus which we used is composed of a deal box with a cover, and painted white externally and internally. Inside this box are two vulcanised india-rubber square vessels; the larger vessel, B, is capable of containing 336 cub. cent. of water. The smaller vessel, C, has a capacity of 90 cub. cent.

All sensible radiation and conduction were avoided, and the rise of temperature in this vessel during the experiment must have been entirely due to the heat conducted by the square bar of metal used. This bar is 6 centims. long and 1 centim. square, and is so arranged in the experiment, that 1 cub. cent. is in the vessel B, 1 cub. cent. in the vessel C; 3 cub. cent. are covered by the sides of the boxes through which it passes; and the last 1 cub. cent. is covered with a piece of vulcanized india-rubber tubing, and the whole made secure from any leakage by lining the sides of the holes, through which the bar passes, with a varnish made of caoutchouc dissolved in benzine. The bar is placed 54 millims. from the bottom of B, and 12 millims. from the bottom of C.

A small jet of steam, generated in a flask, the water in which is kept boiling during the whole of the experiment, enables the operator to keep up a constant temperature of 90° in the vessel B, during the quarter of an hour which the experiment requires. The operator looks attentively at the scale of the thermometer in vessel C, and as soon as he perceives the column of mercury rising, he carefully marks the second and minute dials of his watch, and makes similar marks fifteen minutes further on. It must be borne in mind that it was not the absolute quantity of heat communicated to the bar in vessel B which was determined in vessel C, but the relative facility of conduction by various metals, all circumstances being the same. The best proofs that we can give of the accuracy of the process are—1st, that the series of alloys which conduct heat in the ratio of the equivalents of the metals composing them would not have shown such a coincidence between the observed and theoretical results if our process had presented any serious defects. 2nd, that we have been able to determine with accuracy the marked influence exercised by the addition of 1 per cent. of a metal to another metal. 3rd, it will be seen further on in the paper, that we have determined with precision, that in copper bars, having different conducting surfaces, the observed result agrees with the calculated one.

* Abridged from a paper read before the Royal Society.

As the determination of the power of metals to conduct is of great importance, a detailed record is given of the results obtained; the following are some of them:—

Name of the metals.	Temperature of the 50 cub. cent. of water before beginning.	Temperature of the 50 cub. cent. after 15 minutes.	Conductibility found.	Mean.	Conductibility. Silver=1000.
Silver 1000/1000 ...	19·8°	51·6°	31·8	31·9	1000
	19·7	51·7	32·0		
Gold 1000/1000 ...	14	45·4	31·40	31·30	981
	13·6	44·8	31·20		
Gold 99/1000 ...	20·3	47·3	27·	26·80	840
	20·3	47·0	26·7		
	20·	46·7	26·7		
Copper (rolled)	19·5	46·3	26·8	26·95	845
	20·	47·1	27·1		
	21·	48·0	27·		
	20·5	47·45	26·95		
Copper (cast)	21·30	47·2	25·90	25·87	811
	21·45	47·3	25·83		
Zinc (rolled)	18·4	39·0	20·6	20·45	641
	19·9	40·2	20·3		
	18·5	38·9	20·4		
Zinc (cast vertically)	19·6	39·8	20·2	20·03	628
	19·2	39·1	19·9		
	14·0	35·	20·		
Zinc (cast horizontally)	20·6	40·	19·4	19·40	608
	20·8	40·2	19·4		
Malleable iron	18·70	32·6	13·9	13·92	436
	19·05	33·	13·90		
Tin	20·5	34·	13·55	13·45	422
	21·2	34·6	13·4		
Steel	15·2	27·8	12·6	12·65	397
	15·5	28·2	12·7		
Cast-iron ...	14·9	26·4	11·50	11·45	359
	15·6	27·0	11·40		
Lead	20·5	29·70	9·20	9·17	287
	18·3	27·45	9·15		

Influence of Molecular Condition.

We found that the conducting power of several metals was different when they were rolled out into bars, or when cast. Thus for example,—

	Conductibility found.	Conductibility. Silver=1000.
Rolled copper	26·95	845
Cast copper	25·87	811

It is probable that the reason why rolled metal conducts heat better than the same metal when simply cast, is that the molecules composing the rolled metal are in closer contact than those composing the cast metal, owing to the process of rolling; and it is worthy of observation, that this view agrees with Mr. J. P. Joule's theory, that heat travels in bodies by the vibration of matter, and not by the fluid called caloric travelling between the interstices of the molecules.

Influence of Crystallisation.

The influence of the molecular arrangement is clearly illustrated in the following examples, where it is seen that the conducting power of zinc, antimony, and bismuth is modified according to the axes of crystallisation. Thus the conducting power of zinc is different if the sample for experiment is cast horizontally or vertically; for example,—

	Conductibility found.	Conductibility. Silver=1000.
Zinc cast vertically	20·03	628
Zinc cast horizontally	19·40	608

If these two square bars be broken and examined, they present a very great difference. The one cast vertically has four axes of crystallisation, all starting from the centre and proceeding towards each angle of the bar. The one cast horizontally has one centre line or axis of crystallisation, which divides the square bar into three parts.

The results obtained with antimony are the following:—

	Conductibility found.	Conductibility. Silver=1000.
Antimony cast vertically... ...	6·12	192
Antimony cast horizontally ...	6·85	215

We shall refer to the extraordinary influence exercised by crystallisation on conduction of heat when we examine some of the alloys.

Influence of small amounts of Impurities on the Conducting Power of Metals.

We have thought that it would be useful to ascertain the influence which 1 per cent. of a metal exercises when added to another, and these are the curious results obtained with gold and silver:—

	Conductibility found.	Conductibility. Silver=1000.
Pure gold	31·31	981
Gold with 1 per cent. of silver ...	26·80	840

Therefore the addition of 1 per cent. of silver, the best conductor, to gold, diminishes its conducting power nearly 20 per cent.

We have observed much more marked examples of the diminution of conductibility of a metal by the addition of 1 per cent. of another metal; for example, whilst the conducting power of pure mercury is 21·60, it is only 13·15 when amalgamated with 1·25 per cent. of tin. Professor W. Thomson having lately discovered that a small quantity of various metals added to copper greatly modifies the conduction of electricity by this metal, we deemed it advisable to try if the conduction of heat by copper would also be altered if we were to alloy it with 1 per cent. of various other metals. We were fortunate enough to obtain results which coincide with his, namely, that some metals increase the conduction of heat by copper, whilst others diminish it.

We have also examined the influence which carbon exercises on the conductibility of iron, and we hope that the results observed will prove useful in a commercial point of view; for as seen by the figures obtained, the difference is about equal to 18 per cent. The following are the results:—

	Conductibility found.	Conductibility. Silver=1000.
Malleable iron	13·92	436
Steel	12·65	397
Cast iron	11·45	359

We have also made a great variety of experiments with the view of ascertaining if there be a general law in connexion with the conduction of heat by alloys, and although we could not trace any general rule, still we observed several useful facts.

The conduction of heat by alloys may be considered under three general heads:—

1. Alloys which conduct heat in ratio with the relative equivalents of the metals composing them.

2. Alloys in which there is an excess of equivalents of the worse conducting metal over the number of equivalents of the better conductor, such as alloys composed of 1Cu and 2Sn; 1Cu and 3Sn; 1Cu and 4Sn, &c., and which present the curious and unexpected rule that they conduct heat as if they did not contain a particle of the better conductor; the conducting power of such alloys being the same as if the square bar which we were examining was entirely composed of the worse conducting metal. A not less remarkable fact is that the alloys of a series such as those of 2 equivalents of bismuth and 1 of lead, 3Bi and 1Pb, 4Bi and 1Pb, 5Bi and 1Pb, all conduct the same, viz., about 1·9, the various increasing quantities of lead exercising no influence on the conductibility of the alloys. The results obtained with this class of alloys are most important to engineers; for it will be seen in the case of the alloys of brass and bronze, that no increase is gained in the conductibility of an alloy by increasing the quantity of a good conductor; nay, in many cases it would be a decided loss, unless a sufficient quantity of the better conducting metal be employed to bring the alloy under the third head.

3. Alloys composed of the same metals as the last class, but in which the number of equivalents of the better conducting metal is greater than the number of equivalents of the worse conductor; for example, alloys composed of 1Sn 2Cu; 1Sn 3Cu; 1Sn 4Cu: in this case each alloy has its own arbitrary conducting power; the conductibility of such an alloy gradually increases and tends towards the conducting power of the better conductor of the two metals composing the alloy.

Before describing the experiments which relate to these three classes of alloys, we deem it advisable to state, that from the numerous assays which we have made, we are led to believe that the conduction of heat by alloys is greatly modified by the crystalline system to which each of the metals composing them belongs, or by the peculiar crystalline form of its own crystals; for we have observed that some of the crystallised alloys of copper and tin, and copper and zinc, have a special conducting power of their own; whilst the alloys which present little or no crystallisation have a conductivity which is in ratio to the equivalent quantities of the metals composing them.

The method which we have followed to calculate the theoretical

Digitized by Google

conducting power of our alloys is the following:—Multiply the per-centage quantity of each metal by the respective conducting power of that metal, add the results together and divide by 100; for example, in the alloy Pb 3Sn,

Pb 36·99 × 9·17	= 339·19
3Sn 63·01 × 13·45	847·48
	100)1186·67

11·86 (theoretical conducting power of alloy.)

Class I.—The first class of alloys are those which conduct heat in the ratio of the conductibility of the metals composing them. This class is represented by the alloys of tin and lead, and tin and zinc.

These alloys are the only ones which conducted heat as above stated; and from experiments which will be described further on, we believe that the metals composing these alloys are simply mixed, and not combined together.

Class II. Alloys containing an excess of the worse conducting metal.—The study of this class of alloys being most interesting, we have made many experiments in order to discover why the presence of one metal completely annihilates the conducting power of the other, especially when the latter is the better conductor of the two.

It will be perceived, on looking over the results obtained from experiments on alloys of lead and antimony, that all these alloys conduct heat almost as if the square bars examined were composed of pure antimony, the conducting power of which is 6·12; for if lead, which has a conducting power of 9·17, had influenced the passage of heat through the bars, the conducting power of the alloys would have been much higher, as shown by the column of theoretical conductibility.

The same results were obtained with the series composed of bismuth and antimony.

We now describe the most important series of this class of alloys, namely, that consisting of those composed of tin and copper.

Copper and Tin.

Formula of the alloys and percentage.	Conductibility found.	Mean.	Calculated.	Silver = 1000. Found.	Silver = 1000. Calculated.
Cu = 34·98 Sn = 65·02	13·2 13·3	13·25	17·80	415	558
Cu = 21·21 2Sn = 78·79	13·8 13·7	13·75	16·08	431	504
Cu = 15·21 3Sn = 84·79	13·6 13·4	13·50	15·33	423	481
Cu = 11·86 4Sn = 88·14	12·8 13·1	12·95	14·92	406	468
Cu = 9·73 5Sn = 90·27	12·6 12·7	12·65	14·65	396	459

It is very interesting to observe, that although these alloys contain such different quantities of copper, viz. from 9·73 to 34·98, and this of a good conductor of heat, still no influence is exercised by it on the conductibility of the alloys, for they all give the same results as if the square bar experimented upon were composed of pure tin. Another fact, which increases the importance of the bronze alloys, is the difference which they present in their conductibility when they contain an excess of copper, not only with regard to the above series, but also between each alloy, all of which have a conducting power of their own.

Copper and Tin.

Formula of the alloys and percentage.	Conductibility found.	Mean.	Calculated.	Silver = 1000. Found.	Silver = 1000. Calculated.
Sn = 38·21 3Cu = 61·79	15·7 15·8	15·75	21·37	494	670
Sn = 31·73 4Cu = 68·27	4·9 5·1 4·95 4·90	4·96	21·88	155	686
Sn = 27·10 5Cu = 72·90	6·5 6·6 6·6	6·6	22·50	207	705

The results obtained with Sn 4Cu were so extraordinary that the experiment was carefully repeated; but with the same results as before.

We concluded that an alloy of tin and copper containing 68 per cent. of the latter metal, has a conducting power five times less than it should have according to theory. From the above results it is highly probable that these alloys of tin and copper, and especially the three last, are definite chemical compounds; for if they were mixtures, they would conduct heat in ratio to the equivalents of the metals composing them, and would not each have a peculiar and different conductibility. These views are substantiated by experiments which we have made with square bars composed of sectional parts of copper and tin.

These results appear to us perfectly to substantiate our views, viz. that these alloys are definite chemical compounds, and not a mixture of metals; for if they were the latter they would conduct heat as the bars, and would not have a conductibility of their own. With bars composed of a row of cubes of copper and tin soldered together in various orders, the conductibility was nearly the theoretical conductibility of an alloy containing the like proportion of the two metals.

Notwithstanding these facts, we were not prepared for the curious results which we obtained with a bar composed of two longitudinal bars of tin soldered to two of copper, and placed in juxtaposition; for although it contained in 100 parts the same weight of tin and copper as the bar in which cubes of copper and tin alternated, it conducted heat at quite a different rate; in fact, its conductibility was the same as if the bar was entirely composed of pure copper, and did not contain half its bulk of tin.

These interesting results were confirmed by having similar bars made of copper and zinc, and copper and lead.

Class III. Alloys in which there is an excess of the good conductor.—Having already described the peculiar properties presented by four of the bronze alloys, viz., those of Sn 2Cu, Sn 3Cu, Sn 4Cu, and Sn 5Cu, we should have nothing more to add to them, if we did not wish to illustrate the extraordinary influence which tin exercises on the conductibility of copper, and also to show that when there is a great excess of a good conductor in an alloy, it overcomes the resistance of the bad conductor, and in consequence the conductibility of such alloys increases with the proportion of the good conductor.

	Obtained.	Calculated.	Silver = 1000. Obtained.	Silver = 1000. Calculated.
Sn = 27·10 5Cu = 72·90	6·60	22·50	207	705
Sn = 15·68 10Cu = 84·32	9·80	23·90	307	749
Sn = 11·03 15Cu = 88·97	12·82	24·50	402	768
Sn = 8·51 20Cu = 91·49	14·85	24·81	465	778
Sn = 6·83 25Cu = 93·17	15·15	25·02	475	784

Alloys of Zinc and Copper.

The reason why we have kept these alloys all together, and have not divided them so as to bring them under the last two divisions, is, that they have a tendency to come entirely under the last division. We say a tendency, for they do not offer the distinctive degrees of conductibility that the alloys of copper and tin or bismuth and antimony present; but this may be due to the conducting powers of copper and zinc being within a few degrees of one another,—cast copper being 25·87; cast zinc 20·03.

Conductibility of Copper and Zinc Alloys.

	Obtained.	Calculated.	Silver = 1000. Obtained.	Silver = 1000. Calculated.
Cu = 49·32 Zn = 50·68	21·95	22·92	688	718
Cu = 32·74 2Zn = 67·26	13·65	21·91	428	687
Cu = 24·64 3Zn = 75·36	16·95	21·44	531	672
Cu = 19·57 4Zn = 80·43	18·80	21·14	589	663
Cu = 16·30 5Zn = 83·70	19·00	20·95	595	657

Digitized by Google

It is probable that Cu 2Zn and Cu 3Zn are definite compounds, for not only have they a special conducting power of their own far below that of the metals composing them, but also they are perfectly crystallised. The most splendid of all the brass alloys is the alloy CuZn, which is of a beautiful gold colour, and crystallises in prisms often 3 centims. long. These crystals are also interesting on account of their extraordinary elasticity. It is surprising that so cheap an alloy has not been employed in commerce, for no commercial brass contains more than 30 to 35 per cent. of zinc, whilst the above one contains 50·68 of this metal. The only explanation that we can give of this fact is, that if copper be alloyed with more than 50 per cent. of zinc, the alloys formed do not possess the colour of brass, but become white as zinc, and therefore the manufacturers have never tried to unite these metals in the exact proportions given above. We say exact, for it is remarkable that a variation of a few per cent. in the relative proportions of the two metals no longer yields the beautiful alloy which we have noticed, but only a white and comparatively useless one.

We also thought that it might be useful if we were to analyse the following commercial alloys, and determine their respective conducting powers.

		Found.	Calculated.	Silver =1000. Found.	Calculated.
'Yellow brass' ...	Cu=64·0 Zn=56·0	17·80	22·73	558	712
'Pumps and pipes'	Cu=80·0 Sn= 5·0 Zn= 7·5 Pb= 7·5	13·60	22·57	426	707
'Mud plugs'	Cu=80·0 Sn=10·0 Zn=10·0	12·60	24·00	394	754
'Large bearings'	Cu=82·05 Sn=12·82 Zn= 5·13	11·00	23·97	345	751

It is extraordinary to find what a low conducting power these alloys possess; for with the exception of the alloy named "yellow brass," they do not conduct heat better than wrought and cast-iron. This is due to the impurities of the metals employed, and shows the advantage that there will be in substituting for them some of the much cheaper alloys above described.

ON DESIGN IN INTERIOR ARCHITECTURE.*

By Sydney Smirke, A.R.A.

(*Concluded from p.* 103.)

But it is time to quit this subject of staircases, and I hasten to enter the apartments to which they lead. Let us first, however, stay our steps for a few minutes, and parley on the subject of the passage or corridor, that we have to traverse before entering the apartment.

Good taste, and indeed common sense, seems to point out the propriety of rendering the architectural aspect of a passage somewhat conformable in style and treatment with the more important object to which it leads, whether it be a church or a chamber. The eye and the mind would thus be in some measure prepared for, and attuned to the subject upon which it is about to be exercised; care, however, being always taken to keep this passage subordinate and comparatively subdued, so that no danger may be incurred of disappointment. Many modes present themselves of giving architectural effect to this passage; variety of light and shadow is an important means of doing so. We all feel the beautiful effects of this variety in natural scenery,—those glimpses of sunshine, those alternations of gloom and cheerful daylight, which are such charming incidents in a forest scene. Analogous effects are obtainable in our own art. A long passage may be greatly diversified by a judicious breaking up of its length with alternations of *chiaroscuro*. With the same object in view—of diverting the attention, and relieving the monotony of a long corridor—we may often perceive the advantage of placing an object of interest for the eye to dwell on, such as a picture or a piece of sculpture at its termination, or at a turn in its course.

In Italy, where our art was always so intimately related to the painter's art, and where the architect scarcely ever failed to see his object with a painter's eye, examples of these tasteful arrangements abound. The most beautiful passage in the world is probably that which Raphael designed, and, with his pupils, executed at the Vatican Palace. Independently of its frescoes, of world-wide celebrity, the proportions of its arches and piers give it an unspeakable grace. Yet, beautiful as it is, the subordination to which I have just adverted has been so well observed that the stanze to which it gives admission lose nothing whatever of their beauty by the contrast; that beauty being of a grander and more elevated character. Whilst on the walls and vaulting of this corridor are depicted light arabesques and playful ornaments, the walls of the stanze bear some of the grandest masterpieces of the genius of painting.

In the vaulted corridors which surround the great Flavian amphitheatre we have another very remarkable instance of correct judgment in our art; a most dignified work of architecture, and strictly consistent in character with the great building of which it forms a part.

There can be little doubt that the imposing corridors which surrounded this, the greatest as well as the most popular public building in the ancient metropolis of the civilised world, were repeated over the whole empire, and became not only the model on which all other works of a like nature were subsequently erected, but the fertile parent also of those beautiful arcades which so frequently court our admiration in works both of the middle and the later ages.

These are indeed two pre-eminent examples which I have cited; and it may be thought, that as in moral training deeds of heroic daring seem to be almost discouraging examples to set before ordinary minds, which need rather lessons of conduct in ordinary life, so those noble works of the highest grades of art, it may be thought offer no available materials for our imitation or study in fulfilling the humbler tasks that fall to the lot of most of us. It is not so however; a right principle is applicable alike to great things and small; and I consider that the rule to which I have just adverted, and which I wish to urge on your attention, viz., that which teaches us to render easy passage conformable in style yet subordinate in treatment to the apartment to which it leads, is of universal application. Let us now proceed to the consideration of those apartments towards which we have been advancing.

There are few objects connected with our art that have been more frequently dwelt on by those who have undertaken to be our guides and monitors, than the right proportions to be given to rooms.

Vitruvius led the way, and subsequent theorisers have laid down, sometimes very dogmatically, their views of just proportions. I find, however, in the actual practice of the ablest men such extreme diversity, and I observe pleasing effects producible by the adoption of such widely different proportions, that I find myself, I confess, much inclined to be somewhat incredulous of all these theories. Certainly if beauty could be thus reduced to a formula, and the proper relation indisputably established between the length, breadth, and height of every room, a royal road would be cleared for us, which would be at least very convenient both to those who teach and to those who learn. I fear I can scarcely hope to furnish you with such a desirable help in your studies. I find rooms of universally admitted beauty, yet of almost every geometrical figure. I have heard of the room in the museum of Florence, the Tribune it is called, which contains the Venus di Medici, spoken of in terms of rapturous approval for the beauty of its form and proportions: this saloon is an equilateral octagon on plan. I have known square rooms greatly admired,—such for example as the saloon in Cobham Hall, which is usually pointed to as one of the *chefs d'œuvre* of Inigo Jones. Who is there that is not charmed with the proportions of the Pantheon at Rome? This, you know, is circular. The classical teacher of our art, Vitruvius, seems to contemplate only rectangular forms, and directs us to adapt the double cube and the cube and a half, whether for a temple or a trichlinium. The Sistine chapel, attached to the Papal palace, upon which the best art of Italy in its best days was expended, is a triple cube, viz., 133 by 44. Whilst of modern French, Italian, and English teachers, each seems to have his own special favorite proportion.

The truth I believe to be, that so bounteously have we been

* Lecture delivered at the Royal Academy.

Digitized by Google

endowed, and so liberally have the laws of beauty in form and proportion been framed, that there exists in fact an endless variety of beautiful forms and proportions. My impression is that it is as little consistent with truth to lay down any one definite form or proportion as the best, as it is to extol any one particular curve as the line of beauty. I believe that there are as many pleasing proportions to be given to rooms, as there are pleasing harmonies of colour and sound.

The purpose of a room must always be an important guide in determining the form and proportions to be given to it. If planned so long in proportion to its width as to remind us of a passage, it loses its distinctive character, and creates a false impression, which it can never be good art to do. It is indeed obvious, that a consideration of the special fitness of a room for its destined uses must always greatly influence its proportions. The octagon form, so much affected by our ancestors in planning their chapter-houses, owes its origin probably far more to the propriety of that form for a chamber intended for the convenient assemblage of the members of the chapter sitting in council, than to any intrinsic architectural beauty, however unquestionable that beauty may be.

This fitness to its purpose should, in truth, be among our very first objects of consideration in designing a room. But it is the diversity of those objects to be kept in view which complicate our art, and render the task of an architect often very difficult. In a public hall, for example, he has to consider not only its agreeable proportions, but its acoustic properties: its aptness for seeing; its capacities for lighting and ventilation; the most serviceable distribution of its means of ingress and egress; and indeed many other considerations: among all which he has to attach to each its relative importance, to determine correctly and judiciously to what extent one object may give way to another, and where a sacrifice can best be made. Unfortunately for our art, whilst these conflicting considerations are taxing the judgment of an architect, the critic stands by regardless of all these embarrassments, and tests the beauty of our work perhaps by the inflexible rules of the dogmatist on whom he may have happened to pin his faith. I am however very far from being inclined to say that the proportions of a room are æsthetically arbitrary.

Were I myself disposed to dogmatise on this subject, I should say that whatever form may be given to a room it should be a definite, unambiguous form, and there should be no doubt as to the nature of its apparent proportions. If square, it should be truly square; and if it depart from the square that departure should be obvious and decided. For the same reason I should condemn a slightly oval form, or an octagon with two parallel sides slightly elongated. It is obvious that for the same reason all rhomboidal plans, and any other anomalous departure from regular rectangular figures offend the eye. In these however and other like matters we must consult the genius of the place, and submit to be overruled by necessity and expediency.

In thus recommending symmetrical forms, I must by no means be understood to urge on you the constant adoption of simple geometrical figures. Beauty and convenience alike suggest variety in the boundary lines of an apartment, especially an apartment adapted to social uses. The deeply embowed recesses that occur so often in our own domestic architecture—far more so indeed than in continental architecture—are a source of great beauty, varying the lights and shadows, and breaking the monotony of parallel lines.

The oriel window of our old halls and mansions, whatever may have been its purpose, is always a pleasing feature, and the deep bays in the principal galleries of those picturesque mansions happily concealed their usual comparative narrowness. "These be pretty places for conferences," says Lord Bacon; and his remark in a lively and agreeable way truly indicates the commodiousness of those cheerful recesses.

The Italian masters, with too sensitive an eye not to be struck with the hardness and dryness of an equilateral rectangular form of room, adopted not unfrequently a very happy and effectual mode of concealing, correcting, or obviating it, by converting the upper part of the room into an octagon, supporting the walls at the angles either by arches or niches, without any material encroachment on the area of the rectangle. This contrivance is in truth of early date. At the Castelle dell'Uovo, at Naples, is a very stately hall, of magnificent dimensions, where this expedient has been most effectively and strikingly carried out.

In ecclesiastical architecture this corbelling over is of frequent occurrence. Wherever indeed an octagon lantern or spire is placed on a square tower, a false bearing is produced that almost necessitates such a mode of construction. This mode of growing an octagon out of a square led to a variety of contrivances for the decoration of the couch, or spandrel space, formed by the overhanging of the four diagonals; among which contrivances, perhaps the most ingenious and elaborate, if not the most beautiful, were the pendentives devised by Saracenic architects, whereby the soffit of the couch was sculptured into a multitude of very small groined arches, rising in a succession of tiers, corbelling over, and forming those singular stalactitic ceilings so characteristic of Moorish and Saracenic architecture.

The most usual form of ceilings in the Classic era, where the spans were great, continued for a long time to be the vault. The remains at Pompeii, and indeed of Roman art over all Europe, show that the semi-cylindrical vault was the customary mode of construction; often varied however by groining.

The diagonal lines of this cross-vaulting were usually executed by Roman builders in a careful way with well-jointed masonry or brickwork, the spandrels being filled in with a more rudely worked and lighter material.

It was from this particular mode of workmanship that mediæval vaulting was derived: the more solid diagonals becoming still more visibly and strongly pronounced, first appearing as square ribs, and ultimately assuming the more familiar aspect of ribbed vaulting; the spaces between the ribs being built, as in the Pantheon and other Roman buildings, with sometimes volcanic scoria, and sometimes tufa. So in mediæval buildings—as at Glastonbury and elsewhere—a sort of calcareous tufa, and still more commonly of chalk, was used.

It is not however to be forgotten that during the whole of these periods, from the Greek era and earlier, downwards, flat ceilings of timber may have never ceased to be formed, although their perishable nature has deprived us of existing examples. We read in Homeric buildings of beams painted in bright colours, and even encased in plates of ornamental metal-work; but we can now trace only indications of their existence in the apertures left in the masonry for their reception. In later Classic times representations of flat timber ceilings occur not unfrequently in frescoes. In the fifteenth century—by far the most actively inventive period of modern art—Italian architects contrived an entirely novel form of ceiling, for which neither Classical nor Mediæval art had furnished the slightest precedent. They reconciled the convenient form of the flat ceiling to the equally familiar but more elegant form of the vaulted ceiling, by uniting with the former a deep cove, or half-vault, springing from the walls. This was first executed in wood,—the earliest examples of which, so far as I know, occur at Venice, as at the Academy; but afterwards these coves came to be formed in plaster,—a mode of construction that hardly can date earlier than the beginning of the sixteenth century. It must be admitted that there is a want of truth in this coved form of ceiling, for which the only plea in justification is the very pleasing mode it affords of obviating the heavy depressed appearance of a flat ceiling. Attempts were made it is true to obtain, in a more truthful mode of construction, somewhat the same effect by turning in masonry an extremely flat elliptical vault. But Sansovino, who ventured this expedient in the Libraria at Venice, was thrown into prison and fined 1000 scudi for his failure,—a fate which must have powerfully operated on the minds of his brother artists in overcoming their scruples bout plaster coves.

Another mode of forming ceilings which was much practised by early Italian artists, was to frame them of deep coffers wholly of wood, often richly painted and gilt. There are few palatial apartments within my own knowledge equal in grandeur of effect to the magnificent halls (now in a melancholy state of decay) of the palace built at Mantua by Giulio Romano. The ceilings are for the most part so constructed, and the gigantic force of their coffers, relieved by the extreme richness of their carving, proclaims the master-hand of the great artist who designed them. At Venice, and at the Farnese palace at Rome, we have also very noble examples of this form of ceiling.

In the nearly contemporary flat coffered ceilings executed in England by Holbein, as in the Chapel Royal, St. James's, and probably by the same master in the Savoy Chapel, we have ceilings designed on the same principle, although but weak and faint imitations; yet even these are almost bold when compared with the ceilings lineally descended from them in later times. The Stuccatori of the last century discarded this coffered and tra-

Digitized by Google

beated form of ceiling, and introduced a more playful fantastic style of decoration, better suited to their special material; until, towards the close of the century, their art in its turn succumbed and gave way to plaster castings of the feeblest kind.

Having now briefly touched on the subject of the forms and proportions of rooms, we will pass on to the equally important subject of giving light to them.

So much of the architectural effect of a building, for whatever purpose it may be destined, and so much of its aptness and convenience, depends on the mode that may be adopted of lighting it, that it is certainly a matter demanding your especial attention and study; the more so, because no definite general rules can be laid down for the proportioning of windows to the area they have to light.

Much obviously must always depend on the purpose of the room to be lighted; much also on the nature of the medium through which the light passes, and on the position of the windows; and above all perhaps on the degree of intensity of the light obtainable from without. The practice of Italy, for example, would be a very unsafe guide for us in our more uncertain climate and more sombre atmosphere. Here the most ample panes and the clearest glass will often hardly suffice; whilst in Italy, such is the penetrating fervour of the sun, that sometimes men are content, as at St. Miniato, near Florence, with the light that can make its way through slabs of alabaster. We know indeed that lapis specularis was much used for this purpose in classic times.

Then again the light that is obtainable in an open country and a crowded street requires totally different proportions; whilst a window filled with stained glass will need, in order to afford a given volume of light, an extent of perforated surface that would be altogether disproportionate where clear glass is used. In the absence then of any definite rule, it becomes especially necessary by habitual observation and comparison, to learn our wants and our resources.

On a former occasion I adverted to the importance of the study of the effects of light and shadow in the design of exterior architecture. At least equal importance is to be attached to this consideration in interior design.

In the production of grand effects *chiaroscuro* plays an important part; for the quality of grandeur depends not only on largeness of dimensions, but on a proper treatment of lights and shadows. When the form of an apartment or hall is simple the impression of grandeur can perhaps only be produced by real size; but when the form is complex, a new element of grandeur arises in the diversity and breadth of its light and dark parts. It is to this, far more than any other cause, that we are to attribute the powerful impression made on the mind by the interior of a Gothic cathedral. The burst of light from the transept breaking the monotony of the nave,—the light on the screen brought out into prominence as seen against the dim haze of the choir,—the splendour of the clerestory contrasted by the comparative gloom below; these are all effects wholly due to *chiaroscuro*, and constitute perhaps the chief charm of those fine architectural compositions.

It has always appeared to me a subject of deep regret that the undue interference of incompetent judges prevented Sir Christopher Wren from carrying out his first and perfectly original idea for St. Paul's Cathedral, where the effects produced by the double vaulted aisle surrounding the octagonal nave would have been truly surprising: my conviction is, that had that design been carried out, an interior architectural scene would have been the result wholly unparalleled in any building in Christendom.

The present is of course not a proper occasion for discussing the utilitarian requirements of a room. No doubt a room destined for pictures must have its light admitted far differently from a room where sculpture is to be exhibited, and both widely differ from the requirements of an ordinary living room; but these are questions, although of the highest importance to every student, which must not now engage us. There are however purely æsthetic considerations connected with this subject of the admission of light, which are, it appears to me, perfectly fit to be entertained within these walls.

Very forcible effects are produced by mere contrast in the degree of light admitted. When an apartment is desired to be marked by a gay and festive character the eye should be prepared by subjecting it to a comparatively dim light. If, on the other hand, a solemn effect is to be aimed at, then advantage is gained by previously subjecting the eye to strong light. I have been frequently struck by the far greater effect of solemnity produced on the mind by entering a cathedral direct from the clear air of the cathedral close, than when entered from the cloisters, where the eye has already got somewhat accustomed to a subdued light. Indeed, for every great architectural scene it is well that the eye should be duly prepared.

I think that it may be broadly stated that a high light is, for almost every purpose of illumination, more pleasing than a low light. This is more especially the case when a grand and broad effect is aimed at.

By lifting the windows above the ordinary range of the eyes the intensity of the light is subdued, and a quiet effect produced. That sombre light which is so striking in the early Basilicas of Italy is due to the absence of lower lights in the aisles. No doubt much of the charm of those remarkable buildings is attributable to the unaffected purity and simplicity of form which distinguishes them from the theatrical straining at effect, the multiplicity of parts, and the flutter of architectural nick-nacks, which are apt to characterise later mediæval works.

Still this pleasing simplicity of form is very greatly enhanced by the light being admitted exclusively from the upper part of the building.

It might be easy to accumulate illustrations on this subject, but I will confine myself to one, and that of comparatively modern date, to show you that the principle which I urge on your attention is irrespective of style. At Milan, the ante-chapel of a church was built, probably in the sixteenth century, as a mausoleum for the family of the great Condottiere Trioulzi. There is little or no light below. At a considerable height from the pavement are deep recesses, within which the sarcophagi are placed, and over all is the clerestory. The whole light that this lofty and simple structure, with its mural sculpture, receives is from above, and the effect appeared to me to be extremely impressive. I may add that a very brief inscription on the walls, alluding to the active life of the great commander, was in excellent keeping with the repose of the scene: "Qui nunquam quievit, quiescit—tace!" (Be silent,—for he who never rested, rests!)

Besides the considerations that I have brought before you as requiring careful study when proportioning a window to its purpose, there is yet another very important one. The colour and texture of the walls must never be overlooked. It is most essential to take into account whether these vertical surfaces to be lighted are themselves light or dark in tone or colour; whether of a nature to absorb or reflect light; whether polished or rough. We all know practically when a room has to be lighted up artificially how much the requisite number of lights depends on these accidental circumstances. Observe the strongly diffused light produced by a single taper in a room with white walls, and compare it with the dim twilight obtained from the same light in a room papered with dark red paper. Of course the same holds good in daylight; and if we must have dark walls and furniture, it behoves us at the same time to have large windows.

You will perceive from these remarks how futile and empirical would be any rule for determining the proportion of solid to void in the external wall of a room. It is in truth experience derived from habitual unremitting observation that can alone safely guide us. "There are rooms"—says the great observer, Bacon—"where you cannot tell where to become to be out of the sun or cold,"—and this excess is doubtless a serious fault; but I believe generally that an excess of light is a less serious fault than a deficiency, for in the former case a variety of means readily present themselves of remedying the defect, while in the latter case the defect is irremediable.

I have now touched upon most of the more material subjects of inquiry in the interior disposition of a building. To consider the special arrangement of the several parts of a plan required for each of the various uses for which a building may be destined would be an endless task; nor would such special arrangements form a suitable inquiry within these walls, where, by the very constitution of the Academy, we are limited to that portion of our art which relates to æsthetics. For lessons in the theory and practice of construction you will have to seek elsewhere; nor shall I now enter at any length into the wide field of interior decoration, a subject which might well occupy us many evenings.

I will confine myself to the laying before you a few observations only on the general treatment of interiors. I am afraid that I venture an opinion much at variance with the general practice of many of our highest authorities, when I express my conviction that the introduction of a complete order into the interior of a building is a solecism and an indefensible inconsistency.

Digitized by Google

The entablature, as usually composed, is essentially a piece of external architecture. The frieze occupies the place of, and represents, the ends of the horizontal cross timbers of the roof or ceiling, and the cornice is but the overhanging extremity of the roof for the protection of the vertical face of the wall from the weather. To introduce such features within is irrational. The masters of the Greek art, so truthful in all they did, committed no such offence against propriety; nor do we find, as far as I know, any complete internal entablature (except in the cella of hypæthral temples, where of course they are perfectly legitimate) until our art had lost its youthful purity, and the original meaning of the component parts of the entablature had been lost sight of. Without going so far as to deny the applicability of these regular orders to the interior of great halls, or other large interior areas, they are at all events, I think, inapplicable to the ordinary purposes of interior designs, or in rooms of moderate capacity.

I am aware that this dogma carried out to its full limit would extend to the condemnation of labels over interior arches, inasmuch as they are but an over-hanging weathering or drip-stone; to the condemnation also of internal battlements and other features exclusively belonging to external architecture. Nor do I see how such can be defended, except on the ground that the practice of these solecisms prevailed during the most admired epochs of the art. At all events I would seriously counsel you to be on your guard against a too ready acquiescence in the practice of applying to the interior of buildings the forms and features of exterior architecture.

Before paper and paint had usurped their undivided dominion over the decorators of our apartments, our ancestors resorted to many means of internal mural decoration,—means, it may be, more costly, but certainly more tasteful, and more worthy of the character of art. Tyre supplied its rich drapery to embellish the walls of Roman buildings; and, following in the steps of Egypt, Assyria, and Greece, the artists of Rome loved to depict the fairest forms and most brilliant conceptions over the walls and vaulting of their apartments.

Inspired by the examples of eastern art, the founders of ecclesiastical architecture incrusted their walls with mosaics and painting. The looms of the east also enabled them to clothe their walls with the richest hangings,—rivalled afterwards by the weavers of France, of Flanders, and of England. But the general demand for economical decoration in latter times has created whole branches of mechanical manufacture to supply the place and mock the semblance of more durable, solid, and real enrichment. Costly hangings are represented by fabrics manufactured daily by the mile, and the most precious woods and rich marbles are reproduced by the simple process of the paint-brush and varnish-pot.

In the observations which I have addressed to you this evening I have referred to many existing examples of our art by way of illustration; but I have made those references with little regard to the special style of the examples. I do so because it is of far higher importance to study the principles of design rather than styles. Style is an accident in art; whilst principles, if they be sound, are permanent and universal.

The architectural style that has prevailed at any time or place will be found to be the involuntary result of a combination of circumstances: the political and social condition of a people; their degree of culture; their relations with other countries; and the materials for building which happen to be at their command. The fine arts in their destinies seem to have some analogy to the destinies of man himself. Each style of art has its infancy, its adolescence, its manhood, its decay. But there the analogy ends, —for man is continually reproducing in his children, and neither his physical nor his moral qualities are necessarily or generally deteriorated in the lapse of successive generations. But in architecture I fear it is a vain struggle to attempt to renew exactly any phase or state of existence that the art may have passed through. We may exactly reproduce a building—we may exactly repeat a form—we may mimic every feature; but I greatly doubt whether we can ever really and truly recall to life a style that has once passed away.

No observer of passing events during his own day; no one versed in the history and progress (if progress it be) of our art, can fail to see that, as it has had, so is it likely again to have vicissitudes in its fortunes, and that there are prevailing—perhaps cyclical and periodic—revolutions in popular architectural taste.

Contemporaneously with the revival of letters in the fifteenth century there was a resuscitation of the Classical styles. It gave birth at its outset to something very nearly approaching to an orginal, and therefore vigorous, style of building, which however fell ultimately into insipidity or extravagance. Within thirty years a like change has come over us. The film is supposed to have fallen from the eyes of a refined criticism, and we are busy in disinterring the relics, and detecting the beauty long latent in the free and fanciful chisellings of the fourteenth and earlier centuries.

I am addressing those who will live long enough to see another revolution in the wheel of architectural fortune. In the meanwhile, you who hope to lead must in some respects be content to follow; and all I can advise you to do is fairly to study and appreciate the merits of those several styles which have in their turn secured the favour of cultivated minds.

Make yourselves acquainted with their general principles, and apply to them the golden metre of your reason and good sense. I would venture to advise those of you to whom these lectures are especially adressed, to study diligently the venerable vestiges of bygone art in its best days, but study them in the free spirit of progress and advancement,—not of retrogression. Study principles, I repeat it, rather than styles; and in a painstaking, truth-loving spirit, work and hope. Utterly discard from your minds the bigotry of a mere antiquarian, and every tendency to uninquiring prepossession. Study the purposes and objects of art, and the lessons of nature. Study well the faults of our ancestors, as well as their beauties; but above all, let us not be content to rattle the dry bones of antiquity and fancy that it is music.

SMOKE CONSUMING BOILERS.

*Abridged from Reports of Inspectors to the Admiralty.**

Newcastle-on-Tyne, 19 August, 1858.

Sir,—In obedience to the orders of the Lords Commissioners of the Admiralty, dated the 1st of June 1858, directing us to proceed to Newcastle, to superintend and report on a repetition, or if requisite an extension, of a series of experiments upon the relative evaporative values of coal which has been instituted by the Steam Collieries Association of the North of England; and also to report on the merits of the plan proposed by Mr. Williams of Liverpool, and of the modifications introduced by the Association for Consuming the Smoke of Bituminous Coal when used in Tubular or other Marine Boilers,—We beg to state that we have performed this service.

The description of coal selected for the repetitional and comparative experiments with north-country coal, was to be obtained from the original West Hartley pits; and that for the comparative experiments with Welsh coal should be Powell's Dufferin; as the association in anticipation of our trials had obtained part of a cargo of this description of coal, which with other cargoes had been sent from Wales, for the purpose of coaling the Hudson, a large steam-ship built by Messrs. Palmer and Co. of Jarrow, for the German Lloyd's Company, for the purpose of navigating her to Bremen, and which is verified by the certificate attached to this report.

As our experiments proceeded, we considered it to be desirable that a comparison should be made with north-country coal and Welsh coal as supplied to the service; and therefore on the 3rd instant we wrote to their lordships, requesting that six tons of each description of coal should be forwarded to us for this purpose, and which were forwarded and received here from Woolwich Dockyard, and experimented upon.

We may here observe that the experimental boiler is a marine multitubular one. Upon this boiler, at the top of the uptake and the bottom of the chimney, is placed an oval vessel filled with tubes, through which the heated vapour from the boiler tubes passed before entering the chimney, and which may be called a water-heater, as all the feed-water to the boiler passed through this vessel. This heater is 5 ft. 4 in. in height, 5 ft. 8 in. in larger diameter, and 3 ft. 8 in. in smaller diameter; having 76 tubes 4 inches in diameter and 4 feet in length. The heating surface in the boiler being about 750 square feet, and that of the heater about 320 square feet.

All the experiments for the association having been made with the feed-water passing through the heater into the boiler as

* Ordered by the House of Commons to be printed, March 8, 1859.

Digitized by Google

before described, the whole of the experiments made by us, were made with this heater attached to the boiler and the feed-water passing from the supply tank through it into the boiler; but as this appendage is not common to boilers generally, we had it removed; and our concluding experiments have been made without it, the feed-water passing directly from the supply tank into the boiler, the results of which are contained in the following table.

During part of the experiments, the experimental boiler was fitted with Mr. Williams' apparatus for preventing smoke, which consists, in this case, of two hollow furnace fronts divided into three air chambers, and having a hollow fire door each, one chamber over the fire door with two apertures, one chamber at each side of the fire door with one aperture each, and the fire door, with two apertures in their exterior parts for the admission of air, and the whole of their interior parts perforated with small holes for the purpose of diffusing the air in streams amongst the gases arising from the burning coals; the area of the apertures and perforations being in the proportion of about 6 square inches for each square of fire-grate. The air passages of this apparatus were kept open when north-country coal was burnt without smoke, and closed when this coal was burnt to make smoke, and when Welsh coal was burnt.

During the experiments with north-country coal, the fires were kept from 12 to 14 inches in thickness, and the fresh coals at every firing were thrown alternately to the sides of the furnaces, so that at each firing one side of one furnace was charged at one time, and then after an interval the corresponding side of the other furnace was also charged; then, after another interval, the opposite side of the first furnace was charged, and then, after another interval, the opposite side of the second furnace was also charged; and so on, continuously, with the two furnaces. In every charge the coals were invariably thrown upon the fronts of the fires, and when requisite the incandescent fuel was pushed back at either sides of the furnaces towards the fire bridges, so that the gases arising from the fresh coals always passed over the hottest parts of the fires. This system of firing was also pursued in the two experiments when smoke was made, for the purpose of ascertaining the differences existing in the evaporative powers of this coal when preventing and not preventing smoke; thereby showing that this system of firing, although of great use when the air passages of Mr. Williams' apparatus were open, was of no material value when they were closed, for the smoke in these two instances was both dense and black.

It appeared from the experiments, that although the north-country coal, when burning the products that would otherwise make smoke, is slightly inferior in its evaporative powers in pounds of water per pound of coal, yet it is in some degree superior to Welsh in rapidity of combustion and evaporative velocity per foot of fire-grate, or, in other words, work done in a given time per foot of fire-grate; and therefore it has the advantage when a certain speed is to be obtained in a certain time without reference to economical considerations, the coals in both cases being supposed to be smokeless.

The experiments made with the long fire-grates, the fire-bars being 7 feet in length, and that one made on the 31st of July, very clearly showed the capabilities of Mr. Williams' apparatus for preventing smoke, when the system of firing before described was pursued for the prevention, was all but perfect. It may be here remarked, that the system of firing before described does not require more than ordinary attention on the part of the stoker, and gave no additional labour to the stoker employed throughout our experiments over that which he exerted when stoking with Welsh coals, the one system requiring no more practice than the other to make the stoker. The experiments made with Lambton's Wallsend house coals on the 27th of July, and also that made with the steam jet, are additional proofs of the efficacy of Mr. Williams' apparatus.

With reference to the advantage to be gained by the prevention of smoke in the saving of fuel, the experiments as compared with the average results of the north-country coal direct from the collieries, show a saving in pounds of coal for pounds of water; but they also show a nearly average rapidity of combustion and evaporation when the smoke is not prevented. Some of the experiments made after the water heater was removed, for the purpose of determining the difference of making or preventing smoke, also show that although this appendage to the boiler had some advantage in the evaporative powers of the fuel in pounds of water for pounds of coal, yet the rapidity of combustion and evaporation had been checked by it when north-country coal was burnt.

In further obedience to their lordships' orders, which direct us to report upon the modifications of Mr Williams' plan for consuming smoke introduced by the association, we inspected a modification of this apparatus, which consists of a furnace frame fitted with two fire-doors, the hinges of which are so placed that when the doors are opened they open back to back, the upper part and sides of the door frame being pierced with a number of holes, and the lower parts of the fire-doors having horizontal slits in them for the admission of air into the furnace. The object in having two fire-doors on one frame, opening in the way described, is to cause the stoker always to throw his coals to the sides of the furnace, instead of throwing them immediately into the middle of it, and of necessity forcing him to fire each side of the furnace alternately, and in the manner pursued in firing our experimental boiler. This modification of Mr. Williams' plan was fitted to three boilers which were in constant work, and the prevention of smoke appeared to be almost perfect.

We proceeded to the Bedlington Collieries, and there saw another modification of Mr. Williams' plan. In this the fire-doors are double, but open in the usual way; the fire-doors having horizontal slits in their lower parts, and the dead plate of the furnace being also made with slits in the centre part for the admission of air into the furnace. At these collieries there were four boilers fitted with this modification which were in constant use, and here also the prevention of smoke appeared as in the former apparatus to be almost perfect.

In the Expert steam-tug, the boilers, two in number with two furnaces each, are fitted with a modification of Mr. Williams' plan. This apparatus consists only of an ordinary furnace front fitted with one fire-door, which is perforated with a number of small holes in the lower part, and the dead plate of the furnace having an opening at each end and at the sides of the furnace for the admission of air into the furnace. As we were on board this vessel for several hours, we had every opportunity of seeing the effect of making and preventing smoke; and although there was no very careful stoking, yet the prevention was almost perfect.

From the average results of the experiments, and from our general observations, we came to the following conclusions:—

1. That when the smoke from north-country coal is consumed, its evaporative value is nearly equal to that of Welsh coal, while its rapidity of combustion is greater, and therefore that it is capable of generating a larger quantity of steam in a given time.

2. That from the harder nature of the north-country coal, it is less liable to be broken up from motion than Welsh coal, and from the large heaps which had been exposed at the pits' mouths for nearly twelve months, which we saw at some of the collieries, without exhibiting any symptoms of falling into small particles, thereby showing that atmospheric changes had but little effect upon it; and therefore, for these reasons, it is better adapted for store or conveyance to distant parts of the world than Welsh coal, which from daily experience is found, not only to be greatly reduced in size by motion, but to be reduced to dust when exposed to the changes of atmosphere in stores, &c. These comparisons are only made upon the supposition that the smoke from the north-country coal may be reduced to the same minimum as that which may arise from Welsh coal, or be entirely prevented by Mr. Williams' or some effective apparatus for this purpose.

3. That from our experiments at Elswick, and our observations elsewhere, it is possible to consume the smoke arising from north-country coal by the use of Mr. Williams' apparatus, and by the modifications of it as introduced by the association to some of the collieries in this part of the country, and also fitted on board the Expert steam-tug, and now being introduced generally into the steam-tugs of this port. For in the experimental boiler smoke was prevented when the firing was pushed to a greater extent than 30 lb. to the square foot of fire-grate; in one instance, on the 31st of July, the firing having been for one half-hour at the rate of 55½ lb. to the square foot, with but very light smoke, and for the next hour at the rate of 40 lb. per square foot without any smoke; and again on the 10th of August, when a steam jet was used to force the draught, the firing throughout the experiment was nearly 36 lb. to the square foot, the jet being produced by 20 lb. steam.

Experiments on Coal at Cardiff.

Woolwich Dockyard, 31 December, 1858.

Sir,—With reference to their lordships' order of the 7th December, and your instructions of the 8th, directing us to proceed to Cardiff to witness experiments on Welsh coal, also properly to inspect the boilers and furnaces, and to keep a careful record of the trials, reporting the results in a similar manner to the report recently made by Mr. Taplin and Mr. Miller of the trials of coal at Newcastle,—

We beg to report that we were conducted to a steam-vessel (the Isabella Croll) lying at her moorings in the Bute docks, having a boiler in which experiments on coal had been made previous to our arrival, of the same description as those which they intended to make in our presence on north-country (Hartley) and on Welsh coal (Aberdare). We found the boiler to be of the ordinary class used for marine purposes, in shape and proportions similar to those employed in Her Majesty's service. We found the furnace doors to be of the common description; but after the first four experiments were completed, and the quantity of smoke well tested, a modification of Mr. Williams' plan for the prevention of smoke was applied to them. A pyrometer, to register the temperature of escaping heat, was placed in the chimney immediately above the uptake.

It was interesting to witness how much the temperature of the escaping gas was affected as the stokers varied their mode of firing when the two descriptions of coal were used. This was strikingly apparent on the 16th December, when the Hartley coal was burnt and the fires were urged. The practice of using the whole of the cinders produced while the evaporation was progressing was adhered to here, as at Newcastle with the north-country and with Welsh coal. When large and small South Wales Aberdare coal were experimented on, the small coal was mixed with the cinders, and thrown on the fire in a mixed state, but they were used separately in experiments on Northumberland Hartley coal.

Williams' Apparatus for Consuming Smoke.

TABLE of average results from the Experiments with North-country and Welsh Coals, to compare the evaporative values of the two descriptions of coal.

Description of coal experimented upon.	Area of Fire-grate.	Results calculated from the latent heat of steam, being 966°, as taken by Messrs. Armstrong, Longridge, and Richardson, in their reports to the Steam Collieries Association of the North of England.				Results calculated from the latent heat of steam, being 988°, as adopted by the Admiralty in their reports of trials of coals.	
		Economic value on the evaporation from 212° by 1 lb of coal in lb of water.	Coal burnt per sq. foot of fire-grate per hour.	Rate of evaporation from 60° per sq. foot of fire-grate per hour.	Total evaporation from 60° per hour.	Water evaporated by 1 lb of coal, calculated from constant temperature of 100°.	Water evaporated per hour, calculated from constant temperature of 100°.
	Feet.	lb	lb	Cubic feet.	Cubic feet.	lb	Cubic feet.

North-country coal	22	9·75	29·53	3·94	86·63	8·73	89·87

REMARKS.—The whole of the experiments from which these averages, except the last, have been taken were made with the air-passages of Williams' apparatus open, and no smoke issuing from the top of the boiler chimney, excepting when Welsh coal was burnt, and then the air-passages were closed. The last of these experiments was made to observe the quantity of smoke issuing from the chimney-top, and also to ascertain the evaporative value of the coal when making smoke and when not making smoke.

The results of these experiments appear in the table subjoined, and the distinguishing features of each experiment will be found under the head "Remarks." After the first four experiments were made, and both descriptions of coal were tested, with the furnace doors of common form, it was determined to extend the experiments further by an altered furnace door, a modification of Williams' apparatus for the prevention of smoke. The tracing accompanying this report will convey an idea of this apparatus, specially provided for the three remaining experiments. We beg, however, to remark, that this apparatus was not made precisely on Williams' plan; the rule prescribed by Williams as to the ratio to be observed between the area of grate-bar surface and the perforations for air was nearly identical with that observed in these experiments; but there was a space left around the external edge of the inner plate, which prevented the formation of a close box, or air chamber, when the fire-door was shut. This open space admitted air in bulk, instead of in divisional streams. These deviations from Williams' rule, we are of opinion might have operated prejudicially in the experiments on north-country coal, inasmuch as more air was admitted than was due to the grate-bar surface, and not admitted through the most suitable part of the apparatus, nor in separate streams only, as suggested by the inventor; also the rectangular opening in the outer door was much less in area than it ought to have been.

The results of these experiments, as shown in the tabulated form, make it appear that while the coal from the South Wales collieries (Aberdare), is comparatively superior to the Northumberland Hartley, both in economic value and rate of evaporation, it is inferior in rate of combustion when burnt under the same conditions as to fire-bar surface and time; or in other words, the rate of combustion in pounds of coal burnt per square foot of fire-bar surface per hour is not so high with Aberdare as with Hartley coal.

As witnesses of these experiments, we had some doubts as to the dependence that might be placed on the feed apparatus for the boiler, with reference to the exact quantity actually entering the boiler as measured to the feed apparatus and registered by the meter. Priming of the boilers was evidenced in an especial manner on the first and second day's experiments; it was not constant, but intermittent. Owing to these circumstances, we cannot place so much dependence on the accuracy of the results of the experiments as could be wished.

REVIEW.

The Carpenter and Joiner's Assistant. London: Blackie & Son.

The favourable impressions conveyed by the appearance of the earlier parts of this work have been amply confirmed by that of the subsequent numbers; and if the price of issue be thought to range beyond the average in publications of the kind, so most assuredly does the quality of the contents, and the style of the getting up of the book generally. Of the twenty numbers in which it is proposed to embrace the subject, fourteen have now appeared,—all more or less valuable. In the last two will be found several well executed plates, illustrating the framing of trusses, circular and polygonal domes, bridges and centreings, joints in joinery, finishings of windows, hinging, and the construction of timber houses. Among the letterpress, the article

on the strength and strain of materials will be studied with interest, as also the tables of experimental results. We extract a portion treating of

Resistance to Tension.

"Although mechanically considered, this is the simplest strain to which a body can be subjected, it is yet the one in regard to which fewest experiments have been made, in consequence of the great force required to tear asunder lengthways pieces of timber of even small dimensions. There is too a want of agreement sufficiently baffling in the results obtained by different operators. The results of the experiments made by Muschenbroek, Buffon, Barlow, Bevan, and others, are given in the following table, reduced to a section of one inch square:

TABLE I.—*Tenacity of a square inch of different woods, expressed in the weight in pounds that will produce rupture.*

Although on many considerations it is not to be expected that experiments made on such small scantlings of timber as were used by the experimentalists above cited (some of these being only a square line in section), would agree with each other; yet the discrepancy is so great as to give little confidence in the results. Mr. Barlow, on mature consideration, has given the following table of the tenacity of wood usually employed by the carpenter; and subjoined is the mean result from the foregoing table, for the sake of contrast:

TABLE II.—*Tenacity of a square inch of timber in pounds.*

	Barlow's mean results.	Mean results of Table I.
Oak	10,000	13,316
Ash	17,000	14,670
Beech	11,500	14,720
Teak	15,000	12,460
Mahogany ...	8.000	18.950
Riga fir	12,000	12,776

As Mr. Barlow's experiments were very carefully conducted, his table may be assumed as a safe guide.

As the strength of cohesion must be proportional to the number of fibres of the wood, or in other words to the area of the section, it follows that the tenacity of any piece of timber, or the weight which will tear it asunder lengthways, will be found by multiplying the number of square inches in its section by the tabular number corresponding to the kind of timber."

Resistance of Timber to Compression in the direction of the Length of its Fibres.

"Experiments on this kind of resistance are not numerous.

Mr. Rennie found that to crush a cube of 1 inch on the side, the weights in lbs. required were, for—

African oak	6720 lb.
English oak	3860 ,,
White deal	1928 ,,
American pine	1606 ,,
Elm	1284 ,,

M. Rondelet obtained higher results; that is the timber experimented on by him presented a greater resistance. According to this author, a piece of timber diminishes in strength as it begins to bend; so that the mean strength of the wood of the oak, which is 44 lb. French for every line superficial in the case of a cube, is reduced to 2 lb. for a piece of the same wood when its height is 72 times its base. From a great number of experiments he compiled the following progression:

In a cube the height of which is	1,	the strength is	1·	
In a piece,	,,	,,	12,	,, ·833
,,	,,	,,	24,	,, ·5
,,	,,	,,	36,	,, ·33
,,	,,	,,	48,	,, ·166
,,	,,	,,	60,	,, ·083
,,	,,	,,	72,	,, ·041

Thus, in a cube of oak of 1 inch superficial of base, submitted to the action of a force pressing vertically, the mean force is expressed by 144×44=6336	While the mean of experiments gave	6346
In a bar of the same wood of the same base, and 12 inches high, the strength by the progression would be 144×44×·833=5278	,,	5310
In a bar 24 inches high, the strength by the formula 144×44×·5=3168	,,	2911
In a bar 36 inches the strength by the formula 144×44×·333=2110	,,	2163

In a bar 48=144×44×·134=849.
In a bar 60=144×44×·083=526.
In a bar 72=144×44×·042=266.

In fir bars the following results were obtained:

	By calculation.	By experiment.
In the cube of 1 inch, 144×52×1·	=7488	7490
In the bar of 12 inches ,,	×·833=6238	6355
,, 24 ,,	,, ×·5 =3744	3429
,, 36 ,,	,, ×·33 =2471	2575

These results, M. Rondelet observes, accord with the experiments of MM. Perronnet, Lamblardie, and Girard.

In an experiment described by the latter, a piece of wood 2 metres 273 millemetres long, and 155 by 104 millemetres in section, broke under a weight of 33,120 kilogrammes.

Reducing these into English measures, the length is 7·35 feet, the sides of the base 6·05 and 4·06 inches respectively. The area of the section is therefore 24·5 inches, and as the weight is 72,864 lb., the weight on the square inch is 2974 lb.

The height of the piece is about twenty-two times the size of its base and the progression would give a reduction of half the strength. If therefore 2974 is doubled, 5948 lb. are obtained as the absolute resistance per square inch,—a result which agrees very closely with the experiments of M. Rondelet.

The same author arrived at the following conclusions:—

1. That the resistance does not sensibly diminish in a prism, the height of which does not exceed eight times its base.

2. That when the height of the prism is ten times its base it begins to yield by bending.

3. That when the height is 16 times the base, the piece of wood is incapable of resistance.

Tredgold says that when the length of the wood is less than eight times its diameter, the force causes it to expand in the middle of its length, and split into several pieces, but when it exceeds this length it yields by bending. In practice the last case is almost the only one which occurs."

The following table (p. 124) of the properties of timber will be found comprehensive and useful.

The subject of practical carpentry as applied to Roofs is as yet scarcely entered upon; we shall therefore reserve any observations on this topic till the essay is complete.

ON THE ARCHITECTURE OF THE THIRTEENTH CENTURY.*

By GEORGE GILBERT SCOTT, A.R.A.

IN my last lecture I gave a hasty outline of the developed architecture of this great period. I will now endeavour to give an equally hasty glance at some of its more marked creations, beginning—as in duty bound—at home. Their number however is so great, that one is perplexed to know where to begin, or in what order to take them. Perhaps the most profitable way will be to imagine the student to live in London, and to commence with the works of this century which he may study within a walk of his home.

To begin then with the church of St. Saviour, formerly St. Mary Overie—in Southwark. When I first knew this church the whole of it was standing: externally, it is true, the aspect it presented was not very pleasing, for it had been cased almost throughout with red brick, and the Lady Chapel was little else than a ruin. The choir was then in course of restoration. The interior was a most noble structure, and was almost perfect, and nearly all of this century, though some small portions westward were earlier, and the south transept possibly a little later. The whole was on a very symmetrical design, that of the nave being very much on the same with the choir. Its character may easily be judged of from what remains. It was nobly massive and grand, not of lofty proportions, but still such as to satisfy the eye. The pillars were alternately round and canted squares, flanked with attached shafts; the triforium consisting of arcades, interrupted only by the vaulting shafts. At the east end is a beautiful Lady Chapel, vaulted on light clustered pillars. The restoration of the choir was carried out by the late Mr. George Gwilt, aided by his sons; and it is impossible too warmly to praise the zeal and ardour with which they pursued the work, their study of the style then so little understood, or the untiring pains they took to render their restoration accurate. All these ardent lovers of ancient art are now deceased, and I feel a melancholy pleasure in bearing witness to their merits. I was intimately acquainted with one of the sons, and never did I meet a man more enthusiastically devoted to the style on which his artistic education had been founded. He absolutely adored everything which was Early English; and in carrying out restorations—in one of which he aided me—so faithfully did he reproduce the whole work, that nothing could induce him to alter even the positions of the jointing of the ashlar work. The pains which Mr. Gwilt took in restoring the choir disgusted the heartless parishioners, who, on proceeding to the transepts, placed the work in other hands; but on the Lady Chapel being undertaken by private individuals, Mr. Gwilt nobly undertook the work gratuitously, and carried it out with the same care he had bestowed on the choir. Shortly after this a report having arisen that the nave roof was decayed, a surveyor was employed to examine it; who, recklessly condemning it as unsafe, it was taken off, and none put on in its place. The walls, being of chalk, became shattered by exposure to the frost of several winters; and when the restoration of the nave was proposed to the parishioners, that enlightened body of men negatived it, and, taking down the glorious old structure, erected the present monstrosity in its place. Happily however the interiors of the choir and Lady Chapel are still perfect. Let us hope and pray that their widowhood may not be of much longer duration, but that a reproduction of the noble nave may be substituted for its unworthy supplanter. I should mention that the nave was entered on the south side by a very noble double doorway, of great height and depth, though when I knew it its decorative features had perished. I will only add that if measured drawings of this church are in possession of the family of Mr. Gwilt, it would be most desirable that they should be deposited among public archives, to await the time when they must be wanted as a guide to the re-erection of the lost portions. In the mean time, let me beg of you to study well what remains.

NEXT in importance, and probably in date, comes the choir of the Temple Church, which was consecrated in 1240,—a more fortunate building than the last, and not needing from me any chronicle of its restoration. It is in idea a magnified transcript of the Lady Chapel of St. Saviour's, being, like it, vaulted throughout upon pillars of equal height, and is probably about the most perfect specimen in England of this beautiful mode of construction.

The only other important instance I recollect in London of the earlier portion of our style is the chapel at Lambeth,—a very good Early English chapel, though somewhat dishonoured by plaster vaulting, the ribs of which I myself saw being prepared for by a core of spikes and tar cord. Let us hope that this is the last instance of such construction, especially of its introduction in a time-honoured building like this.

We now come to one of the noblest of England's temples,—the Abbey Church of Westminster; and you will readily excuse me from dishonouring this truly glorious temple by attempting its description in the course of a hasty catalogue like what I am now giving. As you all know, it was commenced in 1245 by King Henry III., and the eastern portions finished about 1269. This makes it contemporary, in a certain sense, with Amiens; for though the latter was commenced in 1220, it was not completed till 1288. There can be no doubt that the cathedral at Amiens was, at the time of its erection, viewed as the most perfect development of the style; for it is clear that it was made in many instances the model on which the designs of other churches were formed. Cologne Cathedral, for instance, was commenced in 1248, during the erection of that at Amiens, and is manifestly a free copy of it so far as concerns its earlier portions; and though Westminster Abbey is by no means built on the model of Amiens, it was probably influenced by it. That prodigious pile, carried forward through so long a series of years, would be a great object of interest to all contemporary church builders; and Henry, who was much in France, would naturally send the architect of his own sacred mausoleum to see the great work of his day. Westminster Abbey is a church built on a French ideal, but with English detail,—a great French thought expressed in excellent English. The windows are of the perfected bar tracery, which had not yet been much used in England; but in other respects I cannot find a distinctively French detail—or scarcely any—in the building, excepting the work of a single French foliage carver. Even the plan, which is purely French in idea, is carried out in a manner quite different from that of any French church I have seen.

In the architecture the union of the manners of the two nations is most happy. The pillars are nearly like those of the great French cathedral, but the side shafts, instead of being attached, are separate shafts of Purbeck marble, the nucleus and the capitals and bases being all of the same beautiful material. The use of this hard stone led to that of moulded unfoliated capitals, in which they lose in effect when compared with those at Amiens; but the nobler material would more than compensate for this.

The triforium is far superior to that at Amiens, both in design and detail, and the whole internal design, though inferior in size and altitude, is to my eye far more pleasing; and when its varied materials retained their colour, and the Purbeck marble, which pervades every part, preserved its polish, there cannot be a doubt as to the superior magnificence of its effect. The parts too are much better proportioned, with perhaps the one exception of the too acute form of the main arches; the wall arcading is much more beautiful, and the details generally more richly moulded. We have then here, at our doors, a building whose interior is equal to that of any existing Gothic building, and we have no excuse if we do not avail ourselves of so noble an opportunity of study. Of the exterior I will say nothing. All its old features had perished by the end of the seventeenth century, when they were vilely renewed, and this base restoration is now in its turn decayed.

The Chapter-house is a splendid but melancholy relic, little more than a ruin, and that not like those ruins which seem to do honour to the memory of their bygone glory by the picturesque loveliness which graces their decay. It is choked up with presses, chests, galleries, huge sacks of parchment, and every possible obstruction and disfigurement. Its beautiful windows—which filled the entire width of its sides—walled up, and its elegant vaulting destroyed. Just enough remains to render its restoration practicable. I have with great labour traced out all the old details, and only wish for the chance of restoring it in some degree to its pristine beauty. I exhibit a drawing of it as restored. I should mention that the splendid encaustic floor is still perfect, and that very fine specimens of wall panelling still remain. The vestibule and staircase by which it is approached are beautifully designed, and the doorway from the cloister is among the most splendid relics of English art. The latter is in a dreadful state of decay, but I am happy to say that it has just been stereotyped in its present state by the application of an invisible solution, which

* Lecture delivered at the Royal Academy.

will prevent the further progress of disintegration, and which has set and hardened the crumbling particles, which the gentlest touch would have before displaced.

The foliated carving in Westminster Abbey unites the two great types which characterise this century—the conventional and the natural,—and contain some of the best of each. I commend it to your careful study, and will mention that all within reach has been indurated in the manner I have just alluded to. What remains of the figure-sculpture is also of great merit, especially four angelic figures in the triforium of the transept, and two full-length figures in the Chapter-house, one of which I had the great happiness of discovering.

The internal proportions of the Abbey seem to me to surpass those of any other I have seen. They appear to be generally founded upon the equilateral triangle, and a comparison of this with many other churches will confirm the truth of what I have heard has been stated by an ancient freemason,—that the square will furnish good proportions, but the equilateral triangle much better.

The introduction of Italian mosaic work—both porphyry mosaic on the pavement, and glass mosaic on the tombs of the builder and rebuilder of the Abbey—is a fact of great interest, as showing the high estimation in which the arts peculiar to Italy were then held, so much so as to lead to the bringing to England of two master mosaic workers—Odorico and Pietro (each no doubt with his staff of workmen)—to carry out the two branches of the art. Both artists were from Rome, as the inscriptions still testify; but their work was put together here, as is proved by the use of Purbeck marble, both as the groundwork of the pavement and for the architecture of the tombs. This architecture is not very elegant in its details, excepting only the beautiful spiral pillars and some of the surface patterns prepared for the mosaic; and the introduction of art so inferior to their own for the sake of the rich inlaying it contained, still more strongly proves their appreciation of the merits of the mosaic art. Let us follow the example more wisely, and when we import any foreign speciality, let us not bring with it any of the demerits which chance to accompany it, but unite it with the best art we are masters of.

I know few, if any, churches which possess the same internal beauty as Westminster Abbey. More modern art has done its worst to ruin it, but its intrinsic loveliness overrides every such attempt, and reigns triumphant over every disfigurement. One characteristic it possesses almost alone,—I mean the virgin privilege of perpetual exemption from the brush of the whitewasher. It probably owes this unique happiness to its having been built on the principles of constructive polychromy. It has materials of at least four varieties of colour, and these in some degree systematically and artistically used; and this fact has been sufficient to keep the whitewasher at bay. We are told that it is un-English and fantastic to care anything about the colours of our materials; but let it never be forgotten that the churches which could boast of the chaste dignity of their unvaried stone colour, have been both at home and abroad made over periodically to the tender mercies of the monochromist, while this at least has been spared, —and that on account of the un-English phantasy of using more than one natural colour in its construction. These colours are now nearly concealed by smoke, but they still show modestly through, and still aid in rendering the tone more solemn and striking than that of any church I have seen, excepting that very different one, St. Mark's,—at Venice.

Among the monuments in the Abbey belonging to this century I will mention—in addition to the Italian works already alluded to—the effigy of William de Valence, an oak figure plated with enamelled copper, the enamels on which are of magnificent workmanship;—the beautiful bronze effigies of Henry III. and Queen Eleanor, with the marble altar-tomb on the latter, and its beautiful iron grille;—the pretty little altar-tombs of some of the royal children,—and the gorgeous monuments to Edmund, Earl of Lancaster, and Aveline, his countess; the latter have been among the most splendidly decorated works of their day, and are worthy of the very closest study, both by the architect and the architectural painter.

I will call attention to one other object in the Abbey,—I mean the remarkable ancient retable, or moveable reredos, formerly belonging to the high altar. It is a wonderful work of art, and I call attention to it especially in this place, because it contains the most beautiful specimen of very early painting remaining in this country. It is probably by an Italian artist, several of whom are known to have been brought over about this time; but I confess I have seen no work of its age in Italy which I thought equal to it,—an opinion confirmed by an Italian professor of architecture to whom I once showed it. It is, I believe, contemporary with the early days of Giotto.

I will now pass on to a far humbler building, and one very little known or visited; I mean the Chapel of St. Ethelreda in Ely-place, Holborn. This was the chapel of the splendid town palace of the Bishops of Ely, and was built by Bishop De Luda soon after 1290. The destruction of the palace you will, I dare say, recollect to have been celebrated by Pugin in his 'Contrasts.' It was sold during the last century, and the present untempting looking street built on its site,—a place where one would as little expect to find a gem of ancient art as the ripe strawberries which Dickon of Gloucester saw growing there and begged for.

The chapel is in a wretched plight; its side windows have lost both tracery and mullions,—its west window is in a great measure boarded up,—the cradled roof plastered,—the whole galleried around and fitted up with pewing which would disgrace a tabernacle of the last century;—yet through all this its beauty still shows. The chapel is, as was so usual with private chapels, elevated on an overground crypt, so as to bring it to a level with the principal apartments of the palace. Curiously enough, this crypt is not vaulted, but has over it the original floor, of massive timber.

The east and west windows, of five lights each, are among the finest of their period and size. The side windows, denuded of their tracery, retain internally their beautiful jamb mouldings, and the wall between them has a graceful canopied and crocketed panel to each intervening pier, which gives the sides a very rich effect. I had longed and often lamented their mutilated condition, and was one day trying to get at some clue to the design of their tracery, by examining the scars where it had been amputated, when the thought struck me that the two westernmost of them being blocked up by the adjoining houses, might, if opened out, be found to retain their decorative features. I applied for permission to do this; and what was my delight, on removing the material which obstructed them, to find the old window—mutilated indeed, and shattered,—but still retaining every element needful to the restoration of its design!

The doorway to the chapel is very beautiful, and its foliated ornament well worthy of study. The internal dimensions are about 90 feet by 30,—a favourite size it would seem, and not differing much from the dimensions of St. Stephen's Chapel, that at Temple Balsal, or the Sainte Chapelle at Paris (reckoning the latter in French feet).

The architecture of the chapel is nearly allied to that of a series of sepulchral monuments I alluded to in my former lecture, and some of them again in this. One of these is that of its own founder at Ely; the second and third are those of Edmund and Aveline, Westminster Abbey, and the fourth is that of Archbishop Peckham, at Canterbury. All these date between 1290 and 1300, and are works of exquisite beauty and of the richest decorative art.

I will now lead you on a short excursion out of London, to a glorious old temple, which was in the days of my pupilage considered to be within walking distance, and can now be reached in less than an hour by railway. I mean the venerable Abbey Church of St. Alban.

You probably know the general history of this church: founded over the tomb of the Protomartyr of England, and within ten years of his martyrdom, and rebuilt on a larger scale by Offa, king of Mercia; it was again rebuilt of its present enormous dimensions by the earlier of the Norman abbots, using the materials excavated from the ruined city of Verulam.

The Roman brick was not a material very suggestive of ornamental architecture, and we accordingly find the original portions to be plain and massive in the extreme, but nevertheless highly impressive and interesting. In the work of the later Norman abbot we find this unshapely material cased with stonework, and of richly decorative details; but the church in general retained its severe simplicity undisturbed till the accession of Abbot John de Cella, in the reign of King John.

This worthy abbot was more a man of taste than of business, and his temperament more sanguine than calculating. He had no sooner taken possession of the abbacy than he embarked on a magnificent project for rebuilding the western façade of his abbey,—only a prelude probably to the reconstruction of the whole in the new style.

Digitized by Google

The massive brick front, with its flanking towers, would have formed an excellent nucleus for his work, but his ardent spirit would not submit to such an expedient, and he at once took down the vast façade, and that before he had collected money for the new one. The consequence was that he had scarcely got his new work out of the ground before his funds were exhausted. His first builder turned out a rascal, and he had to discharge him; the stone he used was destroyed by the frost; and mishap after mishap following his undertaking, the worthy man was led, as is so common with bad men of business, to bend his proud spirit to a paltry trick, and, as a means of raising the wind, he sent one of his monks about the country with a man whom he declared to have been raised from the dead by the agency of the relics of St. Alban, and begged money on the strength of the miracle; but all would not do, and after ten years' labour, during which the old historian tells us that all the funds he procured were merely like rivers flowing into the sea, which was no fuller for receiving them, he could not bring his work above the level of the masons' shed; and at length, giving it up in despair, contented himself with more humble undertakings.

He was succeeded by Abbot William de Trumpington, a man who united with the taste for building inherent in the age, a more moderate ambition and greater aptitude for business. He resumed the suspended works, but moderated their costliness; and making all the details plainer, and giving up or postponing the flanking towers, he was not only enabled to complete the rest of the front, but also to carry on the new work a long way down the nave, and subsequently to make many other alterations.

Now, I beg you to go and examine these works, and in doing so to bear in mind their history. You will find—as the chronicler tells us—that just about the height of a mason's shed there is a sudden change in the work. Up to that height the details are very superior, and far richer than above. Below we find traces of the artist,—above, of the constructor and man of business, though not to the forgetting of art. Thus, round the piers below are bases for marble shafts; somewhat higher are the marks where their moulded bands have been broken off; but above their capitals are wanting,—

"For William's shears had cut the bauble off."

The three portals I alluded to in my last lecture are the work of the unfinancial artist; the range of pillars, &c., down the nave of the not inartistic man of business. Both are noble works: Trumpington's works are bold and massive, and his details good, though simple; but, for beauty of design, we must award the palm to his less thrifty but more *spirituel* predecessor: indeed I know few works equal in design to what he commenced, and had he been able to carry it out, this façade might have vied with that of Wells. Unhappily there are externally little remains of the work of either of the abbots. Late in the century the choir also was in great measure rebuilt. Its character is less forcible than the earlier works, yet exceedingly beautiful.

The eastern chapels—which opened by five arches into the church—were at the same time commenced, but only in part carried out,—the Lady Chapel having been stopped short after rising a few feet from the ground, and the chapels which opened from the choir, having suffered considerable alterations from their first design. They are now virtually in ruins, but their details are of exquisite beauty. The windows have tracery of very high merit, and the wall arcading—now almost entirely destroyed—has been quite charming.

These works form a continuous series, from the last days of the twelfth to the end of the thirteenth century, and are admirable illustrations of the architecture of this great period.

I will dip seven years into the succeeding century to mention the exquisite fragments of the substructure which carried the shrine of the protomartyr. They have recently been exhumed in opening a walled-up arch. They are of Purbeck marble, and, in spite of the stubborn material, are most wonderfully carved, the leaves being so much undercut as in places to be quite detached.

This venerable church possesses claims upon the student residing in London, second only to those of our own Abbey of Westminster. I recommend it to your special and diligent study, and you will I am sure never blame me for my advice.

On some of your visits there, pray go on to Dunstable, where you will find a noble priory church in the later Norman style, whose western portal was probably in its day the finest in the kingdom; but, owing to the friable clunch of which it was constructed, has lost the greater part of its decorations. The west front contains excellent work of the thirteenth century. It is a great architectural enigma, which I believe I have solved, but I will not spoil it for you by explaining my conjectures.

I begin to see however that I have embarked on an endless task and have got half through my time without getting through the home district. I will therefore leave it, with a request that you will not consider Stonechurch, near Gravesend, the worse for having become somewhat hackneyed. It is a mutilated work, but what remains of it is as exquisite an example of a period about agreeing with that of Westminster Abbey, as can perhaps anywhere be found.

As I cannot pretend to give you a complete architectural itinerary, I will imagine—not seeing my way to a better—a northern tour in search of works of the age I have been treating of, and giving a passing look at Waltham Cross, in which I once delighted—though now I confess its so-called restoration has rather damped my enthusiasm—and hastily looking in at Jesus Chapel at Cambridge, a very excellent specimen of Early English, let us proceed to Ely. I have repeatedly alluded to the two great works in our style which it contains: the western porch, built between 1197 and 1214, is by far the noblest in this country. It is peculiar in its size and position,—more of a narthex perhaps than a porch, or rather the western arm of the cross formed by the western transept. Externally it is covered with decorative arcading in four ranges. It is of two stories, the upper one having formed a spacious chamber. The angle buttresses are of that beautiful kind which are almost peculiar to this period, being of the form of clustered pillars.

The two portals—the outer and the inner—are, in their leading forms, alike: they are double, and of very lofty proportions. Their heads were formerly filled with the Vesica Piscis, probably containing sitting statues; but this—why, it is impossible to divine—was taken out in both instances, and a wretched piece of flowing tracery substituted by Bernasconi, to the no small detriment of the doorways. The inner doorway is an exquisite work of art, the mouldings being most beautifully foliated. The sides of the porch are arcaded in two stages in a most beautiful and artistic manner, and probably contained sculpture. The capitals are among the finest to be found in any English building. The porch measures internally 40 feet by 30 feet.

The other great work of this century, at Ely, consists of the six eastern bays, with the eastern front. They were commenced by Bishop Northwold in 1235, and completed in 1251. It forms one of the finest specimens of the Early English style. The noble development of its triforium is an inheritance from the Norman church, with whose levels it was made to range. The liberal use of Purbeck marble adds vastly to the beauty of the work; the pillars are entirely of this material, including even these richly-foliated capitals, as are the long and elaborately-carved corbels which carry the vaulting shaft. The carrying out of the whole—its proportions, its details, its mouldings, the massive strength of its construction, united with just a sufficient degree of lightness, the great elegance of its vaulting, and the grandeur of its eastern façade—render it one of the most valuable objects of study which we possess. The tomb of its founder is a wonderful work of art,—a canopied effigy surrounded by statuettes, angels, and even subjects, all in a single block of Purbeck marble.

There are other works of our period at Ely, and fine ones; but we must not linger there, but proceed onward to Peterborough. If the three great arches which form the west front here are to be viewed as portals, I was certainly wrong when I said that English portals were small and inconspicuous. These are in fact of such vast elevation as to deprive them of that title. The whole may be viewed as a vast portico it is true, but the doorways are within it, and of moderate dimensions, while above them, and still below the arches, are considerable windows. It is in fact a design which stands quite by itself, and can scarcely be judged of by ordinary parallels.

I confess that to my eye it has always appeared as a glorious conception, though one not often to be repeated. Had its flanking towers been completed in the same style, the two great towers which backed it up completed with their spires, and the odd little chapel which has been thrust into its central arch been omitted, I know few fronts to which it would yield in grandeur, and none in originality.

Peterborough once possessed a noble work in the latter part of the century, in its Lady Chapel, but only a few fragments remain. Its mutilated cloister, the gateway to the Bishop's Palace, and the

Digitized by Google

ruins of the Infirmary, are beautiful works of this period. I know few cathedrals which externally I more enjoy than Peterborough. In old coaching days I used often to pass through between four and five in the morning, and if daylight permitted, I made it a point of conscience to run round the cathedral while the mail bags were in course of arrangement, and never will the impression it produced on my mind be effaced. I know no more beautiful group than its western transept presents as you return upon it from the north-east.

We come here into a country replete with village churches, many of which are in our style. Warmington, for instance, between here and Oundle, is an almost perfect thirteenth-century church, and I only mention it as one specimen, for time would fail me to enter upon even an enumeration. Off to the north-east too, there is West Walton, with its splendid and unique detached tower—an almost unequalled example; and nearer at hand are the mournful and tottering relics of the sister Abbey of Crowland, the details of whose western front are hardly to be surpassed, and are the more interesting as having been evidently the work of the architect to the eastern part of Lincoln Cathedral. Even the stone is from Lincoln, though it is a material not used in the district.

As you go from Peterborough to Lincoln, whichever road you take, there are endless series of village churches, as well as others of greater pretensions. Stamford is rich in work of this age, but I will only allude to the churches of St. Mary and All Saints. Close by is the beautiful Early English tower of Ketton. Grantham possesses the most stately steeple (next only to Salisbury) in the kingdom; and on another road I may mention Frampton, as having the most perfect of all simple early towers and spires that I know. But let us hasten on to the crowning glory of the district, whose lordly towers preside in serene majesty over the whole surrounding country.

No English cathedral is, externally, so imposing as that of Lincoln, nor do I recollect any abroad which as a whole surpasses it; and nearly the whole of its sublime architecture belongs virtually to this century, though in actual date it begins a few years earlier, and ends a few years later.

It is the custom to speak of Salisbury as the great typical example of the Early English style, and its unity and completeness may warrant the claim; but, both for the grandeur of the whole and the artistic beauty of every part, and also as a complete exponent of English architecture throughout the whole duration of its greatest period, Lincoln far surpasses it. Its leading features form a perfect illustration, and that on the grandest scale, of the entire history of our architecture from the last years of the twelfth to the earlier part of the fourteenth century.

As I have so often mentioned, the Pointed style commences here with the choir, the smaller transept, and the chapter-house, all of which seem to have been erected before the year 1200, by Bishop Hugh. It is commonly stated that his architect was a Frenchman from Blois; and M. Lassus broadly states that he reproduced at Lincoln, in 1188, the design of a church commenced at Blois in 1138. I am not able to speak as to the authorities on which these statements are founded, but I must say that the internal evidence afforded by the building itself gives it, so far as I can judge, little or no support. In the first place an eastern transept, in addition to that at the main crossing, is much more frequent in England than in France: whether the cathedral of Blois (now destroyed) possessed this I do not know. In the second place the polygonal chapter-house is an equally English feature. In the third place one of the most remarkable characteristics of this work is the nearly universal use of the round abacus,—that distinctively English detail, and that at a period somewhat earlier than that of its general predominance. The general distribution of the parts seems to me rather English than French, and though the work displays some idiosyncrasies, I do not see in them anything to indicate a French origin, unless it be in the capitals of the main pillars; indeed, it is a work in which distinctively English characteristics appear in a somewhat advanced state of development. As to its being a reproduction of a work commenced at Blois in 1138, the assertion carries with it its own refutation; for, in an age of restless progress, is it likely that they would take the trouble to bring over a foreign architect of so retrograde a taste as to ignore the artistic progress made in his own country during half a century? In fact, the wonder of the work is being so much in advance of its age, and that advance is not in a French but an English direction. The Church of St. Nicholas, at Blois, is in the Early Pointed style of the latter half of the twelfth century, but bears not the least resemblance to this,—it is of the same character which is usual in French transitional works, and its carving is strictly Byzantine, not a trace of which I have observed at Lincoln. If then a French architect was engaged here, he must not only have made over the details of his work wholly to Englishmen, but have studiously followed English forms in the general features.

The rebuilding of the cathedral seems to have been followed on systematically westward by the two successors of Bishop Hugh, till the completion of the nave by Bishop Grostete, about 1240.

The nave is by far the finest portion of the work as then completed, and is probably in the whole the grandest example of the Early Pointed style in this country,—it exhibits our Early English style in its highest state of development: massive without heaviness, rich in detail without exuberance, its parts symmetrically proportioned and carefully studied throughout, the foliated carving bold and effective,—there seems no deficiency in any way to deteriorate from its merits.

The west end is unique, being a vast and almost unperforated wall covered over with range upon range of decorative arcading, flanked by two vast stair turrets, and backed by two noble towers, the completion of which was however delayed till a much later period. It always strikes me as a very impressive front, but I find that it does not strike all eyes so favourably. I would call attention to the beautiful chapels to the right and left on entering from the west, with their light and elegant columns contrasting most agreeably with the massive piers of the nave; also to the noble rose window in the north transept, perhaps the finest in England.

The most gorgeous part however of the cathedral is its eastern portion. This was added between the years 1256 and 1282, and is consequently a little later than Henry III.'s work at Westminster. It agrees with it in style, but carries out the principle of window tracery on a far grander scale. It is in fact the most splendid work of that period which we possess, and, did it not lack internal height, I do not think it could be exceeded in beauty by any existing church. The sculpture with which it was once profusely enriched was of a very high order, the foliated carving perfectly exquisite; the mouldings and other details of the most perfect character. The east window is probably the finest in the kingdom, as is the east front in general, after allowing a certain abatement for the error of having false gables to the aisles. I have already mentioned the exquisite portals, the sculpture in which is superb, and our gifted Professor has published his views as to that which adorns the triforium. The student of mediæval art ought to make a long sojourn at Lincoln, and study its treasury of art at his leasure; not forgetting by-the-bye the beautiful remains of the chapel to the Bishop's Palace hard by the cathedral.

In passing northward from Lincoln a profitable digression may be made to Southwell, whose noble choir seems to be an emanation from Lincoln, and its far-famed chapter-house from York;—and to Newstead, whose beautiful west front and lovely carving agrees in style with the eastern portion of Lincoln.

Yorkshire is especially the land of minsters and abbey churches: to attempt here a description of them would be vain. A Yorkshire tour is one of the richest treats the student can look forward to, and one to which he ought to be liberal in his allowance of time. At York itself the transept is among the finest examples of the earlier part of the style; and the ruins of St. Mary's Abbey of its later portion. I know few works so enchanting as the latter. It agrees in date with the east part of Lincoln, and is not unlike it in detail. It is a mere wreck, but worthy of the closest study; and the shattered fragments which lie on every side offer melancholy facilities to the student. The chapter-house of the cathedral is a little later, and has been well called a *Domus domorum*, though I would not willingly admit its superiority to those of Westminster or Salisbury. The neighbouring village church of Skelton—said to have been built by the same hands as the transept of the cathedral—and the ruined chapel of St. Leonard's Hospital, in the gardens round the abbey, show how unerringly the same style fitted itself to works of the most stupendous and on the humblest scale.

This great county is filled with the noble productions of the thirteenth century. The minsters of Beverley and Ripon owe much of their beauty to it; and scarcely one of the abbey churches whose lovely but mournful ruins add a charm so melancholy to the secluded valleys of Yorkshire, fails to show the work of the great period. I cannot attempt even a cursory description. Go,

Digitized by Google

I pray you, and study for yourselves. Go to Fountains Abbey, and study well its choir and eastern chapels, with their massive pillars—the tallest perhaps in England—and the remains of its wonderful abbatial hall, exposed to view by the recent excavations; and its many other wonders. But do not be satisfied with a passing visit,—take up your quarters at Ripon, and follow up your studies from day to day: a week is but a short allowance for so rich a school of art. Then go to Rievaulx and Whitby,—twin works, it would seem, of the same accomplished architect; I cannot award the palm to either,—they are truly a *par nobile fratrum*, and it is fair to prefer whichever of them we have seen the last. Their great point of difference is that the choir of one has been vaulted, and that of the other has shown its timber roof; but in glorious architecture they are equal, and almost unequalled. As you go from York to Whitby you pass a small fragment of the Abbey of Kirkham: stop and look at it, small as it is, it is one of the best designed pieces of work I ever saw. If from Whitby you cross the Moors to Guisborough, you will see what was probably the work of the very end of the century,—the stupendous east end of that abbey, with its east window exceeding even that of Lincoln in height.

If you go on to Durham, the Chapel of the Nine Altars will rivet your attention; and further yet, at Hexham, at Dryburgh, and far on through Scotland, to the Chapel at Holyrood, and the glorious remains of Elgin Cathedral, and that noble temple yet preserved unruined at Glasgow, you will find a long series of the footsteps of the art of this wonderful age. In returning, pray look in at Furness Abbey, where you will find an absolute gem of our style in the ruined chapter-house. I intended to have had prepared an illustration of this exquisite little work, but time has failed. It has been of the same construction with the Temple Church, and of exquisite beauty. But a mere catalogue is both useless and wearisome. I have passed over the whole series of southern examples,—as Hythe, Shoreham, Winchester, Boxgrove, Wells (the glory of our style), Llandaff (one of its most original productions), Worcester, Lichfield, Hereford, and a hundred more examples, all of which supply proofs of the wonderful perfection of the architecture of this century.

I ought also to have called special attention to the circumstance, that while in France nearly every great church is vaulted, such is not the case in English works,—they seem to have acted with perfect freedom in this respect; and their churches, even the largest of them, have frequently had open timber roofs, and suffer little by the variety.

One thing cannot fail to strike every one who closely studies our old architecture. In early Norman buildings we often find rude and clumsy workmanship; in works from the middle of the fourteenth century, on to the extinction of Gothic architecture, we frequently meet with the same,—the work of rude untutored hands, evidently unable to do justice to their style. But from about 1175 to the end of the thirteenth century, and a little later, we scarcely ever meet with this inequality. The art seemed to be all-pervading. Certain buildings may have been plain to a degree, and rustic in their object and material, yet you rarely find anything you can call rude in workmanship, or unskilful in treatment. It was a great period, and its greatness seemed to pervade even the most secluded districts, and the workmen everywhere to have felt a pride in keeping up the period of their art in which their lot had been cast. Nor need we wonder at this, for everywhere were buildings going on; scarcely a village church escaped the notice of the builders of this wonderful age. The whole country was engaged in the one work of building, and that with an ardent feeling to render their work worthy of the style they had generated.

And let us not imagine that the architecture of the age developed itself only in building cathedrals, abbeys, or churches of any kind; all other buildings evince the same spirit: a barn of the thirteenth century shows the nobleness of the pervading style as clearly as even the cathedral itself, and what remains of their domestic architecture tells the same tale. Everything was done well, in good taste, and in accordance with reasonable and practicable requirements and the means at command. Nor was it to architecture alone that the arts of the period were devoted: we find the same art expended on stained glass, on metalwork of all sorts, on enamels of the most magnificent character, on the illumination of manuscripts, the painted decoration of the buildings, on jewellery, on ivory-carving, on embroidery, on woven fabrics, tapestry, seal-engraving,—in fact on every branch of decoration; every one of which arts are carried out with a degree of skill and instinctive taste truly amazing. All these branches should however be treated of separately.

In my enumeration of buildings I have limited myself to our own country; but we all know that in France the same great facts are if possible yet more wonderfully proved. The architecture of the thirteenth century in France is rendered illustrious by an endless category of buildings, the most glorious perhaps which the world has produced.

Germany, though her style is broken harshly by the cause I have before alluded to, nevertheless furnishes, whether in the native variety of the former, or in the adopted one of the latter half of the century, a series of buildings of which any country might well be proud.

In Italy the style was certainly imported from the North, but was it an unnatural transplantation? I should say, by no means so. Had not Italy her own Romanesque, which she had in some degree imported to northern countries; and have I not shown that Pointed architecture was a natural and logical development from Romanesque? Why, then, should it be accounted foreign to the land from which Romanesque itself had sprung?—and if the growth of Pointed architecture was aided by ideas culled from Byzantium and the East, why should those ideas be less suited to Italy than to France or England, whose communications with the East were far less direct? Did not she take part in the same crusades,—nay, did not the Byzantine element in French art actually come there through the medium of Italy? Let us not then deny to her a fair participation in the architecture of the age. We had it before her it is true, but let us not on that account say that it is none of hers.

The great fault in the mediæval architecture of Italy lies in its details, such as its mouldings, &c., which evince too much of their antique original; its great value lies in its use of materials of varied colour, of inlaying, mosaic work, and other decorative arts, inherited also from the past. These arts ally themselves well to our style, though the classic mouldings do not so, and in our judgment of Italian work we should never lose sight of this; we may otherwise be led either to reject real merit from the offence which incongruous detail offers to our taste, or we may be led to accept what is bad and spurious, because gilded over and its demerits concealed by beautiful art, which would appear to greater advantage if united with purer architecture.

Another point however which gives great value to the mediæval art of Italy, arises from the somewhat accidental circumstance that her internal position was such as to require town buildings very much of the kind which we want now. The consequence is that Italy was, even in these earlier days, the land of street palaces, and that we find yet remaining there numberless buildings of a class which we find but rarely in other countries, and those treated in a manner very parallel with what we often require at the present day. Not, let it be born in mind, that they are treated in a manner essentially different from the coeval works in more northern countries, but rather that there were more of them,—that these were on a larger scale, and that more of them have remained to our own day.

It is a mistake to suppose that the secular architecture of Italian cities essentially differed from that of the same period elsewhere. If you will carefully look through any book showing specimens of the domestic architecture of France in the thirteenth century, you will find that it closely resembles that of Italy, except in having purer details. The same kind of window for instance which from habit people had got into the way of calling Italian or Venetian, prevailed in France and Germany, and is often found in England.

I could give you a series of Italian, French, German, and English windows of early date where you could scarcely distinguish the one from the other; indeed, you would seldom be able to detect an Italian window at all if divested of the accidental clothing of its non-essential details. This establishes the unity of the style; yet the fact remains that works of the kind are more abundant, larger, and more developed in Italy, and that they may consequently be studied there to great advantage as an aid and expletive to what we learn elsewhere.

This brings me to the concluding subject of my lecture,—the question of what lessons we should learn from what has passed in array before us, and what effect it ought to have on our own artistic practice.

It would be hopeless to enter upon the general question of the revival of styles. I will suppose that question to have been dis-

Digitized by Google

posed of for us, and limit myself to considering what is the most reasonable course to follow in conducting such a revival, or rather in carrying on the development of a style upon a revived basis, such as that of the architecture we have been considering.

Now such a revival, to begin with, is hardly to be viewed as a deliberate act; a man would scarcely be bold enough to make up his mind, *à priori*, to revive a style of architecture: circumstances must have gradually led to such a course, and it must have been set about gradually, and almost unconsciously, to give it a chance of success. We may, in looking back upon what has taken place, construct a very good theory for it all, but no such theory really led to it,—it came about very much of itself. We may by thought and by studying our position do a little in finding an existing movement,—but the movement itself must have arisen from some more hidden and deep-seated cause, or it would have died away long ago. What then does this deep-seated feeling demand, and with what will it be satisfied?

It craves spontaneously after a great style of art, which it sees to have been once the birthright of our race. It demands that we should,—I will not say simply *revive* that style of art, but that we should *revivify* it; not that it should be reproduced as a splendid pageant, to be re-enacted for the sake of gratifying our romantic or antiquarian predilections, but that we should rekindle its actual life; and having done so, should not only think, and design, and invent in that style as the living medium for the expression of our artistic aspirations, but that we should cause it to take root, to spring forth, to germinate and ramify,—to shape itself to all the demands of our age, and to adapt itself to its materials, its discoveries, its inventions, and its science; in short, to become in every sense a living, a vigorous, a growing art.

Now, to further such an object, what is the best manner in which we can make use of the lessons to be learned from the past creations of that style? One of the lessons I think we should learn is to work in the same free and liberal spirit in which our forefathers worked; not to do what they did, but as they did. If we, on the one hand, shut ourselves up in our own country, and, reproducing the style we find to have prevailed here, sulkily reject the lessons to be learned from neighbouring lands, we may produce a servile reproduction of what was done by our predecessors, but shall be acting anything but as they acted. If, on the other hand, we travel widely, and, giving free license to our individual preferences or momentary fancies, we import now this style and now that; here building in a French, there in an Italian variety of our style,—we shall in each case be doing what was done in one or another province of mediæval art, but shall be equally free from doing as the old artists did: the one course involves servility, the other adds to it frivolity.

The great principle on which the mediæval architects of each country instinctively acted was, while adhering in the main each to the dialect of the great art which happened to be current amongst them, to improve it by the free importation of ideas and adoption of hints from whencesoever they might be derived, but especially from the dialects of the same artistic language. Thus for instance, the Pointed architecture of the Royal Domain of France is as a whole a logical sequence of the Romanesque of the same district,—yet no scruple was felt at importing into it the Byzantine capitals and foliage which had come to them through the medium of Venice, and to this foreign importation they owed some of the greatest beauties of their architecture; nay, if the oriental origin of the Pointed arch be true, they went further, and engrafted upon their traditional art a feature learned from the infidels they were combatting. Again, the English Pointed may be traced step by step from the preceding style, yet they had no hesitation about introducing into it details developed by the French. The Germans carried the principle too far: giving up their own traditional variety of Pointed architecture, they adopted the French developments ready-made,—yet, having done so, they worked them up in a manner quite their own: while in Italy, the new style having been brought in upon the pre-existing Romanesque, they soon elaborated it into a dialect as distinctively characteristic as those of other European countries. Besides this, no nation had any scruples about employing artists belonging to another; so that the advancement made by each became in a degree the common property of all, and even the woven fabrics and other manufactures imported from the far East were allowed to offer suggestions to the European decorator.

To follow out the same principle we ought, while especially making ourselves masters of the architecture of our own country, and using it as the groundwork of our revival, nevertheless to view the style as a whole, and, while not forsaking our own provincial dialect, to make ourselves masters of the entire language. We should not wish our revived art to be indistinguishable from that of our forefathers. It should certainly reflect some of the characteristics of our own age, one of which is our enormously increased habits of locomotion; and as we visit all the districts where our style prevailed, nothing can be more natural than that our revived art should show the effects of our more extended sphere. Knowing, as we do, that France was the central district—the very heart—of mediæval art, should we not be insane not to study well her glorious monuments, and having studied them to enrich our own style by the many lessons we may learn from them? It has been suggested that we should do this, especially as regards those of the provinces of France which were once subject to the English kings. I would not reject the historical interest which this connexion naturally gives rise to, and I doubt not that those provinces are rich in instruction; but I would not on that account neglect the fact that it is the *Royal Domain* of France—the district of which Paris is the centre—which was the special focus of our art. Look again at the ancient cities of Germany,—perfect storehouses of old architecture; let us never be so suicidal as to reject the lessons they offer! "So far," some may however say, "is all very well; but, for goodness' sake, do not cross the Alps! Ruskin has driven you all mad about Venetian, Veronese, and Florentine architecture; be more of men than to be led astray by popular writing. You cannot but see that Italian Gothic is very corrupt, though somehow or another very captivating. Listen not then to the syren's song; reject the enticing bait, nor pollute the pure stream of Northern art with the corrupted waters of the South."

I admit that there is some ground for such a caution,—there is a mysterious fascination about Italy, which has led astray many who have visited it before they had grounded themselves firmly upon a northern foundation; but is this a reason for rejecting all the lessons she offers? Was not Italy the land of ancient art, of painting, of sculpture, of mosaic work? Is she not the land of marbles and richly coloured material, and the land of ancient municipal institutions and of the edifices to which they gave birth? Her Romanesque architecture was the parent stock of our own; and if our Gothic was in its turn the stem from which her's sprung, surely its transplantation into so prolific a soil offers the greatest possible *primâ facie* grounds for expecting a rich variety to spring forth from it,—and such has been the result. It is for us to use it with judgment: rejecting what is in its own nature defective; not bringing into the north any features which are the result of a southern climate, but judiciously culling such suggestions as will with advantage unite themselves to our English nucleus; and especially let us take advantage of the lessons it affords us in the use of rich materials of mosaic and fresco-painting, and in any suggestions it offers for the perfecting of our secular architecture. Only let us do so with judgment, never forgetting that it is in England that we are working, and that if we borrow ideas from France, from Germany, or from more southern lands, those ideas must be expressed *in English*—a language, in art as in literature, of whose antecedents we find abundant cause to be proud.

Let us also remember that, though we must be ever learning, it is not by this alone that an art is to be generated; that we must act for ourselves, as well as learn from others: and that it is to our own vigorous and manly exertions we must trust to make the art we are reviving shape itself to the necessities and the spirit of the age we live in.

A correspondent of the *Journal of the Franklin Institute* writes,—"In almost every instance of destruction of steamers by fire, access to the engine has been cut off; and while the flames are driven aft by the speed of the vessel, they have no means of obtaining water. Could not a syphon-like pipe be introduced when the vessel is being built, extending the whole length of the same, through which the water would flow freely, so as to give motion, when necessary, to a hydraulic ram when required? The highest part of the pipe should be well aft, and it should not be higher above the water line than the point to which the minimum speed of the vessel would cause the water to rise; cocks could then be attached at various places, so as to draw water if necessary."

NEW GRAND ENTRANCE TO ST. JAMES'S PARK.

TO THE EDITOR OF THE CIVIL ENGINEER AND ARCHITECT'S JOURNAL.

SIR,—"If you move I stickee; if you don't move I stickee," is said to have been the salutation addressed by a negro private of one of our West India regiments to a gentleman to whose front he presented his bayonet, the gentleman being found one night within some interdicted boundary, and unable to give the requisite pass-word. Now this salutation appears to be pretty much of the same character as the treatment the Metropolitan Board of Works has received. At first the public press voted them altogether *too slow*, because they could not immediately and by intuition settle what was the best plan of dealing with the great and complicated question of the main drainage of this metropolis, and the very ticklish question of how to get the metropolitan rate-payers to pay the piper. Having, notwithstanding the confusion and clamour created by the advocates of the various rival systems, arrived at some kind of conclusion in this matter, and being about to carry out a plan which had received the sanction and concurrence of the great engineering authorities of the day, it was then found the Board was going *too fast*, and it was deemed right to watch their proceedings very closely, to see whether some extravagances were not being perpetrated which ought to be publicly and energetically denounced; and at last it was discovered that the Board intended to remove its offices from the neighbourhood of the Seven Dials (where they now are)—a nice secluded position, very proper for the jog-trot Commissioners of Sewers of the olden day, but not quite the sort of situation for the offices of a public body charged with the management of this great metropolis—to the centrality and prominence of Charing-cross; it being proposed at the same time to make a grand entrance into St. James's-park from Trafalgar-square. Now the throwing open of the mall of St. James's-park to the Strand and Trafalgar-square, one would think, ought, *if properly done*, to be one of the most magnificent of London improvements, and it would appear wise not to oppose the project of removing the offices of the Board to Berkeley-house, St. James's-park, provided the opening is a sufficient and proper one; that is, that it extend from Cockspur-street to the entrance to Spring-gardens, opposite King Charles' statue, which would afford a grand *coup d'œil* from Trafalgar-square or from West Strand, somewhat resembling the Champs Elysèe of Paris. It need not be feared that the "quiet seclusion and sylvan character" of St. James's-park would be affected by this alteration, for such opening would not affect the inclosed part of the park, except beneficially by letting in more air; and that inclosure is the only part of the park that can be fairly deemed "quiet" or "secluded." It does not follow that because we should then have a broad and noble entrance for passengers and carriages, that therefore omnibusses and Pickford's waggons must race up and down as they please; the roadway along Birdcage-walk is not subject to heavy noisy traffic, and the proposed roadway might be similarly privileged.

This scheme of the Metropolitan Board, if looked at in a broad and liberal manner, deserves not public opprobrium but public support, and it certainly is anything but charitable to say that the motive which induced the Board to select Berkeley-house for head-quarters, was flunkeyism, or the desire to possess a fashionable *locale!* Without a personal knowledge of the members of the Board one cannot of course say whether this imputation is or is not founded on truth, but it is only fair to take the least offensive aspect of the question, which is,—that the Board, being a new municipal institution, of such character that, if it is to be anything at all, must be one of the first importance to this great capital, that therefore it is not meet and proper that it should be hid away in a corner, and truly Greek-street, near Seven Dials, is not a suitable public situation, whilst Charing-cross is an eminently central and accessible one; and the removal would afford the opportunity of effecting a splendid improvement. Doubtless the Metropolitan Board is not all perfection, but it is not a congregation of incapables, and although all the members may not belong to the upper ten thousand, yet they are gentlemen of good social position, and in Mr. Tite we have an eminent architect of high character and position. For the sake of the great improvement which may be effected in connection with this change of offices, it is to be hoped the scheme will be persevered in, and properly carried out; and if it be, it need not create any very heavy burthen on the rate-payers, as the value of the building sites on each side of the entrance ought considerably to lessen the expense.

MEGALOPOLIS.

CONTINENTAL ART GOSSIP.

EXCAVATIONS of great interest have been making beneath the well-known basilica of San Clemente, at Rome. In working towards the atrium, two Christian sepulchres have been discovered, which must have stood in the aisle close to the entrance of the primitive basilica. One is supposed to contain the remains of St. Cyril, and has been carefully sealed up. The other is highly enriched with sculptured foliage, and a head in basso-relievo unfinished.

A new museum of Christian antiquities of the utmost interest has been formed by Pius IX. in the Lateran palace. The walls of the principal *sala* are adorned with original frescoes removed from the walls of the Catacombs, or copies from others which it was found difficult to detach. About the floor are disposed various Christian sarcophagi, some of them exceedingly rude and even grotesque, others of great beauty,—but all deeply interesting for their typical and symbolic representations. The corridors of the Lateran are to be employed as a lapidarian museum, to relieve the over-crowded Vatican of the *embarras* of these precious records graven upon stone and marble.

The very interesting basilica of Sta. Agnese fuori le Mure has undergone a thorough repair, and workmen are now engaged upon the adjoining circular church of Sta. Costanga.

Flatz, a German artist of the ascetic school, but who combines with intense religious sentiment in his works great grace and purity of drawing, has several commissions for England on hand, —notably those works for the domestic chapel of Mr. Blundell, of Ince, the principal subject being "Christ leaving the temple after his dispute with the doctors."

Gibson, "*il famoso*," as the Italians call him, is hard at work. He has completed a copy of his famous coloured Venus for Lord Sligo. He is now engaged upon an exquisite statue of Pandora, for Lady M. Alford, and this is to be painted and gilt; and he has a Hebe on hand, also to be coloured. Gibson's refined taste in his coloured sculpture is more likely to remove a general prejudice against this revival than pages of angry controversy.

The Prince of Syracuse has paid a compliment to an English artist, by reproducing in the most exact fac-simile as to form, illustrations, paper, &c., a translation into Italian of the little but most curious and interesting *brochure*, 'On the Proportions of the Human Frame,' by J. Bonomi, F.R.S.L., the principles of which were explained by that gentleman in a paper read by him before the Royal Institute of British Architects, and given to our readers in our number for February.

Tenerani, the eminent Roman sculptor, is working on a grand colossal group to form a monument to Pius VIII. It exhibits all the admirable qualities of the artist,—breadth, dignity, and repose.

We fear the result of the Lille competition will hardly have encouraged English architects to enter upon the competition which was invited some little time ago for designs for the restoration of the central tower of the noble old church at Bayeux As the building exists at present there is a rich octagonal Flamboyant lanteru, terminated by a miserable dome in the Italian style.

At Nantes three churches of unusual importance have been just brought to a conclusion. St. Nicholas is one of the most important ecclesiastical edifices of the day, consisting of nave with double aisles, transepts, apse, with procession-path and radiating chapels. The style is the pure French 13th century, most admirably carried out; the name of its lamented architect, Lassus, being a guarantee for its excellence. A presbytery full of character and common-sense architecture adjoins the church. St. Clement is another spacious edifice, also in the 13th century style, and of very considerable merit; it is from the designs of M. Liberge, of Nantes. Notre Dame de Bon-port is in the Renaissance style, with a dome at the crossing of its nave and transepts.

A remarkable church is about to be erected in Algeria, from the designs of M. Fromageau. It has a vestibule, square nave, and apsidal transepts, and chancel, with a dome at the crossing. The architect has exhibited considerable ingenuity in combining Byzantine and Moresque characteristics, but we are inclined to think has allowed his ingenuity to trench upon good taste in some regards. A large amount of decoration is to be obtained by a free use of enamelled earthenware; and the dome is to be covered with gilt copper banded with crowns of bronze and points of crystal.

LOCOMOTIVE ENGINE SHED AND TURNTABLES AT THE GATESHEAD STATION.*

(With an Engraving.)

In the arrangement of large engine sheds the important points requiring consideration are capacity and economy of construction, combined with facility of ingress and egress for the engines at all parts of the shed. In the shed forming the subject of the present paper, which is erected at the principal locomotive works of the North Eastern Railway, at Newcastle-on-Tyne, an unusual number of engines had to be accommodated in one place; so many that five separate buildings of the ordinary polygon arrangement would have been required, entailing a very heavy cost of construction.

From the convenience of the polygon arrangement for access to all the engines, the same general plan was adhered to as regards the engine pits and turntables, which are arranged as shown in the general plan, fig. 1 (see Plate), in the same manner as if five ordinary polygon sheds had been constructed close together, in two rows alternating with each other, so that the lines joining the large turntables AA, in the centre of each polygon form three equilateral triangles. By this arrangement of plan, a direct line of rails is obtained communicating from every turntable to each of the adjoining ones; and several distinct roads are obtained for entrance or exit at each of the turntables, one of them having five separate roads, while two of them have four, and the remaining two have three roads each. Then instead of having the expense of building that would have been involved by the construction of five separate polygon sheds, requiring a long range of wall and an expensive construction of roof on account of the large span and polygon form, the whole area has been inclosed by a plain rectangular wall FF, and covered in by five ordinary parallel roofs of moderate span, supported by four rows of columns running the entire length of the building, and falling into the intermediate spaces between the pits, without interfering with any of the lines of rails, as will be seen by the plan.

The result obtained is a covered area of 126,000 square feet, instead of 88,257 square feet, which would have been the area of the five polygons, or an increase of 43 per cent. in the area, with a reduction of 37 per cent. in the length of walling, which is 1476 feet in the rectangular building, instead of 2340 feet; the cost of construction being reduced in a considerably greater proportion, from the simpler and cheaper description of work in the rectangular building as compared with the polygons.

The additional space obtained in the rectangular building is found of great utility and convenience for carrying on the minor repairs done in an engine shed, such as changing wheels, &c., which is here accomplished without occupying any of the lines used by the running engines. For this purpose strong lifting frames are fixed over the spare lines in those parts of the shed, as shown at BB in fig. 1, fitted with gearing for lifting the engines. Fitters' benches are also erected in the open spaces of the shed, as shown at CC. At DD are fireplaces for warming the shed and lighting the engine fires.

Fig. 2 is a transverse section of the building, showing the five separate roofs, of which the three centre roofs are 65 feet span, and the side roofs 42 feet 6 inches, making the total width of the building 280 feet. The total length of the building as shown in the drawings is 450 feet; but only two thirds of this, or 300 feet, is at present built; the portion EE in the plan, fig. 1, including two of the turntables, not being yet constructed.

Fig. 3 shows an enlarged transverse section of one of the 65 feet roofs. The principals are fixed at 12 feet 6 inches apart, and the purlins are trussed with wrought-iron flitches, 4 inches by ¼ inch, with 4½ by 4 inches wood. The principal rafters are constructed of two bars of channelled iron 4½ inches deep by 1½ inch wide on the flanges, with a 2¼ inch space between them, into which the T iron struts are fixed. The cast-iron columns supporting the roof are fixed at 25 feet apart, and connected by cast-iron girders; and at F in the plan, fig. 1, one of the columns is omitted for the convenience of the oblique lines of rails, and a wrought-iron girder of 50 feet span is introduced.

A plan of one of the engine turntables is shown in fig. 4, and a longitudinal section in fig. 5, with a transverse section at the centre in fig. 6, and a section at the end in fig. 7. The table is 42 feet diameter, and consists of two main wrought-iron girders GG, 3 feet deep at the centre, and 2 feet deep at the ends. These girders are secured together by a cast-iron cross H, which fits upon the fixed centre pin I, by a cylindrical socket, extending the whole depth and turning freely upon the pin. The centre pin is of wrought-iron, 9 inches diameter, and is fixed into a socket 2 feet deep in the pedestal K, bolted down to the foundations; the pedestal is shrunk upon the pin, which is then secured by a key. The bearing for the table is taken at the top of the fixed centre pin I, by a short steel pin L, 6 inches diameter, which revolves in a socket 5 inches deep in the top of the fixed centre pin I. The bottom of the pin L, is rounded at the edge, and turns upon a steel plate 1½ inch thick at the bottom of the socket. The pin has a flange at the top carrying a cast-iron cap, from which the whole table is suspended by six bolts taking hold of the cast-iron cross H, the bolts giving the means of adjusting the level of the table.

The outer ends of the girders are fitted with sliding wrought-iron wedges, which are moved by the handles M, and when pushed out rest solid upon cast-iron chairs, fixed upon the outer foundation curb at the end of each line of rails, and support the ends of the girders whenever an engine is being moved on to or off the table. A pair of safety rollers N, is added at each end, running upon a circular rail O, but not in actual contact with the rail in the ordinary working of the table, being applied only as a precaution to prevent strain, from the weight not being balanced on the table, or in case of accident to the centre pin.

An engine and tender is readily turned upon the table by two men pushing at the end, without requiring gearing; the weight is so nearly balanced upon the centre pin that the rollers at the ends do not take any appreciable weight in regular working; and the due placing of the engine on the table for this plan is sufficiently ensured in practice by the circumstance that any neglect in this respect would increase the resistance to be overcome in turning the table.

An important advantage in this construction of turntable is the great facility for examining and keeping in order the only part that is subject to wear, namely the steel centre pin; this is readily done by fixing the sliding wedges at the ends of the girders, when the table becomes a rigid portion of the line of rails, and the steel centre pin is taken out by simply unscrewing the six nuts, and the socket is readily examined, being close to the top of the table. These turntables have now been two years in constant use, and have given entire satisfaction, no attention having been required beyond ordinary oiling, and only one of the steel centre pins having required to be taken out for examination during the whole time.

* Paper read at the Institution of Mechanical Engineers.

CHESTER CATHEDRAL.

It is proposed to raise a memorial in Chester Cathedral to John Pearson, once bishop of that diocese—well known as an author—and who died in 1686, being buried in the cathedral, within the rails of the altar, but without any memorial even to record his name. The kind of memorial is to be determined hereafter, according to the wishes of the subscribers; it will probably be either a monument bearing the effigy of the Bishop, or a window of painted glass, erected at the east end of the chapter-house; or a restoration of the great east window of the lady-chapel, near which his body lies. This latter subject has been for some time in contemplation, independently of the purpose just adverted to, inasmuch as the present "perpendicular" design is not only unworthy of, but quite inharmonious with, the surrounding architecture, which now, after a long and expensive process, may be considered as restored as nearly as can be ascertained to its original design. The *coup d'œil* which the lady-chapel now presents is one of surpassing beauty (with the above exception), the details throughout are of the best period of the Early English era, and the whole is delicately, yet richly relieved by polychrome and gilding. This latter department has been most efficiently undertaken by Mr. Octavius Hudson, the results of whose skill at Salisbury and Ely are well known. It may be well to add that Mr. Hudson's system of colouring has not been founded on conjecture, but his extensive acquaintance with the subject, based on the examination of our principal mediæval edifices, renders him a peculiar authority in such matters, and for the decorations at Chester it appears that he has in most cases been able to detect remains of ancient colouring, which, it is needless to say, have been reproduced with scrupulous care.

INSTITUTION OF CIVIL ENGINEERS.

JOSEPH LOCKE, Esq. M.P., President, in the Chair.

February 15 and 22.—The Discussion upon Mr. JAMESON'S paper, "*On the Performance of the Screw steam-ship Sahel, fitted with Du Trembley's Combined Vapour Engine; and of the sister-ship Oasis, with Steam Engines worked Expansively, and provided with partial Surface Condensation,*" occupied both evenings.

In commencing the discussion it was observed, that experiments made with great care and continued over some time induced the opinion that surface condensation would ultimately supersede condensation by injection. It was found that a condensing tube 4 feet long and ½-inch in diameter would be sufficient for a non-expansive engine of $\frac{1}{10}$ H.P. Such a tube placed concentrically within one of slightly greater diameter, so as to allow only a thin stratum of condensing water to pass between the two, would condense 3 lb. of water per hour; the pressure in the condenser being only 0·96 of an inch of mercury, the temperature of the condensed water 24° centigrade, and the temperature of the condensing water before and after doing its work 7° and 18° centigrade respectively. The same tube would condense 30 lb. of water per hour, the pressure in the condenser being 23·2, the temperature of the condensed water 85° cent., and the temperature of the condensing water before and after doing its work 8° and 36° cent. respectively. An approximate formula for determining the vacuum in any particular case applied to the same condensing tube might be thus expressed:—the deficiency of the vacuum in the condenser, compared with that due to the temperature of the condensed water, was directly proportional to the quantity of water condensed in a given time, and inversely to the difference between the temperature of the vacuum and that of the condensing water.

A further account was then given of the voyage made by Mr. Rennie in the ship Du Trembley, in the year 1853, from Marseilles to Stora, in Algeria, and back. From this it appeared that there was a saving of fuel of from 50 to 60 per cent., and consequently that an increased amount of space was available for cargo. This advantage was partly counterbalanced by the cost of the ether, and the inconvenience and possible danger of its use, particularly in hot weather, when the vapour was at times diffused over the vessel, and became very inflammable. But these defects might yet be remedied.

It was remarked that the difference in the consumption of fuel in the combined engine and in an ordinary expansive engine being respectively 3·1 and 7·4 lbs. per I.H.P. per hour, seemed to indicate the superiority of the former system. But before accepting this conclusion it was desirable to examine the conditions of the experiment. In the first place, it was evident that there was a bad vacuum in the ether cylinder, which might be attributed partly to the difficulty of condensing that liquid, and partly to the exhaust ports being insufficient in area; for ether steam being five times heavier than water steam, the ports for its discharge should be twice the usual area. On the other hand, it was doubted whether in the expansive engine the cylinders had been properly protected; and it was stated that a loss of 50 per cent. had been known to occur from condensation in an unprotected cylinder when working expansively. It seemed therefore essential to inquire into the relative merits in a theoretical point of view, of the combined ether engine and a well arranged expansive steam engine. According to the dynamic theory of heat, heat and power were identical. The particles of a heated body were in a more agitated condition than in a cooler body, the motion of the particles being greatest in elastic fluids, and their pressure upon the sides of the vessel such, that if one side yielded (as was the case with a working piston), the reaction would be less than the impact. Hence the motion of the particles would be diminished in proportion as the piston was urged forward, and the result would be reduction of temperature. Expansion might be carried to a point where the elastic force was entirely exhausted. Commencing with steam of the density of water, and expanding it until a perfect vacuum was obtained, would form in point of principle a perfect engine. But the practical difficulty of carrying expansion to its utmost limits, was the great strength and size of cylinder required for the purpose. All the different air and other engines designed to supersede steam had aimed at one point, that of carrying the expansive action to a further degree without its being necessary to resort to such large and strong cylinders. In the combined engine the analogy was evident. The expansive action was stopped at a certain point, and the steam was made to impart its heat to another liquid, which evaporated at a lower temperature, and the vapour of which occupied less room than steam at a given temperature; so that a smaller cylinder could be employed. It was a matter for calculation whether this advantage was sufficient to balance the disadvantages of an imperfect vacuum in both the steam and the ether cylinders,—of the complications, and of other drawbacks which had been mentioned in the paper. It was believed, that by properly protecting the ordinary steam cylinders against the loss sustained from condensation, results would be obtained equal to those claimed for the ether engine.

It was remarked that a theoretical comparison of the relative merits of the ether or combined engine, and of an ordinary steam engine, was in favour of the former, as there was undoubtedly an addition of power. With reference to the possibility of improving the ordinary steam engine, by carrying the expansion of the steam to the furthest practical point, and thus utilising the maximum calorific power, that was a problem of great complexity, the practical solution of which had not hitherto been attained. It was thought that the apparent difficulties in dealing with ether should not be considered an insuperable obstacle to ultimate success. The present leakage at the joints required attention, as it involved waste of ether, and increased the chance of danger. There was no apparent reason why this should not be accomplished, as, although ether penetrated more readily than water, and thus necessitated a better joint, yet it was not a corrosive liquid, and had no appreciable action upon metals.

It was believed, that the right way of looking at this question was to compare the performances of the combined marine engine, first, with ordinary marine steam engines, made by experienced makers; secondly, with the most economical engines working on land; and thirdly, with a theoretically perfect engine. With regard to the first point, it was found that the use of the combined engine, setting aside the cost of the ether, effected a saving of two-thirds or one-half in the consumption of fuel. In the second place, 2 lb. of coal per I.H.P. (the ascertained consumption in the Kabyle), represented one hundred millions of duty in a Cornish engine, which was very good work,—many engines doing much less; therefore there was an engine used for steam navigation as economical in point of consumption of fuel as some of the best engines employed for pumping. The third comparison, that an equal amount of economy would be gained by a proper expansion of the steam at a low point, without the intervention of ether, might be answered by the fact that marine steam engines were still made which consumed at least one-half more fuel than those under the combined system. It should be borne in mind that where the practice was pursued of working steam very expansively, more fuel per indicated horse power was stated to be burnt than when working with full steam,—at all events, the expected economy was not produced. As regarded the question of the leakage of the ether, the waste was now so small, that it was commercially worth while to use it, and thus to effect a saving in the consumption of coals. The vapour caused little or no inconvenience. It was not simply whether the cost of the ether was equal to that of the coals saved, for the space which the coal occupied in the ship must be taken into consideration. The danger was not greater than was incurred in the use of gas in a dwelling-house, and no objection could be made to the system on that ground. An explanation was offered as to the reason why the system had not been employed in England. As an illustration of the difficulty of getting any new invention tried in this country, it was mentioned that an offer had been made to a large steam-boat company to apply the vapour engines to a vessel of 60 H.P. free of cost to the company. Their performance was to be tested on land, before being placed in the vessel; and if when fitted in the ship an economy of 25 per cent. was not obtained, then the ordinary engines were to be replaced without expense to the company. This offer was refused, the company giving as a reason that they did not like trying experiments. It had been stated that other fluids than ether might be applicable. The bi-sulphide of carbon was cheaper, gave more bulk of vapour, and was in every respect a more desirable vapour than ether. A description was then given of a modification in the method of effecting a junction between the wrought-iron tube-plate and the tubes of the vapouriser, which also acted as the steam condenser. When thus constructed it was proved with air pressure, and the loss was ascertained to be only 1 lb. per hour, so that it was practically tight.

Some remarks were then made to show how objectionable it was to work without a steam jacket to the cylinder, especially when using steam very expansively, as the cylinder then became a condenser at the commencement, and a boiler at the end of the stroke. Great credit was due to M. Du Trembley for introducing a system for concentrating the light pressure of the long end of an expansive figure; but it was not thought that any more power could be obtained from a given quantity of heat by this means than by the proper use of steam.

It was thought that the vapour engine should have been compared with a pumping engine, and not with an ordinary marine engine, as the actual efficiency of and the real duty performed by the latter could not be ascertained; whilst the load upon a Cornish pumping engine was a known and definite quantity. For comparison in respect to load, engines should be divided into three classes:—first, the Cornish engine, in which, with a known weight at the end of the beam, an effort was exerted in each succeeding stroke of similar and equal value. Secondly, with a factory engine, working with a load, which might be, but was not generally known. Thirdly, with a marine engine, in which the load on the engine could not be stated, as there were no means of determining or measuring the friction of the vessel. One of the chief peculiarities of the pumping engines, constructed on the Cornish principle, was the employment of a steam jacket around the cylinder, and in direct communication with the boiler, the cylinder being situated at a higher level than the boiler. It was now also frequently the practice to surround the jacket in addition with a coating of ashes twelve inches in thickness. The amount of benefit derived from the use of the jacket was capable of being precisely determined. It had been ascertained that the water, converted into steam to keep the jacket warm, amounted to one forty-fifth part of the whole quantity of water used as steam in the cylinder. In Cornish pumping engines the pressure of the steam in the boilers and the jackets was 35 lb., whilst on the

Digitized by Google

piston it never exceeded 25 lbs, and when working expansively it did not amount to more than from 10 lb. to 20 lb. In applying expansion to marine engines it was the custom to expect, in ordinary working with full steam, that there should be the same pressure on the piston as in the boiler. But if the same amount of effort was to be got in one stroke of an engine when worked expansively as when using full steam, then the initial steam must be considerably higher to allow to a certain extent for the cutting off.

It was urged that the true measure of the efficiency of an engine was the quantity of water passing through it, as steam, in a given time, and that the application of meters to engines would enable this to be ascertained with accuracy. This was considered preferable to recording the quantity of coals burnt; because when the duty with a given consumption of fuel was stated, that represented the degree of attention of the stokers, the quality of the coals, the construction of the boilers, and the perfection of the engine combined, and it was well know that the coals and the boiler might cause a variation to the extent of 50 per cent. in the quantity of steam generated. It was also contended that there was no practical value in the employment of ether, and that if high-pressure steam was used, expanded in a double cylinder engine, with proper precautions against radiation, equally economical results might be expected.

It was observed that the discussion so far had reference principally to the administration of steam in an ordinary engine rather than to the combined vapour engine described in this Paper. It had been said that high-pressure steam, used very expansively, would lead to as economical results as the ether engine; but it seemed to be forgotten that the latter was made the means of utilising the temperature of the exhaust steam, and that by this system, after the most favourable results had been obtained by the use of steam alone, a still further economy might be produced by the addition of the ether engine. It was the means of utilising 5° or 6° of temperature which were ordinarily lost, to boil another liquid to produce another atmosphere.

It was admitted that the arrangements of the combined engines were admirable, and the workmanship excellent, all the joints being apparently tight. The experiments on the whole had been made in a most satisfactory manner, and seemed to induce the belief that the difficulties still to be overcome were but few, that the danger was less than had been anticipated, and that the use of two liquids, evaporable at different temperatures, might hereafter be profitably introduced.

It was agreed that if ether was used in combination with steam, as in the Sahel, as much duty might be performed as with steam alone used expansively; but it was believed it could be shown theoretically that a higher performance could not be obtained. To boil ether the vacuum in the condenser of the steam cylinder must be reduced to 6 lb. or 7 lb. per inch less than in the condenser of an ordinary steam-engine worked expansively. Again, an inch of water would produce about a cubic foot of steam at the pressure of the atmosphere, but the same quantity of ether could only produce about one-eighth of a cubic foot of vapour at the same pressure. Therefore it was believed better results would be obtained by using steam expansively in a cylinder entirely cased with a steam jacket, and combining other recognised improvements.

Some recent experiments on steamboats gave the following results:

No.	Name of Vessel.	Absolute pressure of Steam on admission.	Rates of Expansion nearly.	Consumption of Coal per I.H.P. per hour.
		lbs. per square inch.		lbs.
1	Admiral	34	5	2·95
2	Callas	38	6⅔	2 7
3	Not yet named	63	8	1·88
4	Not yet named	106	15	1·018

It was observed that the last experiment was incomplete, as it had been stopped by a fog. In reference to the combined engine it was stated that theory showed that for a given initial pressure and temperature of steam the combined engine must be the more economical, because of its enabling a lower limit of minimum temperature to be reached, and diminishing the loss by overcoming back pressure and friction; but it appeared that by using a high enough initial pressure and temperature of steam, the steam engine could always be made equal or superior in efficiency when required.

It was thought that expansion in marine engines might be resolved into two considerations: first, could a pound of steam develope more power when used very expansively than when carried to the usual point of about three-fourths the length of the stroke before cutting off, as in the ordinary full-powered marine engine? Secondly, was the expenditure of coal per I.H.P. increased or diminished as expansion was extended? A series of trials, with H.M.S. Renown, Victor Emanuel, Algiers, and Racoon, showed that when only half the number of boilers was used and the steam was worked expansively, being cut off at 6·5 of the stroke of the piston, more than half the power was developed which was given out by all the boilers, though the excess was not considerable. As to economy of coal, it was stated that in H.M.S. Dee, with steam jackets embracing the cylinders, the consumption of fuel, when working at full power with common steam, amounted to 3·9 lb. of Welch coal per I.H.P. per hour. When the steam, after leaving the boilers at a temperature of 237°, had been superheated to 377°, the result was 2·74 lb. per I.H.P. per hour. In this case the steam was cut off at exactly half the stroke. It was found that when cut off at an earlier portion of the stroke the consumption of the fuel was immediately increased. The most economic result, when working at full power and with superheated steam, was 2·97 lb. per I.H.P. per hour. The advantage in horse-power by expanding beyond the half stroke was more than compensated by the increased consumption when working beyond that point in ordinary marine engines with steam of a pressure of 20 lb. It was of great importance that the mean temperature in the cylinders should be such as to prevent condensation. With regard to the use of high-pressure steam in marine condensing engines, it was observed that the difficulty with the Government gun-boats and block-ships, in which steam of a pressure of 60 lb. was employed, was to insure for any length of time the necessary tightness in the tube plates, whether of iron or brass. The consequence of any failure in this particular point was, that the ends not only of the leaky tubes, but of all those around them, became incrusted in a short time, and all the lower tubes were so plugged up as frequently to require boring tools to clear them. Surface condensation might have the effect of preventing this leakage and of obviating the incrustation of common salt and the closing up of the tubes, in which case the boilers would become like those of a locomotive engine.

It was said that the mechanical arrangements of M. Du Trembley's engine were fairly entitled to great praise. That engine presented a theoretical and practical advantage in utilising the waste heat of the condensing water, supposing the ether vapour to be eliminated, without the necessity of costly apparatus. But still it was felt that attention should first be directed to a system of perfecting the ordinary marine engine, rather than obtaining more favourable results by the addition of the ether system to the present engine. A marine engine, with proper adjuncts for using steam of from 45 lb. to 60 lb. pressure, precautions being taken to economise the heat at a high temperature, and the difficulties in the way of dry and rapid condensation being successfully overcome, would if the laws of heat and elasticity were to be believed, result in greater economy, with more safety, than was promised by the combined system. In such a case the consumption of fuel might be reduced even below 2 lb. per I.H.P. per hour, as the result of ordinary working, not of a series of short experiments, the results obtained from which could rarely be received or recognised as facts. When this economy was accomplished M. Du Trembley's system could, if it was hereafter thought desirable, be adapted to the then existing arrangements.

It was considered that the subject had been treated in the Paper rather in a commercial than a scientific point of view, and that the gross consumption of the fuel, as it had been taken, was a loose standard to adopt. It was argued that the combined vapour engine should not be compared with theoretical marine engines working at very high pressures, for whatever pressure was employed in the ordinary engine might be used in the combined system. It was shown from indicator diagrams, taken when high pressure was used, that the power of steam was equal to the power of the vapour of ether. It also appeared that whatever power was gained in the ether engine was so much deducted from the steam engine.

Therefore theoretically there could be no gain by the adoption of the combined system. But a practical advantage might result by reducing the consumption of fuel from 3 lb. or 4 lb. per I.H.P. per hour to 2 lb. per I.H.P. per hour. The present steam engines were constructed for fixed gases rather than for saturated vapour. One of the chief reasons why the combined engine was practically more economical than the marine engine was, that in the latter, when the steam was used expansively, there was a certain amount of condensation and re-evaporation going on in the cylinder, as had been previously explained. But if the heat of the cylinder was maintained, and its size was increased, this effect would disappear. To produce the most favourable results it was contended that the surface of the condenser should be equal to half that of the boiler.

In conclusion it was remarked that if the steam could be so expanded as to leave the cylinder at a temperature of only 60°, then there would be no advantage in the combined system; but it was difficult in a marine engine to have a cylinder sufficiently large for the purpose. From some experiments which had recently been made it was ascertained that the latent heat of ether was 175° Fahrenheit, equal to 97·3° centigrade. This result agreed nearly with the estimate given by M. Du Trembley, who stated it to be 96·12° centigrade. The difference might be accounted for by the apparatus employed and the process followed not being the same in each case. The former was deemed to be the more correct figure, and the mode in which it was obtained was described in detail. It was also found that the heat required to generate ether vapour was less than that necessary for eliminating steam in the proportion of 76 to 96.

After the meeting of February 1st, Mr. DENISON, Q.C., exhibited a small crab, or winch, capable of lifting half-a-ton with a single pulley, although light enough to be carried in one hand. It had two short barrels with five grooves in them for the rope, and a wheel at the end of each barrel, both of which were driven by equal pinions on the winding arbour. The rope passed from one barrel to the other; and the loose end was either pulled off by hand or fell by its own weight, or by the weight of the de-

Digitized by Google

ascending blocks, or empty bucket attached to it, if the crab was worked alternately like buckets in a well. This avoided the loss of power and increased strain on the wheels from the accumulation of rope on the barrel when worked in the common way, and the loss of time in fleeting, or passing the four or five coils of rope back from one end of the barrel to the other (which required special apparatus for it), and brought the whole machine into a smaller compass, with less weight than a common crab of the same power, because thinner and smaller wheels could be used, on account of the strain upon them being always uniform in lifting any given weight, and because the barrels need not be longer than five times the thickness of the rope.

Several members stated that the machine was a very good one, but it had been invented long ago, and was now in use in many factories. To this it was replied, that it was surprising that so valuable an improvement of such a clumsy machine as the common long-barrelled crab, should have been unknown to the various engineers, builders, and other persons conversant with such matters, to whom it had been shown or described. It was found that the time spent in fleeting the chain was no less than a quarter of the time spent in actually lifting the Westminster bell to the top of the tower, and two crabs were used for it; whereas with one such machine as this it could have been lifted the whole 201 feet without any interruption. Some persons to whom it had been described, before they had seen the present machine in action at Mr. Dent's clock factory, doubted whether it would answer; some said it was just what they wanted; some were surprised that it had not been invented before; but not one of them appeared to have had the least idea that it had not only been invented before, but that it was in common use, as was now stated. The only object in bringing the machine to the Institution was to make it generally known, and to show its convenience, and it was hoped that the present conversation would assist in doing so, as it probably would, even more completely than if the invention had been really new and comparatively untried. There were some details of construction for diminishing friction in machines of this kind, which would be gladly explained to anyone who might think it worth while to inquire about them, as they might not occur to everybody who merely set to work to make such crabs from the general description which had been given.

At the meeting of February 22, some specimens of timber recently imported from the north-west coast of America, were exhibited by Mr. G. R. BURNELL. It was observed that the quality and dimensions of this timber, which came from near Vancouver's Island and the district bordering upon British Columbia and California, appeared to be such as to justify rather more than the passing notices hitherto given in the technical journals of the metropolis.

There were now lying in the Commercial Docks between fifty and sixty logs of this timber, upwards of 100 feet in length, and measuring at least 22 inches on a side. There was one log in particular which was 129 feet long, die square, perfectly straight and sound, apparently free from dead knots or shakes, and measuring 39½ inches on the side at the middle of its length. At the butt end it was nearly 4 feet square, and at the taper end it was about 2 ft. 4 in. square; and it contained 1302 cubic feet, or upwards of twenty-six loads.

No experiments had been made on the specific gravity or on the strength of this timber; but from the manner in which it floated, it would appear that its specific gravity was about the same as that of yellow pine. The strength would appear to be equal to that of the best crown Memel, if an opinion might be formed from the way in which some planks had been bent, and the conditions of elasticity indicated under such circumstances.

For bridge-building, roofing, and scaffolding purposes it was suggested that this North-western American fir would be of great value on account of its length and its remarkably uniform character.

Some light spars of the same kind of wood, about 119 feet long and 15 inches diameter at the butt end, had also been imported from the same coast.

The price of the very long spars was at present about six shillings per foot cubic; this was high, but no doubt it would hereafter be diminished. The price of ordinary lengths was nearly the same per foot cube as that of the best crown Memel deals.

Attention was directed to the number and closeness of the annular rings, which indicated that the trees were of slow growth; and it was thence inferred that the wood would probably be durable.

It was suggested that it would be desirable to make some experiments of an authentic character on the properties of this timber.

March 1.—The Paper read was "*On the Co-efficients of Elasticity and Rupture in Wrought-Iron, in relation to the volume of the metallic mass, its metallurgic treatment, and the axial direction of its constituent crystals.*" By R. MALLET, M. Inst. C.E.

It was assumed that amidst the numerous theoretical treatises upon and practical investigations into the strength and other properties of iron, the two questions which formed the prominent features of the author's present experimental inquiry had remained comparatively untouched. The conditions of manufacture and the resultant qualities had been hitherto too lightly passed over.

Iron was formerly entirely worked under tilt hammers; the process of rolling was then introduced, and now, in consequence of modern engineering requirements, masses of iron of considerable magnitude were produced by faggoting together, under heavy forge hammers, from large numbers either of bars or slabs grouped together. The masses were not however found to possess ultimate strength in proportion to the number of bars of which they were composed; in fact it appeared that the strength of the mass became less in some proportion as the bulk became greater. This was admitted as a fact, but no one had hitherto attempted to show experimentally — what function of the magnitude was the strength of a given kind of iron manufactured in a given manner; or how the same forged mass, when very large, differed in strength in different directions with reference to its form; or how the mechanical part of the process of manufacture of the same iron affected its actual strength, either as a rolled bar or a forged mass.

Addressing himself to this investigation the author dealt generally with three points of the inquiry, viz.—

1°. What difference did the same large bars of unwrought-iron afford to forces of tension and of compression when prepared by rolling, or by hammering under a steam hammer?

2°. How much weaker, per unit of section, was the iron of very massive hammer forgings than the original iron bars of which the mass was composed?

3°. What was the average or safe measure of strength, per unit of section, of the iron composing such very massive forgings as compared with the acknowledged mean strength of good British bar iron.

In the investigation of these questions other subordinate but very important points arose: such as the determination of the relative longitudinal and circumferential strength of equal sections of the iron in massive cylindrical forgings.

The proper measure of the strength of iron, or any imperfectly elastic material, was the "work done," whether by extension, compression, rupture, or crushing, due to any force applied to it. The co-efficients Te and Tr were designed by Poncelet to express this work done by an extending or compressing force upon any elastic prismatic body at the point where its elasticity became permanently impaired and its form distorted, and at the further point where rupture occurred. The method of arriving at these co-efficients was then given, and it was shown that, though they were were not sufficiently attended to in practice, yet that they were the true measures of the safe and ultimate resistance of materials, when applied constructively in machines or otherwise.

The crystalline structure of iron was then considered, and quoting from the author's communication to the Royal Irish Academy (*Trans.* vol. 23, p. 1, 1855), it was shown to be a law that "Iron, whether in the state of cast or of wrought iron, has the principal axes of its integrant crystals arranged in the lines of least pressure within the mass."

If consolidation from fusion took place undisturbed, as in cast iron, the principal axes would be arranged in the directions in which the heatwave had passed outwards from the body in cooling; which would be perpendicular to its surface contour,—those being the directions of least pressure of the internal constraining forces, produced by contraction in cooling, which were necessarily parallel to the planes of external contour.

The effects of rolling and of hammering masses of wrought-iron of different contents were then treated of, and it was shown that what was termed "fibre" was the longitudinal extension of the principal axes of the crystals. The original development of these crystals under the constraining forces due to change of temperature, &c., was "cæteris paribus" proportioned to the time given for such development. Thus, in very large forgingsthe crystals were generally extensively developed, in consequence of the length of time which the mass had been under the operations of heating and forging.

It had long been admitted that large forgings became weaker in proportion as their bulk was increased, but as no definite ratio was recognised it became of importance to fix the conditions of strength in wrought iron under various circumstances. The author was enabled to undertake this investigation, under the authority of the Minister of War, and with the concurrence of the Royal Society, when making the forgings for the two 36-inch wrought-iron mortars constructed on his design for the Government; he then selected specimens of iron upon which the experiments of tension and compression were tried.

The methods were then explained by which the specimens of iron were obtained from large masses, and the apparatus was described by which the observations were made, when the specimens were undergoing the operations of extension and compression. In cutting and boring into the massive cylindrical forgings to obtain the pieces of iron from the various parts, it was invariably found that there existed internally large transverse rents, with jagged and crystalline irregular surfaces, the opposite faces of which were counterparts, and presented distinct evidences of having been torn asunder by contraction from the centre towards the circumference as the mass cooled. The *rationale* of the phenomenon appeared to be, that this action was simply due to the contraction of the external shell before the temperature of the centre had been perceptibly lowered; this in its turn was cooled, and in contracting produced these visible rents or fissures, and no doubt caused other minor dislocations which detracted from the general strength of the mass.

This was evidently the cause of the difficulty of obtaining very large

Digitized by Google

forgings of a cylindrical form quite sound; as if the diameter was sufficiently great all such cylindrical forgings so built in construction, and so treated by heating, hammering and cooling in manipulation, must become unsound internally by the opening within the mass of one or more of these rents in the direction of the axis during the process of cooling. In solid cylinders, or conic frustra, it must occur whenever the dimensions were such that the total amount of contraction of the metal in any one diameter from its highest temperature down to that of the atmosphere, as fixed by the circumference of rigidity due to the outer cold shell, exceeded the limit of extension of the iron at rupture due to the length of the diameter of the interior core, which cooled last. This was the theoretic limit of size of forging, beyond which internal rents must occur. The practical illustration was, that almost all cylindrical shafts of wrought-iron exceeding 12 inches in diameter were found to have one or more of these rents in them, thus having their strength impaired. This reduction of strength was altogether distinct from any deterioration of quality of the metal, arising from its being alternately heated and cooled and hammered.

The remedy for this play of molecular forces was to construct and work the large forgings hollow. This course had been pursued with success at the Mersey Iron-works, Liverpool. When a cylinder had a large concentric cylindrical hole along its axis it cooled at the same time, though not equally, on both the internal and external surfaces, and thus the extremes of internal strains were avoided, and the hollow centre yielded more readily to the forcible compressive grasp of the exterior.

A minute description was then given of all the irons which had been experimented upon, specimens of each being exhibited at the meeting. They were divided into classes according to their several characteristics and modes of working, and into the most analogous class was imported Clay's puddled steel, a comparatively new material, which had been brought into this investigation for the purpose of comparison, and the results were such as promised to be of great practical importance. The general results were the separation of the several classes into two grand divisions: 1°. The crystalline, or sub-crystalline in fracture, which were always the result of manufacture by the hammer. 2°. The fibrous, or crystallo-fibrous, which were always produced by the rolling process, but which might be produced by careful and continuous elongation under the hammer.

The very weakest wrought-iron of all those experimented upon was found to be that cut transversely from the end of a very heavy cylindrical forging which had been exposed to heat and percussion for nearly six weeks. Exposed to tension its elastic resistance was only 3¼ tons per square inch, which was less than the average of cast-iron; thus, as regarded pressure, it was the very weakest iron produced by any method of manufacture; whilst the faggot bars of which the mass was built and welded up bore a tension of upwards of 12 tons per square inch before losing their elasticity, and of nearly 23 tons at rupture, and a pressure of nearly 21½ tons before losing elasticity, and of nearly 27¾ tons at the point of total distension or crushing: thus proving the fact that the extreme weakness of wrought-iron in heavy forging was not due to any metallurgical alteration in the constitution of the metal, but to changes in its state of aggregation, induced by a process of forging, by the long-continued and unequal heating, and by the hammering.

Hence was deduced the conclusion, that practically the iron of very heavy shafts, forged guns, huge cranks, and other similar masses, might be expected to become permanently set and crippled at a trifle above 7 tons per square inch, and to give way by fracture at about 15 tons per square inch by tension, and to completely lose form at pressures of from 15 to 18 tons per square inch. Therefore it followed, that allowing a deduction of one-half, as sanctioned by practice, from the elastic limits of tension and of pressure for the margin of safety, the iron of such forged masses should not be trusted for impulsive strains exceeding about 1¾ ton per square inch of tension, and about 4½ tons per square inch of pressure, or for passive tensile-strains of 3½ tons per square inch, or for passive pressure beyond 9 tons per square inch.

Further experiments demonstrated that in heavy rectangular forged slabs of upwards of 12 inches in thickness, in the plane of the slab, the resistance to all the forces was much higher, and hence large cranks which were usually cut out of such rectangular forgings were stronger than the shafts to which they were attached, in the ratio of 8 to 6. The physical cause of the difference in strength between large cylindrical and rectangular forgings, although made from the same original material, was to be found in the difference of the molecular arrangement. The integral crystals of the cylindrical masses were strained, distorted, and partially separated by the effects of hammering in various directions, and by the peculiar constraining forces due to contraction in cooling; whereas none of these forces acted to the same extent upon rectangular masses, which were only hammered in three directions, and the constraining forces of cooling were all parallel to the faces of the parallelopiped, or in three directions only.

A special peculiarity noticed in heavy forgings was the sudden and extreme inequalities of texture and of strength found in different and even in closely adjacent portions of the same mass, producing greater uncertainty of result in practice.

Another peculiar feature was that the rates of extension or of compression did not move uniformly, but by fits and starts. This phenomenon obviously arose from the *per saltum* disintegration of planes of crystallisation, and their more or less complete separation in a crystallised but yet ductile body. This had never been observed in fibrous irons, or in those in which the finely elongated crystals were all rolled parallel and in the line of the length of the bar or the sheet.

If the original or integrant faggot bars, from which a heavy forging was built and welded up, had a tensile elastic strength of 12 tons per square inch, the forged mass itself would have a mean tensile elastic strength of only 7 tons per square inch; and correspondingly if the faggot bar had a compressive elastic resistance of 21½ tons, the forged mass itself would range under 18 tons per square inch.

Thus, within the limits of practice, the work of passive resistance sustainable by heavy forgings was about one-half that of the faggot iron from which they were manufactured; but at the ultimate point of rupture they gave a better result. Heavy forgings were also more trustworthy when exposed to tensile strains in direction of their length or to transverse strains, as in girders, which ultimately were resolved into longitudinal strains, than when subjected to twisting strains, as in shafts, or to direct pull across the direction of length.

These and other considerations induced attention to the apparently superior power of puddled steel to support the forces by which the ordinary forged masses of wrought-iron were fractured, especially as by the employment of smaller and lighter masses greater strength in shafts, &c. could be secured. One special peculiarity appeared to be that in the heaviest pieces of this material the internal structure was as fine and close in the grain as it was in the smallest bar. The elastic limit was above that of the best wrought-iron, and the elasticity was so much more perfect, that it might be trusted almost up the elastic limit of about 15 tons per square inch, and in forged masses it possessed this strength nearly equally in every direction. The range of extension at the elastic limit was rather greater than that of fibrous hammered bar iron of excellent quality. Beyond the elastic limit, with equal increments of strain, its extension did not rapidly diverge and increase, as in wrought-iron; it slowly increased up to about 20 tons per square inch, and gradually and evenly enlarged up to the breaking point, which was not reached within 42 tons per square inch, and was often found to reach 48 tons per square inch.

This puddled steel was not like cast steel, a harsh, rigid, and glassy material, which possessed indeed enormous cohesion, but yet was so rigid and unaccommodating to forces variable in direction and impulsive in character as to deprive it of trustworthiness in practice. On the contrary, puddled steel appeared to combine the great strength of cast steel with the ductility and perfect elasticity of the best wrought-iron. Its resistance to pressure was very remarkable, being more than double that of harsh crystalline wrought-iron, and more than three times that of the best fibrous wrought-iron in bars or plates. Thus it may be safely used under a passive strain or load of 20 tons per square inch, after allowing a margin of one-half for security.

Puddled steel would thus evidently become an important practical adjunct in the construction of machinery, in building vessels of light draught of water, and for artillery of the largest calibre. It possessed also the peculiarity of resisting corrosion much better than wrought-iron plates, and thus had an additional value for shipbuilding.

An investigation was then entered into of the causes of the manifestly greater strength of the integrant slabs than of the large forgings built up from them; but it was shown that this quality did not extend to the boiler plates, which acquired a certain amount of rigidity. This was also possessed by the puddled steel, and it was anticipated that it would ultimately be extensively employed for the boilers, and even the fire-boxes of the locomotive boiler.

From this investigation nothing of a certain character could be concluded as to any fixed relation between the strength and the specific gravity of the several sorts of iron experimented upon. The weakest irons—those from the heavy forgings—having generally the highest specific gravities, though always lower than their integrant faggot bars. Thus it appeared that specific gravity was a characteristic to which too great importance had hitherto been attached in relation to strength both in cast and in wrought iron. It was modified, increased, or diminished by the mechanical operations of manufacture to an extent far beyond anything that chemical difference of constitution produced, and in reality it afforded no criterion of strength, although in fibrous irons it did afford an index of their degree of extensibility for equal sizes.

The modulus of elasticity deducible from these experiments, from the mean results of the great forgings, was 12,559,680 lb., or 3,771,675 feet for iron forged in great cylindrical masses. The mean specific gravity being taken at 7663, the weight of 1 foot long by 1 inch square of this iron was 3·33 lb. The modulus for great forged rectangular masses or slabs was 18,079,200 lb., or 5,478,545 feet; the specific gravity being 7610, and the weight of a bar 1 foot long and 1 inch square 3·30 lb. Both fell far below the modulus for good English bar iron of 7,550,000 feet as deduced by Tredgold, or even below 6,787,878 feet as deduced by Edwin Clark from Eaton Hodgkinson's experiments.

The author concluded his Paper by recording the obligations he was under to Messrs. Horsfall and to Mr. Clay, of the Mersey Steel Works, Liverpool, and to the officers of the War Department and Royal Arsenal, Woolwich, for the facilities afforded to him during his investigation.

March 8.—The whole of the evening was occupied by the discussion of Mr. MALLET'S Paper "*On the Co-efficients of Elasticity and of Rupture in Wrought-iron*," &c.

It was explained that Tredgold and other experimenters only gave the absolute forces which would tear a bar asunder. In the present investigation an endeavour had been made to ascertain the amount of permanent elasticity possessed by the metal, as well as the point at which it would become actually ruptured.

It was contended that the drawings exhibited gave a very imperfect representation of the piling of the iron for large forgings, and that hence the author had been led to draw erroneous conclusions. With regard to the manufacture of the two monster mortars, 36 inches in diameter, and capable of throwing a ball weighing about 30 cwt., it was remarked that their merits as forgings were extraordinary At first, owing to large rents in the centre of the core, the forgings were failures, but after a little experience had been gained, the second forgings were quite successful. In the manufacture of these monster guns they were built up in seven distinct layers, the forging occupying seven weeks. So far from any deterioration or crystallisation taking place, the metal was improved by its long-continued heating and working; and the metal in the heart of the gun was found to be of greater strength than the bar-iron of which it was composed, being perfectly homogeneous, strong, and tough. A series of experiments for testing the correctness of the process showed that the ordinary manufacture of bar-iron, by working and re-working several times, had its limits. As a proof that the deductions in the Paper were incorrect, it was asserted that engineers had one universal rule for the manufacture of forgings, whether large or small, and it was not found that the shafts of 1000 H. P. engines were more liable to fracture than those of 100 H.P. This was practical evidence that the metal was not more deteriorated in large forgings than in small from the length of time it was exposed to the action of the fire; indeed no one portion was so exposed for any great length of time. It was urged that scrap-iron, or any other highly-refined iron, was the worst material for the construction of large forgings. It was considered that a strong fibrous fresh-puddled iron was superior in every respect, as the ordinary workings required in the process of forging would be sufficient to improve it to the average maximum of strength; whereas a highly-refined iron had already reached the highest point as regarded strength, so that it was more likely to be injured by additional working. There was another reason why scrap-iron should not be used for the manufacture of forgings. Scrap-iron was composed of many different qualities of iron, all having their own special welding points. When worked together, one portion which was less refined was too much heated, and consequently deteriorated before the more highly-refined portions were at a welding heat; so that there was the difficulty either of burning the one, or of being unable to weld the other. Again, the specimens selected by the author for trial, and which he said were weaker than the original iron composing the forging, were not taken off in the direction in which the fibre was laid for strength—in which it was intended that the strain should be borne. Now, forge-masters always laid the grain of the metal in the direction in which the strain would ultimately be applied; whereas the samples experimented upon had been cut transversely to that direction.

With regard to the new material, "puddled steel," it was believed that it was destined to work a complete revolution in almost all matters in which iron had hitherto been used. It had been proved to possess at least double the tensile strength of the best wrought-iron, and the elastic limit of the material was also greater in proportion to the breaking strain. A piece of this material had been subjected to a strain of 32 tons per square inch for seventeen consecutive hours without exhibiting the slightest appearance of elongation. Subsequently a bar 4 feet in length and 1 inch by $\frac{1}{8}$ths inch in section had been exposed to a strain of 45 tons per square inch, when it was found that an elongation of $\frac{13}{100}$ths of an inch had taken place. Upon the weight being removed $\frac{13}{100}$ths of this elongation were recovered, showing that the elasticity of the material had not been destroyed. On another occasion the elongation amounted to $\frac{24}{100}$ths of an inch, and returned to $\frac{20}{100}$ths of an inch. Upon a second application of a strain of 56 tons per square inch the bar was broken, the elongation having been $\frac{27}{100}$ths of an inch. In other experiments the bars broke at 55, 56, and 60 tons, and one bore the enormous strain of 87 tons per square inch. To attain this favourable result, which it was believed might eventually be accomplished as a rule, it was essential that great care should be taken in the selection of the materials, and great pains in the manufacture. It was entirely a question of good workmanship and good machinery; and a new manufacture of this sort would for years to come require the utmost attention and solicitude. In Germany, where this great improvement in metallurgy had been first introduced, a large number of manufacturers commenced making puddled steel; the consequence had been that an amount of bad material had been thrown upon the market, which had brought puddled steel into disrepute for a time, and from which it had scarcely yet recovered. This was to be feared in this country when the German patent had expired.

It was further contended, that if the calculations in the paper had been based upon forgings faggotted in the manner delineated in the drawings, they were of little practical utility. It was stated that large forgings weighing 20 tons, and measuring 24 inches in diameter, for engines of 1000 H.P., were now made at several places in England, without flaw or defect, except perhaps a small sand speck upon the surface, which was not of any consequence. When Nasmyth's hammer was first introduced, the plan was suggested of having the lower forge block made of a V shape, and the bottom part of the hammer so small as to strike only upon the upper centre of the periphery of the forged piece. The mass was thus struck in three places, and the tendency was to force the material to the centre, so as in fact to render the heart as solid and homogeneous as the other portions.

In reply to an inquiry as to whether the rents in large iron forgings, spoken of in the paper, would not also be liable to occur equally in the puddled steel, it was said, that in forgings of iron large crystals or grains were developed, which would not be the case in similar masses of puddled steel; and that in the latter the aggregation of grains or crystals was not increased by the agglomeration of the mass. These rents might be accounted for by the differential contraction of the metal. In the principal case referred to, the outside of the collar, which was 4 feet in diameter, cooled more quickly than the remainder of the forging, and these internal rents took place after it had left the hammerman's hand. It was stated that plates of puddled steel had already been supplied from the Mersey works for twenty-one vessels, some of them of 250 tons burthen and 38 feet beam. The thickness of the plates for the vessels for Indian river navigation was one-eighth of an inch, and none had yet been made, or called for as a mercantile commodity, of greater thickness.

In conclusion, a hope was expressed that on an early occasion the subject of puddled steel would be again brought under the notice of the Institution; for if it possessed the qualities ascribed to it, it was worthy of the most careful consideration of engineers, who had to design large railway structures, as well as for other purposes. In India and distant colonies, to which so much material had necessarily to be transported for public works, anything which would tend to reduce the weight to be carried, and consequently the freight, was a point of the highest importance. The Institution was therefore under great obligation to the author for having elicited this information.

March 15.—The paper read was "*Account of Experiments upon Elliptical Cast-iron Arches.*" By T. F. CHAPPE, M.Inst. C.E.

These experiments were undertaken at the request of Mr. W. H. Barlow, M. Inst. C.E., for the purpose of ascertaining practically the safe load to which elliptical cast-iron arches might be subjected, as well as the most economical distribution of the metal. The intrados of the arches was in all cases a segment of an ellipse, in order to obtain the greatest headway at the haunches. The experiments were, in each case, conducted upon two ribs, placed two feet apart from centre to centre, and resting on cast-iron abutment pieces, keyed-up tight against the springings. Diagonal stays and longitudinal struts were also introduced to prevent lateral motion.

The first experiment was made upon a model, one-fourth the real size, of one arch of a bridge intended to be erected over the river Trent, near Newark. The (model) arch had a clear span of 14 ft. 6 in., and a rise of 16 inches; a camber of $\frac{1}{4}$ of an inch being given in fixing the halves together. The sectional area of the arch at the crown was 2·43 inches,—that of the curved rib near the springing 2 inches,—about midway between the springing and the crown 1·75 inch, and of the spandril 1·34 inch. The weight of each arch was 1 cwt. 2 qrs. 22 lbs.

The other experiments were made upon a model one-sixth the real size of an arch erected over the Gloucester and Stonehouse and Great Western Railways, at Standish, six miles from Gloucester. The dimensions of the model were—span 13 ft 10$\frac{3}{4}$ in., and rise 1 ft. 10 in. The sectional area at the crown was 1·25 inch, of the curved rib near the springing 1·055 inch, about midway between the springing and the crown 0·993 inch, about the middle of the upper rib 0·883 inch, and of the spandril 0·57 inch. The weight of each arch was 3 qrs. 26 lbs.

The following pressures were given as those to which the arches were subjected in these experiments:—

Experiment.	Ultimate load.	How distributed.	Pressure per square inch of sectional area.	
			At crown.	At smallest section.
No.	Tons. cwt.		Tons.	Tons.
1	30 10	Uniformly.	8·52	11·83
2	18 0	Ditto.	6·80	8·58
3	12 0	Partially removed from the haunches.	4·54	5·72
4	5 0	On one haunch.	2·36	2·98
	3 12	At centre.	2·93	3·70
5	3 14	Ditto.	3·00	3·85

In the first experiment the ultimate pressure was not reached. In the second and third experiments one half arch was out of line laterally, beyond what would be permitted in practice, and was wanting in that

Digitized by Google

assistance which would have been afforded in the number of ribs required for the width of a bridge, so that the ultimate pressures indicated were below what such arches might be estimated to bear. This was also the case in the two last experiments, in which the castings were faulty, and the tests were such as were not likely to occur in practice. It was thought that cast-iron arches of the form experimented upon might safely be considered capable of bearing a pressure of between 8 and 10 tons per square inch of section. From the position of the fractures it was believed that the spandrils were too weak in proportion to the size of the arches.

The communication was accompanied by several tables, showing the deflections on the application of the different loads.

March 22.—The Paper read was on "*The Water Supply for the City of Melbourne, South Australia.*" By M. B. JACKSON.

The city of Melbourne was described as being situated on the north bank of the Yarra Yarra river, at a distance in a direct line of two miles from Hobson's Bay. The population was in December 1857 nearly 95,500 souls, for whose use the supply of water was very inadequate, not exceeding 3¼ gallons per head per diem, at a cost of not less than £105,000 per annum.

The city was built partly on a clay slate rock, and partly on a basaltic rock, or trap formation, the highest point near Carlton Gardens being about 148 feet above the river Yarra, whence numerous schemes were proposed for deriving a supply of water.

About the year 1845, Mr. Patrick Reid proposed a scheme of obtaining a supply of water for the city by means of a water wheel, to be worked by the falls; but the expense was considered to be too great.

In 1850, Mr. James Blackburn erected a small steam engine, by which water was pumped up into a tank, whence it was distributed by means of water carts.

In the same year Captain Cole suggested a somewhat similar plan, which, from want of encouragement, was not carried into effect. About this time, Mr. J. C. King proposed to supply the city from the Yarra, by a tunnel through the hill near Dight's falls, and using the water of the river as the motive power. This project on being referred to Mr. Blackburn, then town surveyor, was not approved of. It however had the effect of calling Mr. Blackburn's attention to the subject; and this induced him to recommend the river Plenty as a source for the water supply. In August 1851, he reported that this source was capable of providing for the wants of twenty thousand inhabitants, at an average daily supply of 40 gallons per head. This quantity, which was much too large for merely domestic purposes, included the supply for watering the streets, irrigating gardens, cleansing the sewers, and all other urban wants. The water, which was purer and softer than that of the Yarra, was to be derived from the Mount Disappointment range of granitic hills, whence there flowed a number of streams, which when united after passing through the swamps, formed the river Plenty. This scheme met with general approbation, but it was not at the time persevered in.

In 1852, Mr. Clement Hodgkinson proposed to obtain a supply from the Yarra by means of steam engines; and in this year Mr. James Oldham reported favourably on Mr. Blackburn's Plenty scheme, recommending the employment of iron pipes, instead of an open acqueduct, for bringing the water into the city.

In January 1853, a select committee of the legislature also reported in favour of Mr. Blackburn's plan, but advised a more careful investigation of the subject, by a commission of four non-professional gentlemen. In June of that year, these commissioners requested several engineers, among whom was Mr. Jackson, to report to them on the subject. This resulted in the appointment of that gentleman as engineer to the board. A more careful investigation was then ordered of the locality of the Plenty river, and finally, in October 1853, it was decided to adopt that river as the source of water supply for twenty thousand persons, at a daily rate of 30 gallons per head.

Mr. Blackburn was appointed consulting engineer, and up to the period of his decease in 1854 the utmost cordiality and unanimity existed between him and the author, to whom the execution of the design was confided.

The Plenty river, as was previously stated, derived its water from several streams rising in the Mount Disappointment range of granitic hills; whence, after traversing the large swamps, they united at a spot a short distance from the intersection of the upper aqueduct with the stream. The total estimated area draining directly into the river was about 40,000 acres, and the quantity of water delivered from the hills was at the driest seasons about 5000 gallons per minute; but at least 40 per cent. of this was lost in the passage through the swamps. The evaporation was estimated by the author at 4 feet 9 inches per annum, and the mean rain-fall at upwards of 32 inches per annum.

The works were commenced at the junction with the Plenty river, by cutting the water-course in a northerly direction towards the Yan Yean reservoir, to reach which a tunnel of 440 yards in length was driven through a ridge of hills; the prevailing stratum being clay slate, which would not resist the action of air and water, unless it was lined with hard basaltic rock paving. This water-course also served to drain the district through which it passed, and augmented the area of the gathering ground.

The Yan Yean reservoir was formed by throwing an embankment across a valley between two spurs of hills, and thus retaining the rain and flood-waters within it. The area, when full, was 1303 acres, and the average depth was not less than 18 feet, giving a cubic content of 38,000,000 of yards, or upwards of 6,400,000,000 gallons.

The area of the natural catchwater basin of the reservoir was 4650 acres, which would give, independently of the Plenty basin, but inclusive of the water-course, a drainage area of 5250 acres, and to this great additions might be made, by drains cut into the slopes of the adjoining hills.

The embankment of the reservoir was 1053 yards in length at the top, and 30 feet high at the deepest part; the general top width was 20 feet, with an inner slope of 3 to 1, and an outer slope of 2 to 1. The inside was finished with rough pitching from 15 inches to 20 inches deep, with an unusually thick puddle trench, which latter was adopted on account of the clay being easily procured, and because the grubbing up of the long straggling roots of the gigantic trees, formerly occupying the site of the reservoir, might have made clefts in the soil which it was desirable to close up hermetically; added to which there was difficulty in securing conscientiously good work in the colony, after the discovery of the gold fields.

The three inlet and two outlet pipes, each of 33 inches in diameter, were contained in a well tower at the foot of the inner slope, and on the outer slope there was another tower and valve chest, with a main of 30 inches diameter. This arrangement was made in order to secure the supply of the city, at times, by means of a compensation pipe, while the inside tower was undergoing cleansing, and also to get rid of any air which might otherwise interfere with the circulation.

The pipes of 33 inches diameter put through the embankment were, in order to save time, cast at Sydney, and when the reservoir was finished and was partially full of water, the author was informed by one of the workmen that two of these pipes at about the centre of the embankment had been fractured for a long time. The water could not be drawn off by means of these pipes without great hazard; so it was resolved to prepare a series of cylinders 2 feet 6 inches long, having an outer diameter of 32⅜ inches and made of boiler plate ⅛ inch in thickness. These were passed seriatim up the main pipes, made fast by wedges of hard wood, and well caulked with iron cement throughout the entire length of the main pipes within the puddle trench and the aprons. This was the only important casualty which occurred during the progress of the work; and there is every reason to believe that the remedy was perfectly effectual.

A description was then given of the course of the water from the reservoir by the main of pipes 30 inches in diameter, carried across gullies on stone piers, and over the river Plenty by a stone bridge. At a distance of 560 chains from the reservoir, the diameter of the main was diminished to 27 inches, which was continued as far as the pressure regulator,—a distance of 623 chains, and thence a main of 24 inches descended into Melbourne. The pressure regulator, which was manufactured by Messrs. Guest and Chrimes, was adopted in consequence of the author's proposition to introduce a valve, in order to diminish the pressure on the lower portion of the main, and his opinion that filter beds were not necessary. The adoption was sanctioned by Mr. Wm. Fairbairn, who acted as agent in England for the commission, with power to alter or modify anything which appeared to him desirable. When these machines were first set to work fractures of the main pipes repeatedly occurred, in consequence of the concussion or recoil on closing the valve. This was ultimately remedied by fixing air and safety valves on the pipes; but the author could not recommend the general adoption of these regulators. Disc valve regulators were also tried; but the author was of opinion that, "despite the beauty of the theory," he was "not prepared to recommend their use for large mains."

Reverting to the system of delivering the water to the city, the regulators, valves, pipes, means of crossing streams, gullies, &c., were described; and it was evident that the author had provided amply for all present contingencies and future extensions of the place.

The distribution of the water commenced at about 19 miles distance from Yan Yean, and at present there were (including these 19 miles of main) about 104 miles of pipes laid, varying from 24 inches to 3 inches in diameter.

In all the streets of more than one chain in width, a main of pipes was laid on each side, whilst in those under that width, the pipes were laid in the middle of the street. All the pipes were 9 feet long, and with the old spiggot and faucit joints. The service pipes were of lead, lined with tin. There were seventeen hundred of Bateman's fire-plugs, and the hydrants were manufactured by Messrs. Guest and Chrimes, a quantity of vulcanised india-rubber hose being also provided. The saving of property in cases of fire had proved to be enormous, and the rates of insurance had fallen 40 per cent. since the establishment of these water-works.

The gross cost of these works was stated to have been 664,452*l.* 1*s.* 2*d.*, but that sum included several large items which would eventually be charged to other works,—so that the net cost up to 1st January 1858, should be stated at 571,816*l.* 17*s.* 3*d.* These works were commenced in December 1853, and were completely opened for public use in December 1857.

Digitized by Google

A compulsory rate was to be levied, for meeting the interest of this capital, and to form a sinking fund for redeeming the capital. During the period of the execution of the works, the rates of wages were—masons, 36*s.* per day; labourers, 13*s.* to 20*s.* per day.

A series of appendices contained reports of the analysis of the waters, and statements of the rainfall and evaporation in various localities, and the Paper was illustrated by drawings and diagrams.

After the meeting, Mr. J. G. AUSTIN explained a "*Double Off-set Plotting Scale*," for the use of civil engineers, land surveyors, &c.

The invention was described to consist in the projection of the line upon which the plotting was to be performed, at a distance from the edge of the scale, by means of the station pointers, so as to admit the smallest off-set being plotted on either side of the scale.

The instrument was readily affixed to the paper and board, by placing the station pointers upon the line to be plotted upon, keeping the scale in use always on the left hand, and the lower pointer exactly at the station from which the line proceeded. Then, by turning the milled-headed screws at each end, the instrument was fixed immoveably during the operation of plotting. Should the length of the line exceed the capacity of the scales, the distance plotted must be denoted on the map, the instrument released by reversing the screws, shifted forward, refixed, and the work continued; but should the line be shorter than the capacity of the scale, the position of the instrument could be determined by the zero line of the off-set scale, without the necessity of extending the line to the length of the instrument.

The scales could be adapted to suit the operator, could be made of any material in customary use for such purposes, or the principle could be adapted to any existing scales.

The off-set scale was intended to traverse between the edges of the lateral scales, and the distance upon the line was to be determined by the edge, and the off-sets plotted on either side of the zero line.

The instrument was said to be simple in its use, to save much time in the operation of plotting the details of railway and general surveys, to insure accuracy, and avoid the possibility of error from shifting, and as the surface to be plotted upon could be seen, it enabled the smallest off-set to be denoted on either side of the line with greater ease and correctness than by the customary mode.

THE DESIGNS FOR THE NEW TABERNACLE FOR THE REV. C. H. SPURGEON.

THE following is the result of the competition:—The first premium of 50*l.* has been awarded to Mr. E. C. Robins, of 19, Arundel Street, Strand. The second premium of 30*l.* to Mr. W. W. Pocock, of Knightsbridge. The third premium of 20*l.* to Mr. Hill, of Leeds.

Mr. Pocock, the author of the design marked "Metropolitan Artist," to whom the committee have awarded the second premium, has also been appointed the architect to the new building.

We have been favoured with a copy of the letter announcing to Mr. Robins the decision of the committee, to which we feel great pleasure in giving publicity. In our own opinion, the *first* prizeman should have had the privilege of amending his plan in preference to the second, especially since the former is most in accordance with the instructions issued by the committee. It will be recollected that our last volume contained illustrations and descriptions of some of Mr. Robins' executed works,—we refer to Springfield House, and the enlargement of Dr. Cumming's schools adjoining his church.

"Dear Sir,—I am requested by the committee to forward the enclosed cheque for 50*l.*, as the first premium. In so doing, allow me to congratulate you upon the architectural taste which is so manifest in your drawings. In my own personal selection, yours was one of three which I considered to be pre-eminent among the many. We have inspected the designs with great care and long deliberation, and although we are compelled to prefer Mr. Pocock's design as the best basis for our future building, we could not but regret that we were thus compelled to lose your services in the erection. You may not be aware that we have received from private friends of yours, and persons for whom you have erected buildings, the most flattering testimonials of your ability. Since these were unsolicited on your part, and probably unknown to you, we thought them worthy of the highest consideration, and should have felt great pleasure in entrusting our great undertaking to your hands.

I am, &c., C. H. SPURGEON."

"To Mr. E. C. Robins.

RECONSTRUCTION OF SUNDERLAND BRIDGE.

THE original bridge, one of the earliest and most celebrated examples of cast-iron bridges of large span, constructed by Mr. Burdon in 1796, over the river Wear, for connecting Sunderland and Monkwearmouth, consisted of six cast-iron arched ribs, forming an arc of a circle of 237 feet span and 33 feet rise, with a clear height of 99 feet above low water; the ribs were of very light and open construction, only 5 feet deep throughout and 4 inches thick, fixed at 6 feet distance apart, and connected together by hollow pillars of cast-iron placed horizontally; each rib was constructed in separate short segments, 2 ft. 4 in. long, connected together by six continuous longitudinal wrought-iron bars, 3½ inches deep and ¾ inch thick, let into grooves on each face of the ribs and secured by six bolts in each segment. In consequence of the insecure and inconvenient condition of the bridge, an Act of Parliament for repairing it was obtained in 1857, and the works were commenced early in 1858. The most important defect of the original structure, was the absence of diagonal bracing; which, although in some measure rectified by an ingenious application of cast-iron crosses between the ribs, by Mr. Grimshaw of Sunderland, had still allowed of the whole of the ribs becoming curved laterally out of their vertical planes to the extent of as much as 16 inches. The bridge is now being strengthened by the addition of three wrought-iron rectangular tubular arches, of the same curvature as the cast-iron ribs, and 5 ft. 2 in. deep by 6 feet wide; the top and bottom plates being ½ inch, and the vertical sides ⅜ inch thick. These tubes are fixed in the alternate spaces between the original ribs, the old bracing being removed, and the ribs securely bolted to the tubes, so as to cause the whole to compress together, the original external form of the ribs being thus preserved; and in order to secure a perfect diagonal bracing at all points, the arch tubes are connected together throughout at the top by a boiler plate ⅜ inch thick, flush with their upper surfaces. The inclination of the road over the bridge on each side is also improved from about 1 in 17 to 1 in 50, by raising up the spandrils of the arch over the haunches; and the width is also increased about 10 feet by causing the footpaths to project on cantilevers. The reconstruction of the bridge is under the direction of Mr. Robert Stephenson, C.E.

SUNDERLAND NEW DOCKS.

THE hydraulic machinery which has been lately constructed by Mr. Armstrong for opening the large sluices employed for scouring the channel at the south outlet, and for working the dock gates and large drawbridge, is worked by an accumulator having a ram 2 feet diameter and 17 feet stroke, loaded with a weight of 100 tons, giving a working pressure of 495 lb. per square inch, charged by a 30 horse power horizontal pumping engine. The sluices are in two sets of four each, situated on each side of the outer gates, each sluice having an opening of 8 ft. 10 in. width and 7 feet height; they are rapidly opened by means of the hydraulic pressure, requiring only about half a minute, and open a total area of 495 square feet, which is done at low water, causing the sudden rush of a large body of water from the higher level within the gates, which effectually scours the entrance channel, and keeps it open to the sea. The large drawbridge, which is 100 feet span and 14 feet wide, slides laterally upon rollers, and is traversed across the opening of the dock entrance by a pair of horizontal hydraulic cylinders 10 inches diameter with multiplying chains, working on one side under the projecting tail of the drawbridge that balances the overhanging portion; and the whole platform weighing 150 tons is then lowered down 16 inches on to a solid bed by means of a pair of vertical hydraulic cylinders 17 inches diameter, which serve to raise it again when the bridge has to be opened; the time of opening or closing the bridge is little more than a minute.

Cathedral of St. Denis.—M. Violet Leduc is actively engaged in the construction of the new vaults of the crypt of the Imperial Chapel of St. Denis, which is to become the mausoleum of the reigning dynasty. The clockwork of the northern steeple will be reconstructed.

SOLDER FOR ALUMINIUM.

M. Mourey has described to the Société d'Encouragement in Paris, a process which he invented for soldering aluminium. He adopts an ingenious device for this purpose. In the ordinary way to solder two metals or two pieces of the same metal, all that is necessary after having prepared the two surfaces which are to be brought together, is to cover them with solder and to heat them. This mode of proceeding does not succeed with aluminium. M. Mourey prepares each of the two surfaces with a first solder, an alloy of aluminium and zinc, and then interposes between the two surfaces thus prepared another alloy richer in aluminium. In this manner the first alloy adheres to the aluminium itself, and the second alloy to the first, and thus a perfectly solid and continuous whole is obtained.

The surfaces to be soldered are prepared by being smeared with a mixture of turpentine, balsam of copaiva, and lemon juice, then placed on hot coals, and into the parts where the soldering is to take place the flame of a gas lamp or self-acting blowpipe is directed.

Small pieces of an alloy of 6 parts of aluminium and 94 of zinc, are brought into contact with the prepared surfaces; these melt and adhere to the surfaces, being pressed against them by small tools made of aluminium. This operation is a rapid one; it requires, like any other soldering of this kind, a certain amount of care, but not more than in the hard soldering of copper. In each case a skill and knack are necessary on the part of the workman, as well as care in adjusting the temperatures, for the melting point of aluminium and zinc are scarcely 100° apart, and there is a fear whilst melting the solder lest the article itself should melt at the same time.

When the two surfaces have been thus prepared, they are brought together and kept in contact by iron wires, pincers, &c., as in ordinary soldering; pieces of the hard solder (80 of zinc, 20 of aluminium) are then placed at the points of contact, and the heat from a lamp is then applied, and the second solder melts, runs in, and adheres to the two layers of soft solder, and thus forms a strong joint.

The articles thus prepared are sufficiently strong and homogeneous to allow of their being reworked, and the joints will bear filing.

NOTES OF THE MONTH.

New Law of Patents relating to Ordnance, &c.—A Bill has just been brought into the House of Commons by the Attorney and Solicitor General and the Secretary for War, to amend the law concerning Patents for inventions with respect to improvements in instruments and munitions of war. It provides that the benefit of any invention for an improvement in instruments or munitions of war, may be assigned to the Secretary for War, and that the enactment shall extend to assignments already made. In case of an invention so transferred or assigned, the Secretary for War may certify to the Commissioners of Patents, that the invention should be kept *secret*. Where the Secretary for War has so certified, the petition for letters patent and all other documents are to be left with the Clerk of the Patents in a packet under seal for the Secretary for War, the packet to be kept so sealed or to be re-sealed with the seal of the Commissioners of Patents. The sealed packet to be delivered on demand by the Secretary for War or pursuant to any order of the Lord Chancellor. At the expiration of letters patent, the sealed packet to be delivered to the Secretary for War. Where the Secretary for War certifies after filing of petition, documents already filed to be put into a sealed packet and kept secret. Copy of provisional specification, &c. not to be sent to Scotland or Ireland, or published, but otherwise provisions of Patent Acts to apply. No *scire facias* to be brought to repeal any certified Patent. The Secretary for War may waive the benefit of this Act as respects any invention; and the communication of any invention for any improvement in instruments or munitions of war to the said Secretary of State, or any person or persons authorised by him to investigate the same, or the merits thereof, shall not, nor shall anything done for the purpose of the investigation be deemed use or publication of such invention, so as to prejudice the grant or validity of any letters patent for the same.

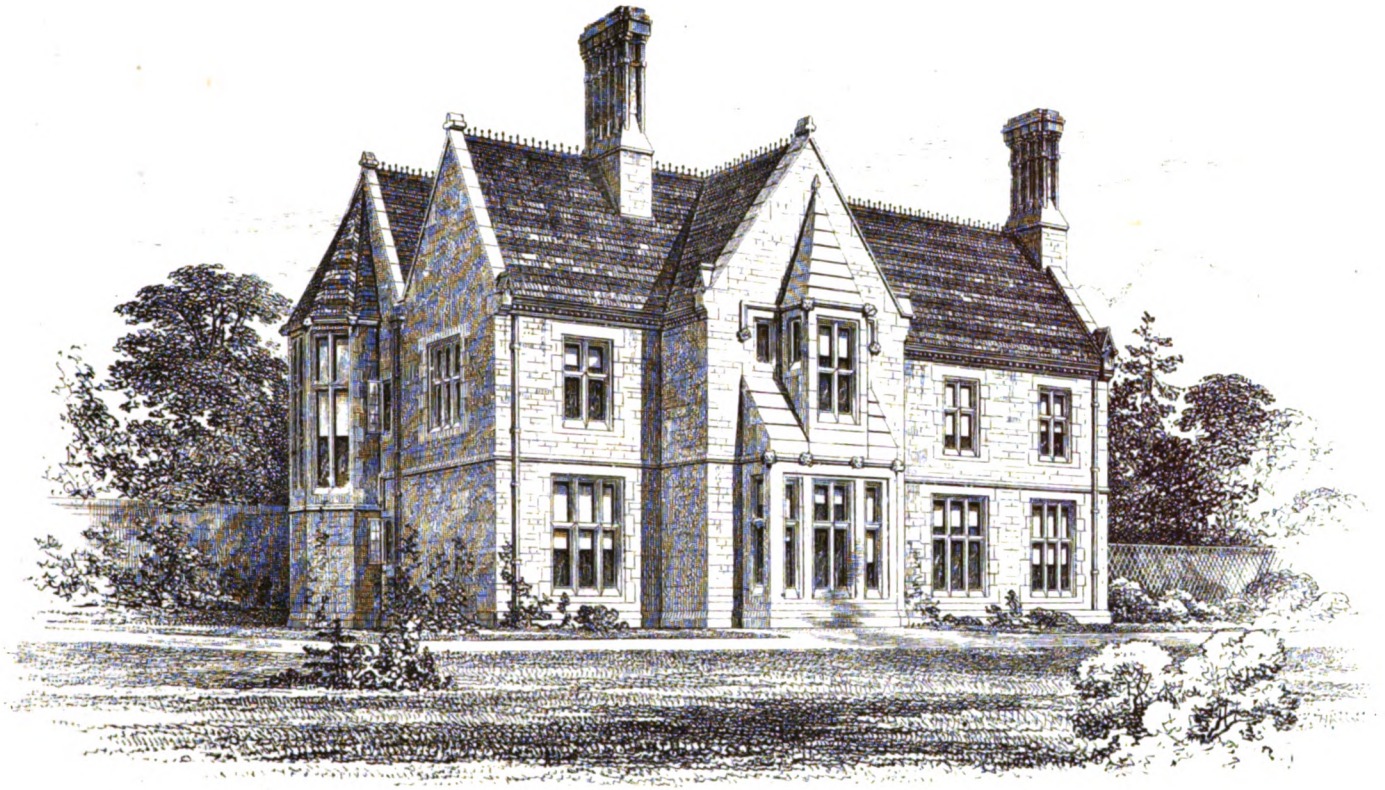
The Society of Arts.—The Society's Eleventh Annual Exhibition of recent inventions will be opened on Monday the 25th instant. The society intimate to persons intending to exhibit, that they should communicate with the Secretary of the Society of Arts as soon as possible, stating:—1st. The title of the invention. 2nd. Whether the article will be a model, drawing, or specimen. The articles must be forwarded to the Society's house, carriage paid. The days fixed for receiving them are Thursday the 7th, Friday the 8th, and Saturday the 9th instant. No articles will be received after the last of these days. Articles which have been included in previous Exhibitions of the Society of Arts cannot be re-admitted. Articles should be accompanied by a short but clear description of the invention, with a wood block (when possible) for illustration, and a reference to any publication in which the invention is described. All drawings exhibited must be framed. No charge is made for space, and the admission to the exhibition is free. The Council have arranged for two Conversazioni during the present Session; the first, on Saturday the 7th May, at the Society's house; the second, on Saturday 28th May, at the South Kensington Museum.

Brussels.—The restoration of the beautiful tower of the Hotel de Ville at Brussels has been completed in all its original richness. There is nothing now wanting but the twelve statues which are to occupy the niches, and which are expected to be placed in their destined positions during the spring. The restoration of the interior of the town hall is to be completed in the course of the ensuing year.

Patent Office Rules.—The following rules, in respect of communications from abroad and provisional specifications, have recently been issued:—I. In any application for a patent which is stated to be a communication, the declaration must state the name and address of the party from whom it has been received, in the following manner:—No. 1. When declaration is made in the United Kingdom, "that it has been communicated to me from abroad by [here insert name and address in full]."—No. 2. In other cases, "that it is a communication from A.B., a person resident at [here insert address in full]."—II. All provisional specifications must be written on one side only of each sheet. (Signed) FITZROY KELLY, A.G.; H. M. CAIRNS, S.G.

Bridge over the Rhine at Kehl.—These gigantic works are pushed on day and night with great vigour. As soon as night sets in the appearance of the Rhine is extraordinary, as the electric light on the Baden side of the river begins to illumine the work, leaving all the rest in a greater or less degree of obscurity. The sinking of the caissons, the dragging of the rivers, and the work of the steam-engines, go on without interruption, except at midday and midnight, when an hour's rest is allowed to the men.

COMPETITIONS.



The committee for the erection of a New Infirmary at Ashton-under-Lyne are desirous of receiving Plans and Elevations, accompanied with a general description. The design to be based on a supposed outlay of £10,000, but the first outlay will not exceed £5000. The remaining £5000, and the extensions to be added at a future time. The elevation to be of stock bricks, with stone dressings of Huddersfield-stone; the passages and staircases to be fire-proof. Internal sanitary arrangements must not be sacrificed to architectural display. Efficient ventilation is specially desired. Premiums. £100 and £50. A plan of the site may be seen, and particulars obtained on application at the offices of Henry Thomas Darnton, honorary secretary to the committee. Designs must be sent in by the 30th instant.

The Winchester Diocesan Board of Education propose to build a Training School for fifty students, with apartments for principal, vice-principal, and matron. Architects are invited to send designs to the Rev. Canon Jacob, Crawley Rectory, Winchester, by the 11th of June next. The arrangements of the building must be such as to meet the requirements of the Committee of Council on Education; and the style simple, without more external ornament than is necessary to give it a distinctive character. The plan should admit of the erection of a chapel; and of additional dormitories and lecture-rooms for a limited number of students of another class, if required. The site has been secured, and should be viewed by architects proposing to offer a design.

Designs are required for the proposed new Jews' Hospital to be erected at Mile-end. Mr. Mocatta and Mr. Digby Wyatt have been selected as referees, who will award the three premiums of £100, £50, and £30 respectively. Particulars may be obtained on application to the Rev. O. P. Mendes, at the Jews' Hospital, Mile-end. Designs to be sent in by the 11th inst.

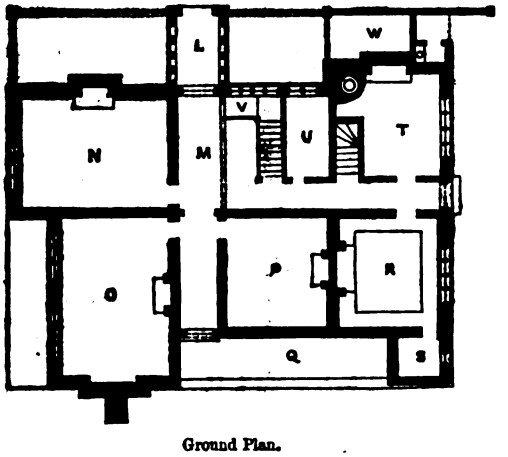
SUBURBAN VILLAS, BIRMINGHAM.



(With an Engraving.)

THE two villas illustrated in the accompanying engraving are both situated at Edgbaston, near Birmingham. In their design it has been the aim of the architect to secure that simplicity of which old work furnishes so many examples, and to avoid that forced attempt at novelty of design which is too often discernible in buildings of this class. The material employed is red brick; in the one case relieved by Bath stone dressings, and in the other by blue bricks and tile bands, judiciously arranged in patterns. The roofs are covered with blue and brown Staffordshire tiles laid in courses.

Ground Plan.

On reference to the accompanying plans it will be seen that they are so designed as to render the entrances as distinct as possible from the principal rooms. The interiors are handsomely finished. Brass furniture and gas-fittings of appropriate cha-

Ground Plan.

racter were supplied by Messrs. Skidmore, of Coventry. The hall is laid with Maw's encaustic tiles. The builders' work was carried out by Mr. Samuel Briggs, of Birmingham, under the superintendence of Mr. Joseph James, architect, Furnival's-inn, London.

THE ARCHITECTURAL EXHIBITION.

(SECOND NOTICE.)

We resume our examination of the architectural works in the Conduit-street Galleries.

Mr. C. F. Hayward, in his buildings, generally exhibits considerable fertility of idea, not always guided by the best of taste. He apparently labours too anxiously after novelty, and in consequence lapses into the error of crowding, and of excessive fancifulness. Proof of this we shall detect, more or less, in all the drawings he exhibits this year; in his domestic work especially, as may be seen in (64, 67, 69), all of which display good points, but are marred by the fault we are complaining of. His "Gateway at Weeley, Essex" (90), in red brick, is an ungainly and over-wrought affair.

There is also, in the "Porch at Mr. Philbrick's residence" (67), a curious combination of wood and brickwork,—the brackets supporting the roof coming down upon the sloped weatherings of brick buttresses, and thus, apparently without any hold or footing, it suggests anything but true or sound construction.

In the "Mansion for A. Edwards, Esq., Balgay, Forfarshire" (70), Mr. Coe aims at adhering to old Gothic details and tracery more closely than is now usual. In some respects the advantage of this is evident, yet there is in the general mass a stiffness and repetition of parts, especially in the three bay windows, which is not germane to the real feeling of the style. We have seen more worthy productions from the same hand.

(74 and 75) exhibit, in some telling photographs, portions of the new street architecture of Leeds, as executed from the designs of Mr. Corson, and both are clever and original in their treatment.—See also (86, 87.)

It is impossible to say as much for the next picture, "The Llwyn" House, near Oswestry (76), which is also Italian, but over-pretentious in character. The most striking object in the view is the mass of chimneys collected in the centre of the building, and which, though well intentioned, are so clumsily managed as to overpower the rest of the design.

In Mr. Horace Jones' "Design for a Training College" (78), we see a very simple treatment of Gothic elements; the result unusually good and cleverly managed.

(80), we merely allude to as one of the drawings which disgrace rather than adorn the walls.

(81), Mr. C. H. Cooke's "Entrance Lodge to Bromsgrove Cemetery" has been already illustrated in our *Journal*, of March 1858, as also the Lich-gate (311).

The large Mansion designed by Mr. Blake (82), shows but little life or feeling. It is characterised by engineering more than artistic conceptions.

(83), "Buildings erected for the Working Men's Institute, Hartshill," is, as a whole, excessively bad (at least as here shown). Coloured materials are freely abused, not *used*, so that, whatever merit may attach to the elementary forms, it is more than counterbalanced by the gew-gaw style in which they are tricked out.—See also (98.)

A pleasant relief, after wandering so long among picture frames, is afforded by the five very choice specimens of paper-hangings, exhibited (84) by Messrs. Williams, Cooper & Co. The great strides which have of late years been made in the art of chamber decorations are scarcely more observable in anything than in the substitution of the more seemly *flat* colouring imprinted on the walls and carpeting, in place of the showy but absurd attempts at relief ornament which till lately was so much in vogue. While referring to this matter we may mention that in the farther gallery (190) is another series of the same kind, prepared from designs by Mr. Owen Jones, and contributed by Messrs. Trumble & Co. of Leeds.

(85) (96). "Portions of the Erections for the South Staffordshire Water-works, near Lichfield," by Mr. Adams, are plain and sensible-looking. They at once explain their purpose; and, as nothing more is attempted, the beholder is reconciled to their comparative plainness. The propriety of facing such an amount of surfaces with Staffordshire blue bricks may be questioned. The unrelieved colour is dull, heavy, and monotonous.

There is unquestionable ability shown in (88), Mr. Peacock's "Schools at Wandsworth," although the drawing is not so inviting in appearance as many. The parts appear to be nicely balanced, and attention to have been given to details.

(89). Messrs. Walton and Robson's "Design for a Town Hall" shows a building of Gothic (continental) character, of the plainest

Digitized by Google

possible kind, and treated in a novel and effective manner. The interior of the principal room has a good open-timbered roof.

Of Messrs. Habershon's Gothic works we regret that we cannot speak in terms of commendation. There is a prevailing line-and-rule appearance about them, and a coarseness of details that are foreign to the true principles of the style. The "Dispensary at Newport" (94), is an illustration of this; and (97), "New Public Rooms," is worse still. In (192) are some "Designs for Villa Residences," which also partake of these faults.

Redcar Church is a thoroughly Kentish old church, and has been very prettily rendered (95) by Mr. Beetholme.

Passing by (99), "The Palace of Art," which even with its full length quotations from Tennyson, remains mysteriously incomprehensible, we come to a pretty group, also by Mr. Beetholme, of "Pompeian Fragments" (100), delineated with taste and exactness.

Mr. Christopher exhibits a capital series of Sketches from abroad (103—107, &c.). They are evidently scrupulously accurate, and to this may be attributed perhaps a hardness of outline, which is not unfrequently observable. In (193) we have an impression of the engraving of the "Tower and Spire of Bow Church," reduced from Mr. Christopher's measured drawings, which obtained a medal at the Royal Academy, and which Mr. Le Keux has very faithfully rendered.

A Church, built in Kentish rag and Bath stone, "to hold 900 persons, with large schools in rear—cost, £3500," may be well left to imagination. Such, however, is the statement appended to (109 and 168), being respectively an Interior and Exterior of the New Congregational Church at Woolwich. The former is unredeemably bad, but the latter, considering the circumstances, has been made the most of. We engraved in our March number a view of a much better design by Messrs. Lander and Bedells, which here is exhibited in (161).

(112). "Fox Warren, Surrey," represents a large Gothic mansion, designed by Charles Buxton, Esq., M.P., a gentleman, we believe, who has devoted considerable attention to architecture. In the design before us the large uncusped windows, without mullions, look tame and unsatisfactory; indeed, the whole reminds one too much of the Strawberry-hill period of the art.

No. 116 is a drawing which will well reward examination, and deserves to have had a better place. It presents a number of suggestions for "saw-pierced brass-work," designed by Mr. W. G. Smith; these are in the best possible taste, and peculiarly adapted to the material intended, consisting chiefly of scroll-work and leafage intertwined, and simply perforated in the flat. Among the subjects thus ably handled are "Eve in the Garden," "The Passion," "St. George and the Dragon," and "Our Saviour Blessing Little Children."

Great Gallery.

The first catalogued work in this gallery is essentially Mediæval, and consists of "Sundry pieces of Painted Furniture," lately executed from the designs of Mr. W. Burges (120). These include "a nest of pigeon-holes," the subjects relating to architecture and the subsidiary arts;—"a bookcase and escritoire," the subjects being the history of Cadmus, and the various descriptions of writing;—"a sideboard," on which is portrayed the dispute between the Wines and the Beers;—"a wardrobe," with figures to represent Flax and Wool; and "a buffet," on which is a sculptured figure in allusion to the sun, through whose influence the other metals represented on the panels were anciently believed to have been produced. In all these is a curious mixture of antiquarian and artistic details. Both as articles of furniture and of ornament, while there is much to admire, it may be questioned whether there is not as much to regret; for, with all the evident pains that the designer has bestowed, and the unrestricted display of his exuberant fancy in gilding and colours, the results, taken as a whole, are not altogether pleasing.

(121) Does not strike us as by any means a desirable *restoration* of St. Margaret's, Westminster, as proposed by Mr. Ashpitel. Although in its present condition the church is far from being comely in appearance, that very peculiarity of ugliness is not in that situation without its advantages; and though its entire demolition has been more than once threatened, it may be hoped it will yet be allowed to survive. If it is destined to undergo the renovating process, we should be more reconciled by its assuming a purer expression of Perpendicular, than the debased ogee forms which are here introduced,—notwithstanding its close proximity to Henry VIIth's Chapel. But conceding our opinion, if need be, as regards the body of the church, the attenuated spire to be added to the tower, and which appears to be of open or panelled tracery, would be decidedly out of place in such a neighbourhood.

Mr. Norton's "Mansion at Nutfield" (123) is Gothic, plainly and sensibly treated; it has the advantage, here at least, of being planted on a spacious terrace, which preserves the architectural symmetry of the whole.

We have in a previous number described the restorations about to be effected in the central tower of Durham Cathedral, under the direction of Mr. Gilbert Scott, with Messrs. Walton and Robson as sub-architects. A large elevation of this tower (127) shows clearly what is proposed; the drawing is in simple outline, boldly touched in with brown ink.

(128), Mr. Hooker's "Frowswell House, Goudhurst," is a capitally managed alteration of one of those delightful old half-timbered houses which abound in the Weald of Kent,—the lower part being of brick, while the upper floors are of framed timbers, having the spaces between filled flush with plaster.

A peep at the old steeple of St. Nicholas, Newcastle-on-Tyne, with its curiously-poised spire, is always welcome; and Mr. Storey has, in (131), done justice to the subject.

A "House at Great Malvern" (132), by Mr. Webbe, is chiefly noticeable for its picturesqueness of groupings. It is in the English Domestic Gothic style, and is well accommodated to the irregularities of the site by a series of terraces, which contribute much to the generally good effect of the mass.

In (133, 134) we have two sketchily tinted interiors from "St. Nicolo dei Mendicoli, Venice," and "Como Cathedral," by Mr. Penrose, who in (324) exhibits the "Sacristy of St. Mark's, Venice." In these the effect only has been attained: it is in vain to look for details, which ought however always to be more or less expressed to render a sketch practically useful.

Mr. J. K. Colling is this year a bountiful contributor. Besides his careful drawings of the South Porch of West Walton Church (164), and the detached Tower of the same church (171),—two of the purest specimens of Early English now remaining. We have a view (317) of the New Picture and Sculpture Galleries which he is now erecting at Hooton Hall, Cheshire, for R. C. Naylor, Esq. The alterations at this mansion from Mr. Colling's designs have been in hand for several years, and some time since we gave a large illustration of the general design, which is in the Italian style. The material of the new galleries is white sandstone from the neighbourhood of Birkenhead, and there are introduced large panels of red sandstone, and smaller ones of polished red granite and serpentine. The total length of the galleries internally is 298 feet.

(135) Exhibits an interior view, and (151) an exterior and plan, of the Church now erecting at Hooton for the same gentleman, and by the same architect. It is in the Byzantine style; hence the prevailing lines in the plan, arches, windows, and roof partake of the semicircular form. The clerestory windows are doubled in each bay, and continued round a semicircular apse. There is a western porch, with a large rose window in the wall behind, whose type we recognise in an old continental example: there is also a well-designed small octagonal tower and spire at the main intersections of the building; and a turret, also with a stone spire, adjoining the south doorway. The stone is red and white sandstone, with polished red granite columns to nave and chancel, entrance doors, and porches. The whole interior is of white sandstone, with bands, &c. in red. The arches are carried by polished red granite columns. The accommodation is for 200 persons, and the contract accepted amounts (exclusive of granite) to £5350.

Mr. E. M. Barry's name appears only once in the catalogue (137), in a somewhat ineffective view of the costly "Tomb recently erected in Norwood Cemetery." The admixture of materials is more successful than the general idea.

(138) is a little architectural subject, completely exemplified by plans, sections, &c.—a "Boat and Summer House at Isleworth," designed by Mr. Lockyer, who has treated the whole cleverly and artistically. In another part of the room are two other drawings (307, 313) from Mr. Lockyer's careful pencil, giving examples of Mosaic inlays of the twelfth century, from different buildings in Sicily; and (312), showing part of the detail of the "Façade of the Duomo at Orvieto—Italian Gothic, between the dates 1290-1300,—and drawn from actual measurements.

The two vigorous etchings (139) of half-timbered "Cottages

Digitized by Google

erected near Gloucester" by Messrs. Hugall and Male, are, though very small, worthy of examination.

(140), A photograph of a "Design for a Circus," by Mr. Vaughan, jun., to which the Soane medallion has lately been awarded, displays evidence of considerable talent. As engravings of this design have been multiplied in various ways, its leading features are probably too well known to need description. In justice to the author it should be added, that the practical has not been lost sight of in the imaginative, as is too often the case, but that the several plans and sections (which we have had an opportunity of investigating elsewhere) are nothing less than thorough working drawings, and those of a very able description.

(143). "Covent-garden Approaches," Burleigh-street, is one of Mr. Gray's corner blocks of building. Like that in Henrietta-street, it is unfortunately faced with cement, not, we believe, by the architect's preference, but in compliance with the requirements of the surveyor to the Duke of Bedford. In the design before us Mr. Gray does not appear to such advantage as usual, owing to a certain disproportion in some of the parts, and a heavy expression of the entire mass. In (309), where less has been attempted, as also (347), where the work is intrinsically of the plainest possible description, he has been more successful.

We now come to several carefully depicted restorations, by Mr. R. J. Withers (146, 147, 148), being views of the Parish Church of Saling Magna, Essex, of which the chancel, aisle, and vestry were rebuilt, and new fittings added last year, at a cost of £433.

In (154, 155, 156) the same architect exhibits his proposed restoration of the church at Great Amwell, Herts, which has a pretty apsidal chancel dating of the 12th century. Beyond this there is not much to notice. The new fittings are throughout in good taste.

The drawings of the "United Service Club, Pall Mall" (158), showing Nash's original plan, as well as the present one, since the recent alterations by Mr. Decimus Burton, are an acceptable addition to the collection. The improvements, both in point of convenience to the members, and external effect, are such as could only have been attained after considerable study. The extra enrichments which the façades can now boast of, go far to redeem the poverty of the original building, and give it a more worthy rank in the "Street of Palaces."

Mr. Street, in his "Church to be built in Westminster" (160), while manifesting the versatility of his designing powers, preserves the same characteristics of a town-church as were shown in his St. Dionis, Backchurch, engraved in our last December number. There is the same severity of outline, partaking of Italian features (especially in the unbuttressed campanile), and the same judicious blending of the parts by frequent banding of materials; carved ornament is almost wholly wanting, and indeed, would scarcely comport with the general conception of the design.

In (167) Mr. Street exhibits a "Design for a Pulpit," which possesses unquestionable merit, but we confess to having seen others more to our mind. (343) is altogether a wonderful production. It exhibits, on a large scale, an elevation of Giotto's famous Campanile at Florence, drawn from Mr. Street's own sketches and measurements, and displaying the richness of its effect, especially attributable to the profusion of inlay marble work, with which almost the whole surface is covered. Mr. Street has also sent photographs of parts of his "Design for the Foreign Office', (386, 389), and one (9) of his "Design for the War Office."

We are sorry to be unable to compliment Mr. Joseph Clarke on his drawings this year. The interior of Walton Church (170) scarcely deserves the name of a "sketch," nor is "St. Peter's Church, Thanet" (172), satisfactory. St. Luke's Church, Heywood, Manchester (331), about to be rebuilt, is also below the average; but in the Schools at Coggeshall (338), Mr. Clarke has been more successful. The subject is one well studied by him, and in which he has had much practical experience.

Mr. Withers' "Glass-Painting Works and Studio," erecting in Endell-street, Bloomsbury, are chiefly in red brick, characteristically treated, and will form a pleasing feature in a locality which can boast of that excellent specimen of design and execution in brickwork—St. Martin's Schools.

The name of Mr. Digby Wyatt occurs several times as a sole exhibitor, but still more frequently in connection with others, as we shall have occasion to observe by-and-bye. The house, 96, Gracechurch-street, of which a not very flattering view is given in (179), is one of the most noticeable alterations in the neighbourhood. Without adhering to the restrictions of any particular style, the architect has blended a variety of features in a more than ordinarily happy manner. The fact that the general face of the house is set back from that of its neighbours gives no slight help in the matter, serving as much to individualise the design as to admit of a few effective projections. Colour is freely used, as also metal and inlay-work, so that we have here a specimen of each, which is at least suggestive for the future, if no more.

Two other drawings by Mr. Wyatt display (180) a sketch of the "State Bed" designed for the Emperor and Empress of the French on the occasion of their visit to Windsor,—which is, purposely no doubt, French in style, abounding in cyphers and emblematical devices; and (181), two "chimney-pieces" in the Renaissance style—very boldly treated, and slightly aided by colour—for the Right hon. Henry Labouchere, M.P.

The "Station and Hotel proposed to be erected at Birmingham," and designed (in conjunction with Mr. Brunel) for the Great Western Railway (181A), is shown in a very tame pencil elevation. It is of Italian character, and a large mass of building, rather too sparing in ornament considering its locality and object.

We now enter the *East Gallery* which is devoted mainly to competition drawings, hung (for we cannot say quite classified) on a screen in the centre. The first number is (190), Mr. Gompertz's "design for the new College at Rawden, near Bradford," a poor Italian design, shown by a perspective and two plans, the latter not without some good points. At nearly the other end of the screen is (258) another design for the same building, still less satisfactory.

(191, 195, 196) are three competition drawings for the "Wakefield Church Institution," by Mr. Robins, Mr. Mew, and Mr. James. It is of course impossible from such trifling instalments to pronounce as to the comprehensive merits of any design, but as far as external appearance is concerned, we should prefer either the second or third of these to the first mentioned.

The "Hanley Cemetery Chapels" competition is represented by portions of the designs of Mr. Sorby (194, 208), and Mr. E. C. Robins (202). Both are Gothic; the former being of red brick, rather tastefully banded, but overdone in some other respects; while the latter, a very ordinary composition, is so overwhelmed by the fantastical border which surrounds it, that its poverty is rather exposed than cloaked by the contrast, and we notice the same thing in some other drawings. Such very elaborate additions are certainly not in keeping with the subjects they inclose, and are otherwise in questionable taste.

That for the "Worcester Cemetery Chapels" is, by name, represented only in one design, viz., that to which the third premium was awarded, and which is shown by its author, Mr. C. H. Cooke, in a perspective view. The style followed is Norman, but while characteristic massiveness is not wanting in its parts, the massing of the whole appears capable of improvement.

The "Mortuary Chapels, at Brighton," by Mr. R. Wheeler (207), are Gothic, and rather above the average in merit.

We must conclude our notice next month, when we shall also refer to the department of Manufactures, &c.

ON THE USE OF COLOUR IN ARCHITECTURE.*

By SYDNEY SMIRKE, A.R.A.

BEFORE entering upon the subject it will be well to take a short retrospective view of the efforts of architects of past times with reference to the use of colour in their works.

The Egyptian and Assyrian builders seem to have dealt with colours as children in art, and although some have supposed themselves able to discern a superior knowledge and a refined practice of colouring in these earliest and least cultivated ages and races, I confess I can anticipate little benefit from an attempt to inquire into their principles, if indeed any principle they really possessed.

The case however is far otherwise when we descend to the period of Greek art. The learned are much divided in their opinions as to the extent to which Greek architects availed themselves of colour in exterior architecture; and indeed until comparatively late times little regard was paid to the subject. The earlier revivers of Greek art seem scarcely to have heeded it, and the natural effects of neglect, and exposure, more or less, to the action of the atmosphere during 2000 years, have of course been so nearly to obliterate all vestiges of colour, that it is not sur-

* Lecture delivered at the Architectural Exhibition.

Digitized by Google

prising that the earlier observers should have altogether overlooked them. Authorities differ even now so widely as to the extent and character of the colouring practised by the Greeks, and the existing visible traces of colour on ancient remains are so scanty, that he would be a bold theorist who would venture to speak with confidence of the general practice of the Greeks. It is very probable that the different schools of art that prevailed in various districts and at various periods during even the pure Greek era, may have very materially differed from each other in their modes of applying colour. But I shall refrain from detaining you on this vexed question of ancient polychromy. I may remark however that the existing evidences of the use of bright colours in Greek sculpture are such as to preclude all doubt of the practice in that department of art to a certain extent. I would instance the red colour known to have been used to mark the bleeding wounds of Greek warriors in archaic sculpture, and the blackened pupils of their eyes. The fact of bronze bridles and javelin heads occurring in marble sculpture, even of the highest class and of the best period, affords presumptive proof of the use of colour; for detached spots of bronze, unsupported by some accompanying colour, on a pure white marble, are hardly reconcilable with the refinement of Greek art; the lavish use of gold and ivory in Greek sculpture seems also to favour this inference. Indeed those who have paid any attention to this subject will not need to be reminded of the various passages that may be quoted from ancient writers, wherein direct allusion is made to the use of colour by Greek sculptors.

Now, seeing that in the composition of Greek temples the architect and the sculptor worked so strictly together that the two arts were animated as it were by one soul, there seems ample ground for conjecture that the architectural features were treated in the same way as the sculptural portions. In truth, undeniable traces of bright colour have occasionally been detected, and few collections of Greek antiquities are without examples of coloured architectural forms. Thanks to the successful labours of Mr. Charles Newton, architectural painted fragments of the date of Alexander have been brought home and deposited in our national Museum; thus furnishing to us the testimony of all others the most satisfactory,—the testimony of our own senses. This strong colouring over large surfaces in Greek architecture is however by no means proved. At the same time I admit, that much as the pure crystalline translucency of Parian marble would lose by any artificial stain, yet the force of evidence renders it undeniable that at least light, probably transparent, general tints were largely used.

It would be tedious here to enter into a disquisition that has already filled many elaborate volumes. I will confine my present remarks to the testimony of my own experience. The coarse limestone, of which the finest temples of Magna Grecia were for the most part built, appears to have been covered with a thin coat of fine calcareous plaster; this plaster was itself so perfectly white that it is quite impossible to believe it to have been left unstained. It is not to be supposed that the susceptible eye of a Greek artist could have endured in that brilliant atmosphere so painful an object as a chalky, opaque white building. Nor need we wonder that the Greeks should have painted their external architecture. Young Greek art adhered with a sort of filial piety to its early reminiscences, and long continued to regard with deference its prototypes in Egypt and Assyria, where unquestionably the brightest colours were profusely employed. By a somewhat remarkable coincidence the "vermilion beams" of a royal palace are named both in the Iliad and in the book of Jeremiah; and there is indeed abundant evidence to satisfy us that reds, blues, and yellows, in dazzling superabundance characterised the immature art of those early periods.

What the Greeks taught by their example we may safely assume their Roman pupils readily practised. But the Romans introduced a new element of decoration in the profuse use of materials naturally coloured. Bronze and gilt decorations had as we have seen previously enriched the external architecture of Greece; but the Romans, by adding coloured marbles, gave an aspect to their structures to which architecture had previously been a stranger. The use of these marbles, applied both to architecture and sculpture, became a passion in Rome, and the mountains of her remotest colonies were ransacked for the sake of their many coloured contents, and the mechanical dexterity acquired by Roman artists in veneering with these precious materials in the thinnest possible laminæ, seems to have far excelled the workmanship even of the present day.

When the tide of conquest rolled eastward, the use of colour in architecture acquired renewed force. It is worthy of observation that those eastern regions, where all the works of nature seem steeped in the brightest colouring, are peopled by races whose greatest æsthetic characteristic has always been a love of brilliant colouring. Their architecture and their costume alike attests this prevailing taste. Nor was it characteristic of any special race or caste. It was a geographical rather than a national distinction. Whether Jew or Gentile, worshipper of Vishnoo or of Mahomet, all alike delighted, and I may say still to this day delight, in the most brilliant colours, seeking the highest gratification of this sense by reproducing, in the texture of their dresses or on the surface of their edifices, those precious gems which were so strongly associated in their minds with the symbols of rank, wealth, and power. There can be little doubt that it was from these eastern sources, quite as much as from the surviving examples of Roman art, that mediæval builders learnt the value of colour in architectural decoration.

After the first recognition of Christianity by the Roman world it sought to make available, for the purposes of public worship, those existing structures which seemed best adapted to its convenience. The triple stoa basilica of the Athenian Archons had been many centuries before naturalised in Rome and in its Italian colonies; its form and arrangements satisfied the requirements of the Christian communities, and became the model after which their churches were designed during several subsequent centuries. These buildings were erected it is true in a somewhat rude style of art; but their simplicity of form and propriety of decoration well compensated for their want of refinement. Let any one enter one of those early basilicas that has not been mutilated or metamorphosed by later art,—let him mark its simple, unostentatious aspect, the propriety and gravity of sentiment that pervade every part of the design,—and few unprejudiced minds will I think refuse to recognise in them a deeper and more earnest devotion than in that exuberant decoration; the fanciful, artistic *tours de force;* that excessive multiplication of superfluous adjuncts which characterised the later development of ecclesiastical art. Those earlier stones speak of the humility and subjective devotion of an as yet uncorrupted faith. These later stones proclaim the triumph of that secular spirit which, after extorting its treasures from stricken consciences or misguided piety, sought to perpetuate its influence by expending a portion of those treasures on the external pomp of a sensuous ritual and an embroidered architecture.

It is, as I have said, probable that much of this love of rich colouring is due to the infusion of an exotic oriental taste. But as Christianity extended northward, the influence of climate over the predilections of the eye came into operation. Northern mediæval art was nurtured amidst grey mist and under clouded skies, and its features accordingly assumed a graver tone; whilst the exterior architecture of parts of southern Europe, of Byzantium, of Persia, and of India, shone in all the splendour of mosaics and coloured exterior decoration, we find those resources of art but timidly and moderately resorted to in the north of Europe; and this distinction is perceptible even within very narrow geographical limits. In France, for example, whilst in the early mediæval buildings of the more northern provinces few traces of external coloured decoration occur, mosaic and tesselated works are not unfrequently found in those provinces where ancient colonies from the East had imported an exotic taste.

In Germany I am aware of but few indications of such mode of coloured exterior ornamentation; whilst on crossing the Alps we begin to find, at Venice and elsewhere, rich marble incrustations abundantly used, evincing the intimate relations of the Venetian states with Byzantium and the East. In England there is but little evidence of any taste having existed for exterior colour in architecture.

The horizontal courses of variously coloured materials—a mode of striated decoration to which recourse has been had of late in this country—are, it is true, a prevalent feature of the buildings of parts of Italy, and in the East very generally; but, as far as I know, they are a peculiarity foreign to English art, and perhaps I might add to English taste. I must however admit that these observations on the general absence of bright colours in northern architecture require much qualification when we consider the decoration of the interior of buildings. There the love of colour, which more or less characterises the natural taste of all mankind, has I think in all climates, and at almost all periods, been largely indulged. Even in the most unfavourable times artists in mosaic

Digitized by Google

were, as we have seen, found to illuminate, with more or less skill, the walls of ecclesiastical buildings, and their art was among the earliest to participate in the general improvement of architecture.

Perhaps interior coloured ornamentation reached its acme when the Sainte Chapelle, in Paris, and subsequently when our own Saint Stephen's Chapel, were built. But it should be noted that these beautiful examples were preceded by the chapel of Saint Francesco, at Assissi, where an example was set of the most elaborate and brilliant mural illumination,—an example which, by its own intrinsic beauty, as well as by the reputed sanctity of the spot, probably influenced all Christendom. I am aware that the crowning decorations of the Italian example, being by the hand of Giotti, bear a date later than that assigned to the Sainte Chapelle at Paris. But the building was erected long before, and having been executed with incredible rapidity, it may be fairly presumed that the mural decorations were at least far advanced before the Parisian work, by Montereau, was begun. The beautiful building at Assissi may therefore I think be safely said to have led to the splendid rival displays which I have already adverted to in northern Europe.

Abundant further examples might be adduced, illustrating the passion for bright colouring which distinguished the artists of probably the whole period called the Middle ages throughout Europe; and when the style that had prevailed for some centuries began to recede before the revived spirit of Classic art, architectural colourists still retained the practice of their art, although they gave it a new direction. Italy still took the lead. There we find coloured marble incrustations, both external and internal, more prevalent than ever; and panelling in various coloured marbles and jaspers is one of the most strongly marked features of the *quatro-cento* and *cinque-cento* schools. I may mention as striking and well-known examples, portions of the Ducal Palace and adjacent buildings at Venice, the church of Sta. Maria die Miracoli in the same city, and that of Sta. Maria at Florence, with very many other remarkable buildings.

Nor did the use of coloured marbles cease for a long time to be a fruitful source of beauty and variety in the architecture of Europe. It was in the beginning of the sixteenth century that the pleasing style of interior decoration became prevalent, which has been named after the great master whose skilful hand and fascinating example first recommended it. The story told by Vasari of Raphael having derived the idea of his arabesques from the casual discovery of ancient Roman decorative paintings, is familiar to all. We may readily admit the probability of the story, for the subsequent disinterments at Pompeii and Herculaneum, and in the Roman states, abundantly testify to the general practice of ancient Roman art. This epoch is a memorable one in decorative art. It is curious to trace all over Europe, and through three centuries, the permanent wide-spread influence that the school of Raphael has exercised over the whole domain of art.

I have detained you long enough on this preliminary sketch of the history of my subject. It is time that I should proceed to a consideration of the theory of colour, and its application to practice in our art. An inquiry into the theory of colour is attended with this happy peculiarity,—its first principles are simple, certain, well defined, and I may add clearly laid down before us by the hand of nature.

There are but three simple colours. All the researches of science or art we may be well assured will never reveal to us a fourth. It is in the manipulation of these three simple elements that the whole art of the colourist lies, and even in the study of this manipulation there is an absence of any bewildering complexity. As there are but three pure colours, so there can be but two classes of mixed colours,—viz., first, those composed of any two of the pure or primary colours; second, those composed of all the three primary colours. It is obvious that there can be no other compound colours besides those comprised in these two great classes.

The colourist's whole care is therefore limited to the study of three pure colours and two classes of compound colours in their affinities and mutual relations. I must however admit that the straightforward simplicity of our path here ends; for our limits very widely expand when we enter upon an analysis of these compound colours. Their range is in truth infinite; for in the class of secondary compounds there is no limit to the degree of difference in the proportions in which any two primary colours may be blended; so in the class of tertiary compounds there is no limit to the degree of difference in the proportions in which the three primary colours may be blended; no limit, that is to say, except such as is imposed by the limited faculties of the human eye.

When Alison says there is no such quality as inherent beauty in anything, he enounces a very bold, and I may venture to say a very doubtful principle; but there appears to be at least some approach to truth in the dogma when applied to beauty in colour. I will not go so far as to say that there is no inherent beauty in any one colour or hue, although it must be admitted we are greatly influenced by prejudice in our estimation of this kind of beauty. The circumstances of its application materially affect our judgment. Burke cites the colour of a dove as one of its peculiar beauties; but if we argue from thence that therefore dove colour is intrinsically and abstractedly a beautiful hue, we must be prepared to admire it on the female cheek, or the hair, or the lip. I am not however venturing to deny that there may be an inherent property in particular hues to cause us pleasure in the contemplation of them; for philosophers tell us of certain physical effects, vibrations as they are called, on the organs of the eye, produced in various proportions by various colours: but this is a subject far too recondite for our contemplation here, and probably of little practical value; I allude to it only to show that it is not prudent to speak *ex cathedra* on this subject. Still I am sure I may with safety say broadly, that colours are so dependent for their effect on association, that they derive an immeasurable accession or loss of power to produce pleasure according to the art with which they are placed before us with reference to each other. In this respect there is a remarkable analogy between colour and sound. We can hardly say with strict propriety that any one note in music is beautiful; but associate it with others into a chord, according to certain laws of harmony, and the most uneducated ear can at once appreciate the result. This analogy between sound and colour is familiar, and has not escaped the observation of natural philosophers.

It is therefore of the first importance to the student who desires to cultivate decorative art to make himself well acquainted with the principles which should guide his practice in the choice and arrangement of colours; for it is a gross fallacy, and yet a very prevalent one I believe among those who have no practical acquaintance with art, to suppose that pleasing arrangements of colour are fortuitous, or at all events dependent more on what is called fancy than on any definite rule or theory.

It is to these principles therefore that I must now call your attention. I will not suppose that any one here is wholly unacquainted with them; but it will be a wholesome exercise for him to step back, as it were, to those first principles as the starting point from whence to make a surer and more rapid advance.

Let me therefore detain you for a few minutes while I repeat some common truths respecting colour. It is found that when of the three primary colours, red, blue, and yellow, any one of them is placed near to a compound of the other two, a pleasing effect is produced, which is called harmony. To produce fully this effect you will understand that it is necessary that these two colours—viz., the primary, and the compound or secondary—should be seen nearly together or simultaneously, just as when a chord is struck in music. These secondary colours are, in the language of art, said to be complemental to that primary which does not enter into their own composition. Thus green is complemental to red, orange to blue, and so on. Such is perfect harmony in colour.

What is called discord in colours can only be produced, in its strictest sense, by placing in juxtaposition two of the compound colours. Thus a positive purple and a positive orange placed in contact produce a direct discord. But as each of these last named compound colours contain a primary which is common to both—namely, red—the nearer the purple approaches to its component blue, the less directly is it discordant with the orange, and when it has so far advanced as to be capable of being regarded as merely a purplish blue, it has so far attained to the relation of a positive harmony. So on the other hand, as the purple approaches nearer to red its discordance with the orange becomes weaker, until, arriving at merely purplish red, its relations to the orange have so far improved that, although not in strict harmony, it becomes at peace with it. Thus it follows, that whenever a primary colour is used no positive discord can take place, for whichever of the three compound colours be used with it, it must either be in harmony or in peaceful relation with it.

Thus far all is pretty simple and obvious. When however a third colour has to be used, great caution becomes necessary.

Digitized by Google

Should you, for example, have succeeded in bringing a purple and an orange together without offence to the eye, by giving to the orange a yellow tendency, mischief would inevitably ensue from the intrusion of a positive yellow, for you would then, by the contrast, throw the orangish yellow back again in the scale towards the orange, and thus, as it were, renew the feud between the two colours. On the other hand, if in proceeding to interpose upon the purple and orangish yellow a third colour you were to use a red, you would do little or no harm, for this third colour, red, whilst not at variance with the purple, would bring out the yellow tendency of the orange by obscuring as it were the red element of orange, and so far improve its relations with the purple, the direct complemental of yellow. Thus for example, in an apartment wherein the prevailing hues of its furniture and decorations are modifications of a cool purple, orange yellow, and red, the arrangement of colour would be more sure of a favourable result than purple, orange yellow, and blue; for in that latter case the blue would, by contrast, bring out in greater force the orange element, and so aggravate the discord between it and purple. I might of course bring similar illustrations from the combination of the other primary and secondary colours, but enough I apprehend has been said to explain my meaning.

I should remind you that in referring to these secondary colours I have, for simplicity's sake, used the strong definite terms orange, purple, and green, but the same general principles necessarily extend to all those numberless and nameless modifications of hues with which, in decorative painting, we have to deal; the discord or the harmony being however always the more decided the purer and more intense the colours are. Artists however are a peace-loving fraternity, and have contrived a thousand ways of counteracting the conflict of hues. By the mere intermixture of black or white in their pigments, they alone can produce a host of broken tints; slate-colours, buffs, greys, drabs, and many other such, whereby the neutralisation may be carried so far as to produce complete pacification; although of course at the risk of insipidity; of which however there need not necessarily be any danger, for there are many licenses permitted, and constantly practiced by those of highest authority, in order to give animation and variety to the association.

The judicious introduction of a moderate discord will occasionally be not only pardonable, but productive of many happy effects. I believe it to be so in musical composition, but certainly in the matter before us. To know when and to what extent the rigid laws of colour are to be violated with impunity, or indeed with advantage, is a nicety especially deserving your study.

Besides the contrast of hues there are other cognate considerations by no means to be overlooked. A knowledge of the contrast of what is called tone requires your careful cultivation; for variety in the depths of your colours is essential in order to give them all the beauty of which they are susceptible. If all the colours in an apartment are alike strong the effect will be sure to be harsh and violent; if, on the other hand, you keep them all alike faint, the effect will most probably be insipid and washy. In a room so coloured it is surprising indeed how much sparkling animation results from adding even a few lines or touches of strong colour. To borrow a well-known illustration from the experience of our sister art, these touches of strong colour are analogous to the red cloak in a grey landscape. Then there is the contrast of warm and cold hues which particularly demands your study. Red and yellow are the two warm primaries; blue the cold one. Blue, as it advances towards yellow on the one side, or red on the other, loses its cold property in proportion as it loses its own purity. No composition of hues is perfectly satisfactory unless these contrasts of temperature, as one might call them, are duly attended to. If, for example, on a wall or ceiling you have a light warm tint for a panel, and another light warm tint for the margins, to interpose a strong red line would be a mistake, for you would then deprive them of the warmth which characterises them, and perhaps render them both muddy; whereas, let the line be of a decided cool colour, and you at once give all the desired effect to the two adjacent warm tints, however light they may be; thus you gain all your effect with the least amount of colour, and to act otherwise would be a mere vulgar waste of force.

Another remark I would here add whilst on the temperature of tints. When you have both a cool and a warm tint, as for instance in the panelling of a wall, the cooler tint should be the lightest in tone. I speak of large surfaces, not of mere lines or small patches of colour. A strong cold tint as the general wall-colour of an apartment can rarely be made agreeable. The fancies of an unlearned upholsterer are sometimes such as to afford us occasional opportunities of studying every species of obnoxious combination. I have been in rooms wholly clothed in strong blue, and nothing could be more painful than the result. It is true a deep ultramarine over a considerable extent of surface may be seen on the vaulting of both the upper and lower church of St. Francesco, at Assisi; and indeed it appears to have been a favourite colour for the vaulting of churches, where perhaps blue has been adopted as a symbolic colour, or more probably as a representative of the sky, studded sometimes with its stars, rather than on any æsthetic grounds; its effect is often admirable, but this application of deep blue is wholly different from the use of it under ordinary circumstances to which I have been alluding. In the vaulting of a lofty church it is in comparative shadow, and rendered hazy, or neutralised by distance. Besides I can call to mind no instance of this deep blue being used without being considerably broken or relieved by a scattered pattern of stars or other devices of a different colour, often indeed gilt;—in this respect, as well as in many others, following the example set by their Classic predecessors, who usually painted their coffers strong blue, relieved by a painted or gilt ornament.

In considering however the decoration of apartments (the field whereon we are perhaps most frequently called upon to exercise our discretion), it should be remembered that the aspect of the human complexion and the presence of the human figure are not to be wholly lost sight of; and you will find that a large surface of wall strongly coloured materially affects the colour of the light in the room. Thus, red walls impart a warmth to the light, which has usually an agreeable effect on the complexions which receive that light; whereas a large surface of the strong cold colour just referred to chills the light, depriving it of that genial character which is proper to it, besides most seriously damaging all flesh colours within its range.

Whilst on the subject of contrasts, I must briefly advert to the valuable property that colours have of clearing each other. The terms muddy and dirty are very commonly applied to compound hues, which owe their title to those opprobrious terms more to the injurious effects of their neighbours upon them than to any intrinsic defect of their own. Place a clear blue, for example, by the side of some purplish hue, such as dove-colour or slate, and you will deprive it of its blue tendency without in any way increasing the purity of its other component, red, and thus you render the mixture faded and impure; whilst the misapplication of pure red to the same hue would, in a similar way, give to this purplish hue a cold leaden or dirty aspect, by depriving it of its warmth, which, to a certain extent, is essential to preserve the proper character of all tints allied to purple. If, on the contrary, you contrast this dove or slate colour with a buff, or even a simple gold moulding, you will at once clear up this delicate hue, and give it all the value which is due to it. In the same way the clearness or muddiness of the numerous and beautiful class of greenish hues—the tea colours, olives, &c.—depends entirely on the character of the colour with which they may be associated. To put a pure green beside a tea colour would inevitably extinguish the latter, or at all events deprive it of its distinctive character, by obliterating that green tendency which is the true source of its utility, and indeed its peculiar merit.

Now with regard to the combination of colours in unison with each other I have but little to say. It is obvious that it requires no great boldness nor art to bring together various hues of the same colour, nor various tones of the same hue, for *simile simili gaudet*. In bringing together these varieties, each having a close affinity to the other, it is clear you are perfectly safe so long as you take heed that one by its intensity does not annihilate its more modest neighbour.

But besides this association of colours in unison, and besides the harmonious contrasting of colours, about which I have probably said quite enough, there is yet another class of associations —I mean that of a primary colour with a secondary, into the composition of which that primary enters. For example, red with purple or orange; blue with green and purple, and so on. This is an association constantly practised, and quite unobjectionable, so long as care be taken to make the compound hue so decided as to prevent its being turned by the effect of the opposition into an impure primary. Blue and green, for example, are often brought into juxtaposition by the greatest masters of the sixteenth century, as by Raphael and his school. But you will find them kept carefully distinguished from each other by each being made

somewhat intense and decided. Take this however as a general rule, that you should never use one hue to deprive another hue of its special character. No doubt in the sister art of painting this rule may have no application; for the painter must often be compelled, by the exigencies of his subject, and much against his will, to introduce an objectionable hue, and he will then neutralise it, or indeed destroy it as best he may. But the room-decorator has no right, for he is under no obligation, to introduce a colour and then to do his best to put it out. When the decorator lays on a tint, either it is the right one or the wrong one. If it is the wrong one, why use it at all? If it is the right one, why neutralise it? I repeat therefore the axiom, never to use one colour in order to deprive another colour of that which is its special character.

The two kinds of association which I have last adverted to,—viz., colours in unison and colours having an affinity to each other, are perhaps the safest to use in the decoration of small apartments. But when the composition spreads itself over a larger surface it is then that we must resort, for variety and effect, to the use of various differing and contrasting colours. If I may venture again to throw light upon the decorator's art by a reference to the work of the painter, we shall find the painters of great historical pieces generally using a force of colour and a boldness of contrast which they would not think of applying to an unpretending landscape or a small cabinet picture of a domestic character. So in our department of art a large hall or apartment of stately proportions demands a force of treatment and a strength of colour which would be wholly inappropriate in the dining-parlour or sitting-room of an ordinary dwelling.

Time will not allow me to dwell much longer on these subjects; but before parting with them it seems necessary that I should touch on what have been termed ternary or tertiary compounds. I allude to the mixed and ambiguous tints produced by the mechanical union of a secondary compound with its complemental colour,—as green neutralised with red; purple neutralised with yellow; and orange with blue, producing hues which have, for the sake of distinction, been called olivine, russet, and citron. I should remind you that in these mixtures the primary can only be introduced as very subordinate in force to the secondary colour, for it is hardly necessary to say that if the primary be made equivalent in force to the two other primaries of which the secondary is compounded, the result would be strictly neutral, or no definable colour at all. These three tertiaries show how important a consideration are these chromatic equivalents or arithmetical proportions of colours. All consist of same colours, but all widely different. As regards these three tertiary hues, although they are in perpetual use, I need say but little of them, for they must be amenable in their application to the same laws that the simpler mixtures are subject to; we have but to keep in mind that, call them by what name you may, they are but neutralised modifications of the three secondary colours, and they are to be dealt with accordingly. These broken hues are often most serviceable, and may be used when pure secondaries might be harsh and violent. I must not here perplex you or myself by entering upon the subject of the exact proportions that these intermixtures require. The discovery of the important principle of chromatic equivalents has led to very remarkable results of great importance to art; but this is a subject fitted rather for the study than the lecture-room.

It now remains for me still to deal with one other cognate matter of essential importance in the compounding and arranging of colours. The two pigments, black and white, hold a very important place on every painter's palette; and although certainly not taking rank among colours (a rank which our most distinguished authority, M. Chevreuil, seems almost unwilling to deny them), yet are they most influential instruments, whether used to qualify other hues, or used in their pure and perfect condition as black and white. It would be an endless task to enter upon an enumeration even of all their effects in combination with other hues, but in their pure state I would wish to impress you with a sense of their high value in architectural decoration. Black, by its perfect opacity and coldness, is of especial use in giving intensity to luminous and warm colours. The buff dress with black border, in the costume of Raphael's well-known portrait, will occur to you at once as an illustration of this. The black pencillings on the blossom of an orange-coloured tulip will also be observed as exercising a similar influence in giving clearness and intensity to the colour.

A black ground gives peculiar brilliancy to almost every colour laid upon it, and by its overpowering depth enables those colours (perhaps I should say requires those colours) to be used in greater intensity than would otherwise be possible without gaudiness. I need do no more than remind you of the beauty of those oriental works where the colours shine out from a black japanned surface. Those medallions, also having a black ground, occurring in the beautiful decorations of Giulio Romano and his school are familiar instances, whilst the black backgrounds to coloured paintings, and other applications of black so prevalent in Pompeian art, give evidence of the early appreciation of black by the accomplished artists of the classic age.

The other pigment, white, on the other hand, by its extremely luminous character, gives depth and value to contiguous hues, however delicate in tone, rendering the faintest tints effective, and redeeming from a faded or washy appearance tints of the most tender and timid character, whilst the brightest colours are found to tell out with augmented brightness upon it.

Before concluding this discourse I may take the liberty of urging on all connected with art the great advantage derivable from an habitual observation of the effects of colour. It is a careful study and a constant habit of observation that will alone secure to us a practical knowledge of the principles of chromatic art, and a well founded confidence in their application. Not only should attention be constantly alive to the effects of colour in its actual application to architecture, but the architect would do well to be habitually observant of colour in pictures, endeavour to enter into the mind of the painter; ascertain his motives, and study the treatment of his colours; for be assured every able painter has as good a reason for every variety of hue that he presents to your eye, as the mechanician has for every screw and lever that he works into his engine.

THE SOCIETY OF BRITISH ARTISTS

Has opened its thirty-sixth annual exhibition in Suffolk-street, Pall Mall, with upwards of 800 pictures, which are seen to advantage under the altered light of the rooms, although perhaps it is now too much subdued. Contrasted with other galleries the difference is very perceptible. The pictures which by right claim the first attention are those by Mr. Hurlstone, the president. Several by Mr. J. B. Pyne, are important acquisitions, and convey a wonderful idea of perspective effect, combined with highly finished and harmonious colouring. Although from their peculiarity of handling they are not likely to be overlooked, we cannot forbear pointing out (64) "The Street of the Tombs, near Rome;" (167) a view of "Genoa," eminently Turneresque in its treatment; and (389) "Boppart, on the Rhine." Mr. E. J. Cobbett's name occurs both early and often in the list. (11) "Heather Belles" is a delightful picture, on which a deservedly high price is fixed. (188), "Children Nut Gathering" is another work of like merit, as is also (515), "A study in Brittany." Mr. Boddington introduces us as usual to some of his favourite atmospheric effects. In (19) the misty vapour of early morning is excellently given. "Tintern Abbey," seen by evening light (187), furnishes a truthful contrast. "The Haunt of the Moor Hen" (458) introduces us to a different scene, very cleverly depicted; and the first snow in "Autumn" (497), shows that fidelity to nature which invariably distinguishes this artist's pictures.

Another number that we have marked is (173), entitled, "The Opinion of the Press," in which Mr. Roberts too faithfully expresses the disappointment of an artist at the non-success of his cherished hopes, owing to adverse criticism on his picture in the public journals. Mr. Vicat Cole sends some very good works—(34), "Spring Time," is one of these, and (174), "The Road over the Heath," another. (350) is one of the most extraordinary pictures in the room; the subject is "Beech Trees," whose foliage and the leafage on the ground are rendered with the utmost artistic skill and Pre-Raphaelite minuteness. (459) is another "peep" in the same locality, viz., Albury, Surrey, a spot well known to artists. We may, in passing, compare these pictures with (387), Mr. Whaite's "Woods above Clovelly," which shows a different mode of treatment, but not less truthful. Several other pretty landscape scenes may be singled out; for instance, Mr. E. Boddington's "Summer Evening" (71); Mr. Danby's "Tynemouth" (232); Mr. Wainewright's "River Scenes" (256 and 281); also the same gentleman's picture called "Grazing on the Mountains" (617);—"Wood-cutting, Rivington, Lancashire" (460),

Digitized by Google

by Mr. T. C. Johnson; "a Grassy Bank" (652), by Mr. R. Collinson; Mr. A. Penley's "Windermere" (728).

Mr. Dobbin has two excellent Spanish views: one of Salamanca, (674), showing the church with its domed tower, and the other (822) is a general view of the city of Segovia;—and Mr. Shayer, a capital "Beach Scene" (77). Among the floral beauties must be mentioned Mrs. Rimer's "Camelias" (79).

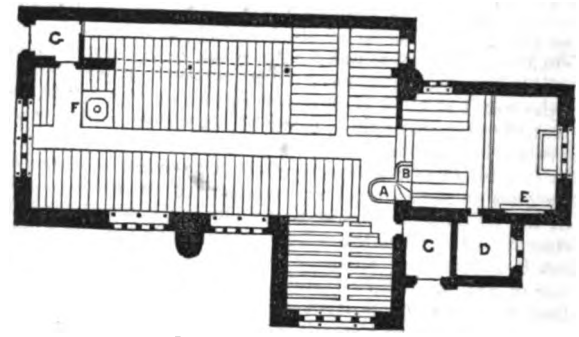
The only picture exhibited by Mr. F. Leighton (213) evidences considerable study, but will not increase the expectations created by his productions in former years. He has chosen a difficult subject—"Samson and Delila,"—and treated it in a bold manner. Mr. Woolmer is, as usual, in full force.

A clever little work, emanating from Messrs. Herring and Rolfe (217), is called "Dangerous Play," and shows three horses in vigorous action. It is also a very good bit of colouring. The "Aguador's Stall at Seville" (245), by Mr. Villamil, is exceedingly well painted; so also are Mr. Dobbin's "Alhambra" (798), and his "Burgos" (779). Mr. Shayer's "Dairy Cottage" (282), with its neighbour (283) "Under the hedge" (J. Rees), also deserve mention. The grandeur of Norwegian scenery has given Mr. West ample scope for producing effective pictures in Nos. 348, 456, and 528.

There are a few contributions of the Pre-Raphaelite stamp, such as Mr. Rossiter's "Fair Musician" (502); Mr. C. J. Lewis's "Home, sweet Home" (598); Mr. Tucker's "Blackberries and Wild Flowers" (638); and Mr. Smallfield's "Late Supper—full with horrors" (727).

Scanty indeed is our architectural list,—more so by far than usual. Mr. A. Allom's views in Bruges (313) and Ghent (570); also Mr. Wood's "Market-place, Rouen" (607), and "Tower of the old Abbey of St. Bertin, St. Omer" (385); with Mr. L. Lewis's "Place St. Croix, Tours" (794). A view of Algiers (242) gives a glimpse of its architecture; and the temple at Philæ will be recognised in Mr. Mawley's view of the island (820). Mr. Luker exhibits three continental views: (330) "Rue St. Catherine, Quimper;" "a Public Well in Brittany" (334); and an "Auberge" (346), also in Brittany. (437), "A Street scene, Sandwich," is cleverly sketched. (575), "Dolbadern Tower, Carnarvonshire," the citadel of the Castle, and a circular building, erected probably as early as the sixth century, is shown by Mr. Swarbreck in (575); and the "Tomb of Henry IV., Canterbury Cathedral," is beautifully drawn by Mr. Nash, jun. (694): the canopy is of wood, and there is some excellent mediæval ironwork.

GREETLAND CHURCH, NEAR HALIFAX.



(With an Engraving.)

This Church is now in course of erection at Greetland, near Halifax, Yorkshire, and when completed will present marked points of difference to any of the churches of the locality. The material employed is entirely the stone of the neighbourhood, known as Greetland-stone, which is used for the interior as well as the exterior of the building. There is not any plaster on the interior walls.

The ground plan consists of nave, chancel, south transept, and north aisle, the latter being separated from the nave by three bays. At the west end of the aisle is a porch, under the same roof as the nave. The sacristy juts out on the south side of the chancel, and between it and the transept is a porch, consisting of an entrance door surmounted by a circular window with plain cross tracery. The chancel arch is a circular one, of bold sweep and excellent proportions, each bracket from which it springs is supported by two elegant polished marble shafts with carved capitals. Each of the three arches in the nave differs from the other, the one nearest the east end being especially to be admired for its noble proportions and elegant span. The roof is an open timbered one, that in the chancel being treated in a different manner to the nave, and the wall plate is elaborated by carving.

The west window is of four lights, as is also that in the transept. In the south wall are two windows of four lights each. The east window is a triplet one. All the tracery work partakes of the Geometric in the earliest style of its development. Every window is deeply splayed, and, both externally and internally, all are enriched with slender shafts either of polished marble or slate, with carved capitals. The bell turret springs from the east gable of the nave. The length of the church is 67 feet, the chancel being 27 feet. The altar is raised upon steps, and the pulpit and reading desk, which are of stone, are grouped together at the south angle of the chancel wall. The font is placed near the west porch; and the stalls for the choir are in the chancel.

The estimate cost is £2300; the number of sittings 500; the fittings are of stained deal. The whole is from the designs of Mr. Thos. H. Rushforth, architect, London.

SIMPLE METHOD OF CALCULATING EARTHWORK.

TO THE EDITOR OF THE CIVIL ENGINEER AND ARCHITECT'S JOURNAL.

Can you or any of your readers tell me whether the following method has been previously applied to the calculation of earthwork?

Let *aghklf* be a section of a cutting, the formation width of which is to be 16 feet, and the slopes 1½ to 1.

Add the width at *a*, 16 feet
" " *c*, 16 "
" " *g*, 40 "

$\frac{1}{3})72 = 24 \times 150 \times \frac{8}{2} = 14400$

This gives *agc*; then take the widths at *g*, *h*, and *a*.

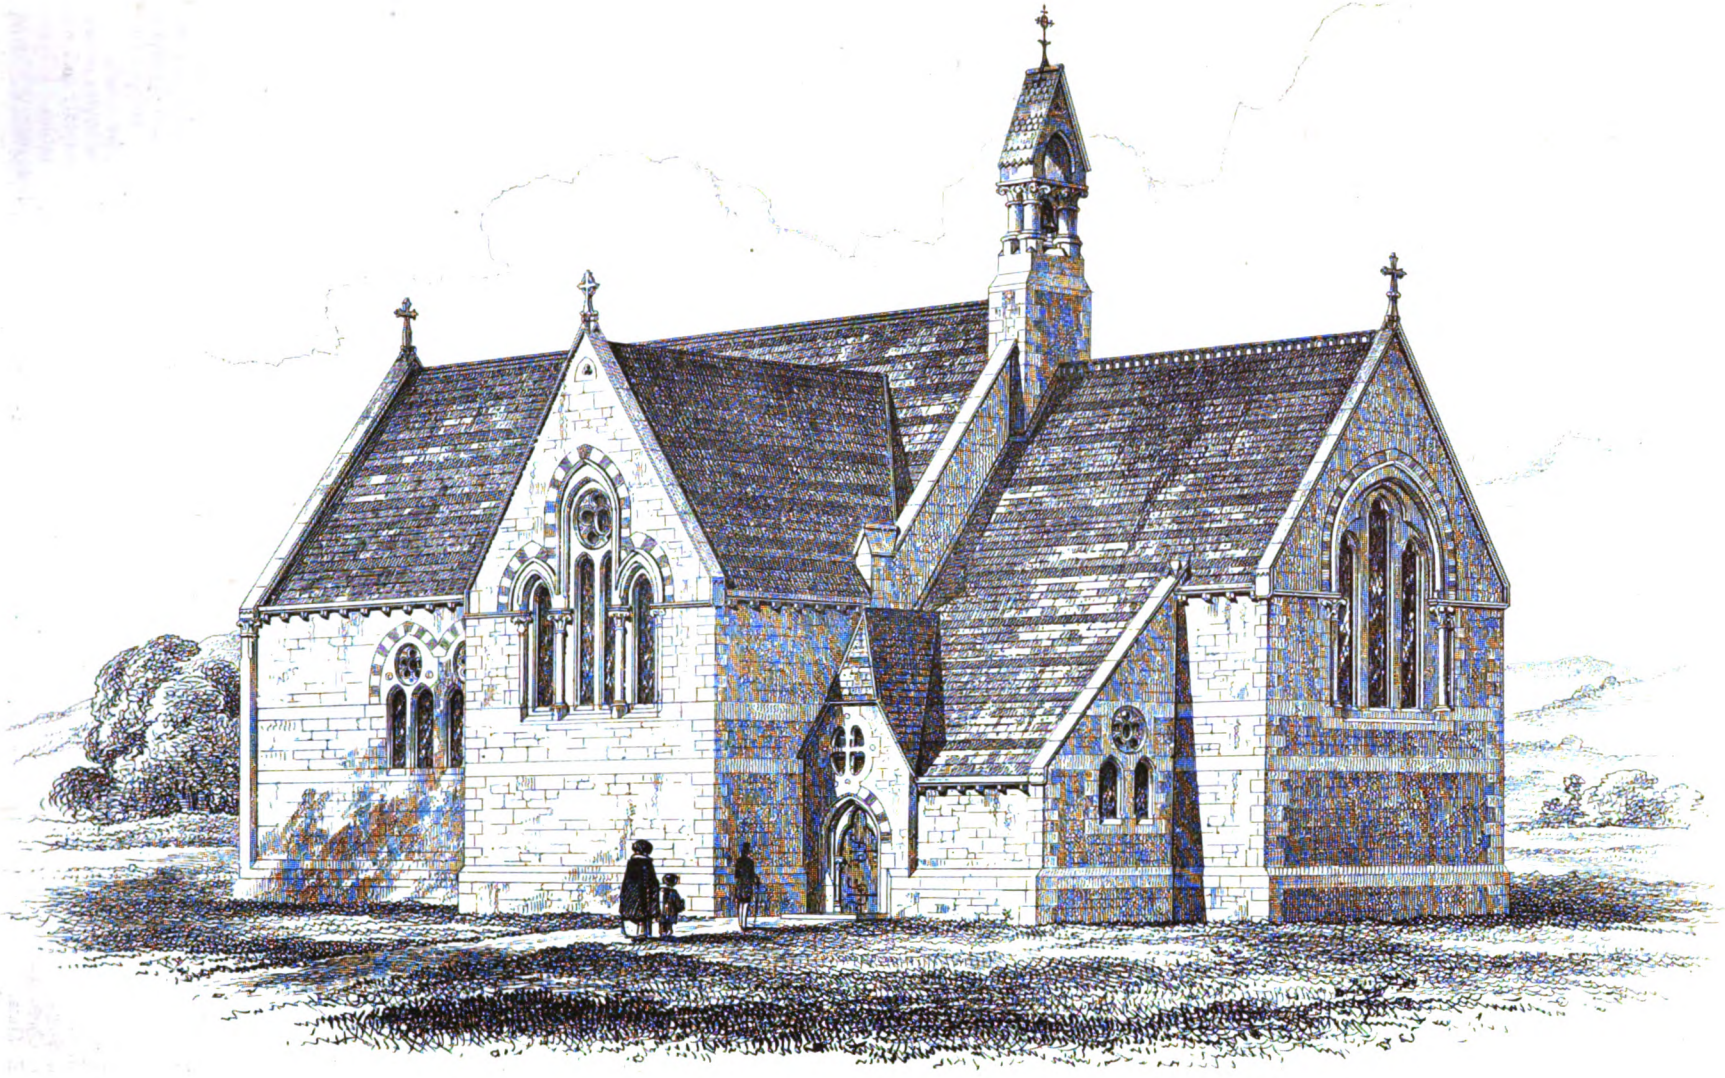
At *g* 40, at *h* 46, at *c* 16 $= \frac{102}{3} = 34 \times 50 \times \frac{10}{2} = 8500$

Then at *h* 46, at *c* 16, at *k* 34 $= \frac{96}{3} = 32 \times 75 \times \frac{10}{2} = 12000$

Then at *c* 16, at *k* 34, at *e* 16 $= \frac{66}{3} = 22 \times 200 \times \frac{6}{2} = 13200$

Then at *k* 34, at *l* 31, at *c* 16 $= \frac{81}{3} = 27 \times 125 \times \frac{5}{2} = 8437$

And lastly at *e* 16, at *l* 31, at *f* 16 $= \frac{63}{3} = 21 \times 50 \times \frac{5}{2} = 2625$



27)59162 feet

2191 yds.

which is precisely the same result as that given by Sir John Macneil's tables, or any others calculated by the prismoidal formula. It will be seen that the method is simply to take the widths at the three points of the triangular piece to be calculated. At the base these are determined by the width of formation; at the surface, by the ratio of the slope. One third of these multiplied by the length and half the height, gives the cubic contents in feet. Unless where one has tables calculated to a given formation, earthwork may be as rapidly and accurately calculated by this method as by ordinary tables. If it is a new method, it may be mentioned that its discovery is due to Mr. Alex. Johnston, assistant engineer, Scottish Central Railway.

TELEGRAPHIC ELECTRICITY.*

On the Practical Bearing of the Theory of Electricity in Submarine Telegraphy, the Electrical Difficulties in Long Circuits, and the Conditions Requisite in a Cable to Insure Rapid and Certain Communication.

By S. Alfred Varley, A.Inst.C.E.

In the year 1838, Dr. Faraday clearly developed the principles of induction and conduction, since which time no further progress has been made in the fundamental truths of the science, though much has been done to confirm their correctness and to develop their consequences. In the 'Philosophical Transactions' for 1838 will be found Dr. Faraday's views on the subject of induction and conduction.

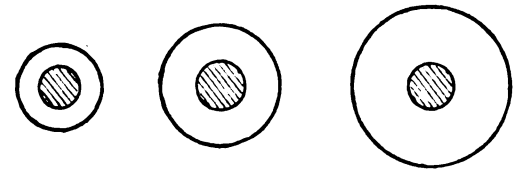
To determine for myself the law which induction obeys, in conjunction with my brother Mr. C. John Varley, I have tried some experiments.

The principle upon which these were based was that of the dual character of electricity, and the fact established by Dr. Faraday, that all statical charge is sustained solely and entirely by induction.

In bodies in their normal condition the opposite forces or electricities being balanced and united, no attraction for neighbouring particles exists, but when these forces are separated, as in the case of a Leyden jar, the attraction which a given quantity of electricity exerts for the similar amount of negative on the opposite coating, will be less in proportion to some law as the thickness of the dielectric intervening is increased.

It was therefore assumed that the amount of free attraction under these circumstances, or more correctly the amount of induction which would be thrown upon neighbouring bodies, would increase inversely as the attraction between the opposite coatings diminished.

The apparatus made use of was constituted in the following way:—A glass pillar, varnished for better insulation, was mounted upon a board. On the top of this a brass plate was attached, and upon this plate the dielectric to be examined was laid. Over the dielectric another brass plate was then placed. A Leyden arrangement was thus constructed, the upper and lower brass plates representing the inner and outer coatings of an ordinary Leyden jar. A brass ball, suspended from a balance, which had an adjusting arrangement, so that it could be raised or lowered, hung over the upper metal plate at a short distance from it.



The *modus operandi* was as follows:—The upper brass plate was connected to the earth, and a series of sparks, through the medium of a sliding rod kept at a fixed distance from the prime conductors of a friction machine, thrown into the lower brass plate of the Leyden arrangements, or the prime conductor was kept fully charged, and a carrier ball attached to a long glass rod was made use of to measure out definite quantities of electricty. The room in which the experiments were performed was heated with a stove, and the dryness of the atmosphere indicated by a hygrometer, so that the insulation might be as perfect as possible. When a certain number of sparks had been thrown into the lower brass plate, the upper brass plate was disconnected from the earth, and the lower one attached to the balance, and if the tension of the charge was sufficient the brass ball suspended from the balance was attracted down, and discharge ensued. The experiment was repeated again and again, and the number of sparks requisite to just attract the ball down noted. Glass plates were the dielectric employed, and the experiment was tried first with one plate, then with two, and then with three plates of glass between the upper and lower brass plates, the brass ball suspended from the balance being kept always at a certain fixed distance from the upper brass plate.

The results obtained from a numerous series of experiments were,—that when two plates of glass were placed between the brass plates, only half the number of sparks which were required to raise the tension of charge sufficiently to cause discharge when one plate of glass separated the glass plates was requisite; and when three plates of glass divided the upper and lower brass plates, then a third of the number of sparks raised the charge to the same degree of tension; showing that through flat plates of glass induction decreases in the inverse proportion to the thickness of the dielectric,—that is to say, if the induction through one be 12, through two it will be 6, through three 4, and so on.

In the case of a gutta-percha covered wire it was anticipated that as when the thickness of the gutta percha is increased the outer surface increases at the same time, the decrease of induction consequent on the increased thickness of the insulating material would not be inversely proportionate to the depths of the gutta-percha, but would follow some other law.

To put this to the test a series of Leyden arrangements were constructed in the following way:—three pieces of tube, of half an inch internal diameter and 2 ft. 6 in. long, were placed in the centre of tubes of 2 feet long, the internal diameters of which were 1 inch, 1½ inch, and 2 inches, and the space between the inner and outer tubes filled with melted resin (figs. 1, 2, 3).

Fig. 1. Fig. 2. Fig. 3.

By this means three Leyden arrangements, with a uniform internal surface, but whose insulating material varied in thickness in the proportion of 1, 2, and 3, were constructed, and the same process as that already described with the flat plates was repeated. The results obtained are shown in the annexed table:

Diameter of inner Tube.	Thickness of Insulation.	Diameter of outer Tube.	Inductive Force.
10	5	20	22
10	10	30	15·5
10	15	40	11·5

These results were very constant, but as resin was the only dielectric employed, the experiment requires repeating with other dielectrics, for there is reason to believe that with glass at least the decrease in induction consequent on an increased thickness of the dielectric would be somewhat greater than that indicated in the above table.

The reasons for this belief are the following:—When a galvanic battery is connected with the inner and outer coatings of a Leyden arrangement, induction will take place through the dielectric, and if the surfaces of the two coatings are equal, then the force will be equally divided over them; that is to say, if the battery force be 100, the tension of the charge on the one coating will be 50, and that on the other will be 50 also, =100.

Let the surface of the outer coating be supposed to be infinite in extent, then the tension of the charge on the inner coating will approach infinitely near to 100, and the tension of the charge on the outer coating will be almost nil. An example of this we have when the earth represents one of the coatings of a Leyden arrangement; and this is the case in the prime conductor of a frictional machine, and also in the suspended wire of a telegraphic circuit; in these two examples the prime conductor of the machine and the wire of the telegraphic circuit represent the one coating, the air the delectric, and the earth the other coating.

Now consider a case where the outer surface is double that of the inner one, the tension of the charge on the inner coating will then be double that of the outer; an example of this we have in the above table, where the inner surface is 10, the thickness of the insulation 5, which may here be regarded as unity, and the outer surface 20,—the battery force being 100. Divide this into three parts, and we get 33⅓. Give two parts for the tension of the charge on the inner coating, and one part for the tension of the charge on the outer coating, then we shall have for the tension of the inner surface 66⅔, for the outer surface 33⅓=100 when united.

Now consider the third example in the above table. Inner surface 10, thickness of insulation 15, outer surface 40, or quadruple that of the inner surface. In this case the tension of charge on the inner surface will be four times that of the charge on the outer surface. In other words, the tension of the charge on the smaller surface will be 80, and that of the outer surface 20, the united tensions equalling 100; but the thickness of the insulation is 15, or three times that of the first example; and it has been shown that induction decreases in the inverse proportion to the thickness of the insulating material; we shall therefore have to divide by 3, and this will give 26·3 for the tension of the charge on the inner surface.

* Abridged from a Paper read before the Society of Arts.

Digitized by Google

In the first example it has been shown that if the force be 100 the tension of the charge on the inner surface will be 66⅔, which to avoid fractions we may regard as 67. In the actual experiment the inductive force measured was 22; 67 therefore represents 22, and as 67 is to 22 so should 26·6 be to the amount of force which would be expected to be obtained in the last example; this, when calculated by a simple rule-of-three sum, gives 8·8 for the amount of inductive force. In the actual experiment the force obtained was 11·5, a result therefore sufficiently near to warrant further investigation, to ascertain whether the law which would seem to be indicated is correct, and whether it holds good with any other dielectric, such as glass, in which case the cause of the discrepancy when resin is the dielectric employed, should be sought after.

I now proceed to conduction.

The law which governs the conduction of electricity has been very accurately ascertained, and would seem to follow the same law as induction; that is to say, if the sectional area be uniform throughout, the resistance which a conductor will oppose to the passage of a current will be directly relative to its length; or the length of the conductor being determined the resistance will be relative to its sectional area. In other words, a wire one mile long will oppose half the resistance of that which will be opposed by a similar wire two miles long; and two wires, each two miles long, placed side by side, which is the same thing as one of twice the sectional area, will oppose exactly the same resistance as a single wire one mile long.

The next thing to be considered is the part which the quantity and intensity of electric currents play in electric phenomena.

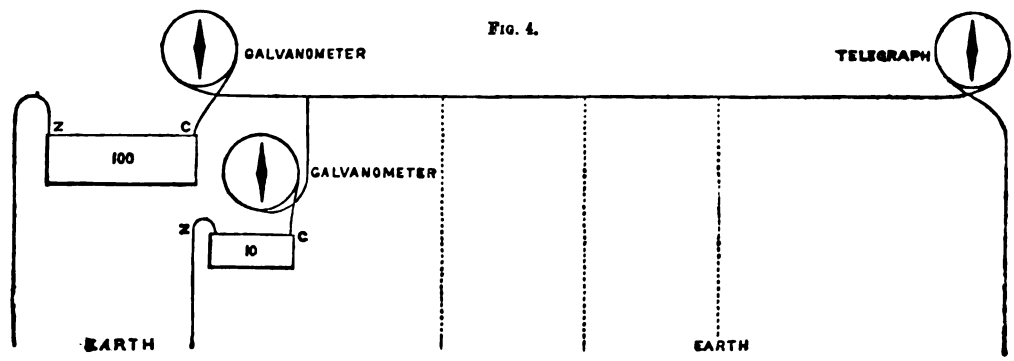
The amount of force developed by an electric current, whether it be the deflection of a needle, the attraction of an armature in an electro-magnet, or the decomposition of water, is always relative to the dynamic quantity flowing.

This fact has been well established, and the difference between quantity and intensity accurately defined; yet still in practice there is a want of a clear comprehension of the relationship of those terms.

Let a battery—say of ten pairs of elements, with 10 inches of surface in each cell—be joined through a circuit perfectly insulated, and opposing very great resistance to the passage of the current; and the amount of force, or in other words the dynamic quantity of electricity flowing, be weighed off by a magnetometer and noted down. If now this battery be disconnected, and another of the same number of elements, but with twice the surface, be connected in its place, practically no more will be found to be flowing through the circuit than in the former case, the resistance which the wire opposes measuring out the quantity passing somewhat in the same way as the height of the column, and not the quantity of water in a cistern, regulates the rate at which it flows from an orifice inserted in it.

Let the series be increased, and more will be urged through; and if the number of cells be sufficiently numerous for practical purposes, the same dynamic quantity as a single cell would generate through a circuit of no resistance would be found to be flowing.

In theory this point can only be approached, for the resistance of the wire can never be completely overcome. In theory also, when the number of elements is not increased, the larger the surface the greater will be the dynamic quantity flowing, for the tension of the current is lower in proportion to the amount of electricity flowing out of the battery; and when drawing from a larger reservoir, which batteries of greater surface may be compared to, this same amount will not lower so much the general tension; consequently there will be more intensity to urge the current through. But to return to practice. If the number of cells has been sufficiently extended so as to generate the same dynamic quantity as a single cell does through a circuit of nominally no resistance, a further addition to the series will not be attended with any beneficial effect, for there is already power enough to urge through all the electricity the battery is capable of generating; and the force developed is directly relative to the dynamic quantity flowing. Tension is only the medium by means of which this dynamic quantity is forced through the circuit.



It will be as well perhaps to define more precisely what is wished to be understood by the term resistance. When it is said that one circuit opposes twice the resistance of another, it is meant that the same tension of current will force half the dynamic quantity only through this circuit that it would through one opposing half the resistance; it follows that a given length of wire opposes the same resistance to half the dynamic quantity of electricity that half its length of wire does to double the dynamic quantity, and hence all circuits oppose to an infinitely small quantity of electricity an infinitely small amount of resistance.

The way in which quantity and intensity affect practical telegraphing has next to be considered, and whether there be any advantage in employing comparatively large over smaller dynamic quantities of electricity.

It may be generally stated that when the insulation is very perfect there is no great difficulty in working with minimum quantities; but when the insulation is imperfect larger dynamic quantities hold out a better prospect of working through.

When a current is flowing through a circuit which offers, practically speaking, no resistance, let the cells of the battery be ever so numerous, it will possess no intensity worth noticing; for as there is no resistance opposed to the force resident in the battery, the intensity is not brought into play. It is something like a powerful engine raising a light weight, the force is latent, but not brought into action. Let the battery however be connected through a circuit opposing considerable resistance; its intensity will then be developed.

Fig. 4.

Let the diagram (fig. 4) represent a circuit which fulfils these conditions, one end of the wire dipping into the earth in the usual way, and the other connected with the copper pole of a battery composed of a numerous series of elements possessing very little surface, and consequently capable of generating only a small dynamic quantity of electricity; and let the circuit be completed by connecting the zinc pole to the earth.

The current will flow from the copper pole through the wire, thence to the earth, and back to the battery, and its working intensity will be dependent on the resistance which the circuit opposes, and can be measured in the following manner:—Let another battery, but with a much smaller number of elements, be connected side by side with the larger battery to this wire, the zinc pole being connected to the earth and the copper to the wire, and introduce galvanometers in the circuit, between the large battery and the wire and between the small battery and the wire, so as to indicate the direction in which the currents are flowing.

Both batteries will desire to send a current through the circuit in the same way, but should the small battery oppose much less resistance to the passage of a current through itself than is opposed by the long wire, then the greater quantity of electricity generated by the large battery will pass that way in preference to through the wire, and paralyse the action of the smaller battery; but if cell after cell be added to this little battery, when its in-

Digitized by Google

tensity becomes greater than the resistance of the wire, a current will flow from it also in the same direction as that from the large battery through the wire, and the number of cells requisite just to do this will be an exact measure of the working intensity of the current.

Let the case now be considered where the insulation is not perfect; if there be sufficient leakage to let the small dynamic quantity which the battery can only generate escape on the road, no appreciable amount will reach the further end, the tension of the current will be lowered, and a less number of cells in the little battery will now be found to balance it.

Adding to the number of these small pairs of elements will not give any appreciable assistance, but let the surface in each of the cells of the larger battery be increased so that a greater quantity may be generated than can escape through the leaks, represented in the diagram by the dotted lines, an appreciable amount will then reach the further extremity, and the telegraph instrument be rendered active. In such a case as this, adding quantity will raise the working intensity of the current, whilst increasing the intensity of the battery alone will scarcely affect it.

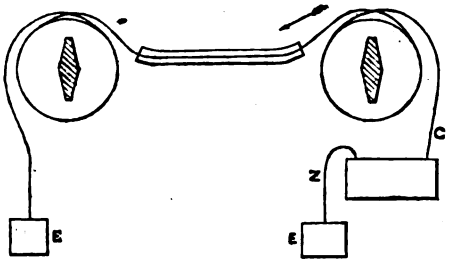
Previous to the first attempt to submerge the Atlantic cable, a series of experiments were undertaken by the company's late electrician, and the result published.* These experiments having been tried at the expense of much capital, and with opportunities which never before presented themselves, are too important not to be noticed, though it is believed that the author of them has lately had reasons to modify some of his conclusions. The chief results published were these:

1. That no adequate result is obtained by increasing the sectional area of the conductor; that, in fact, in the case of a submarine circuit a small wire will transmit signals more rapidly than a larger one.

2. That an insulated submarine wire conducts according to a different law to that of a suspended circuit.

3. That the rate at which a voltaic signal travels is not affected by the intensity of the battery.

4. That magneto-electric induced currents have the property of travelling in the first place faster than voltaic ones; and unlike voltaic currents, when their intensity is increased their rapidity of travelling is increased also.



In the paper I submitted to the Institution of Civil Engineers† I pointed out what I conceive to be errors in these results, and endeavoured to show that some of them necessarily followed from the way in which the experiments were conducted. Before proceeding further, and to prevent the possibility of mistake, it is desirable to make the following quotation from the work previously referred to:—‡

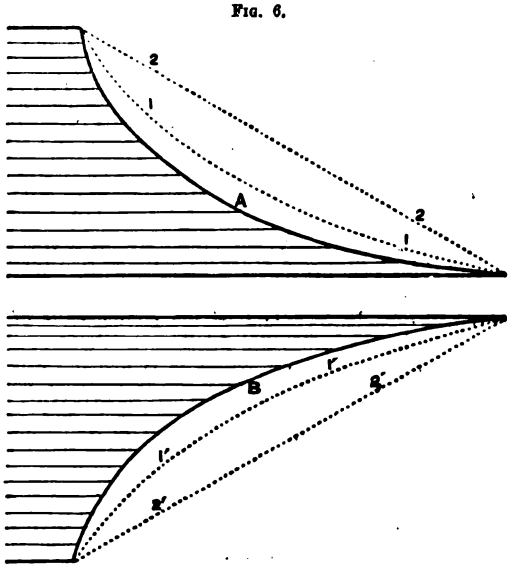
"The law of squares may possibly apply to the transmission of electricity freely along simple conducting wires, but it certainly does not apply to the case of its transmission along submarine and subterranean gutta-percha covered wires (the facility of transmission being estimated by rate of speed), because in this the case is not one of simple conduction, but of transmission, after the wire has been charged inductively to saturation as a Leyden jar."

This quotation shows clearly the reason for concluding that small wires are better conductors for submarine circuits, as far as transmission is concerned, than larger ones; for the smaller the Leyden jar the more quickly will it be charged to saturation. The author, in differing from these conclusions, does not wish it to be understood that he thinks the law of squares is applicable to submarine wires; for he is not aware of any electrical phenomena which obey that law; but he submits that there is a material difference between a Leyden jar and a submarine wire.

In a Leyden jar the inner and outer coatings are perfectly insulated one from the other. If they were not insulated there could be no statical charge, as is well understood by all electricians. Induction therefore involves insulation. But in a submarine circuit this is not the case. If the wire at the further extremity were disconnected from the telegraph instrument and sealed up with gutta-percha, the conditions would be nearly the same. In practice however it is quite open through the instrument to the earth, and the resistance opposed by the very long length of wire is the only insulation between the inner and outer coatings, for it unites both, being in connection with the earth at both ends (fig. 5). It is therefore evident that if the wire offers no resistance there will be no insulation, and as a consequence no induction to retard the passage of the current. It is also equally plain that precisely in proportion to the resistance which

Fig. 5.

the wire opposes, provided always the insulating medium be of the same thickness, will induction manifest itself and retardation be experienced.



There is also another difference between a Leyden jar and a submarine circuit. The Leyden jar is charged uniformly all over, whilst in a submarine wire the tension of the charge varies in different portions of the circuit, being at its maximum at the end where contact is made with the battery, and dying off to nothing at the further extremity.

The next consideration is the part induction plays in submarine circuits of any considerable length.

In a submarine circuit the wire is insulated from the earth by only a thin layer of gutta-percha; the conditions therefore are favourable for induction through the insulating material; the conductor itself from its great length opposes very great resistance, or in other words, insulates to a very great extent.

When a battery is connected to send a current, the first impetus is in part directed forward, in part diverted laterally; but as the wire opposes considerable resistance to the passage of the electricity which the battery can generate, whilst the thinness of the insulating material is very favourable for induction taking place through it, the greater portion of the first rush will be occupied in charging the wire statically at the battery end; as however it is a balance of forces between the resistance which the wire opposes on the one hand, and the ease with which lateral induction can take place on the other, a very minute portion must pass through instantly, and the period which will elapse between the making contact with the battery and the observing the current at the

Fig. 6.

further extremity, will depend upon the capability of the instrument to record very small quantities of electricity.

In fact, immediately on contact being made with the battery a wave will be formed throughout the length of the wire, somewhat like what is shown in the diagram (fig. 6), which is intended to represent a submarine wire the moment after contact has been made with the battery. The line A represents the internal charge having its maximum tension at the battery end, and diminishing

* *Vide* 'The Atlantic Telegraph. A History of Preliminary Experimental Proceedings, &c., published by order of the directors of the company.'

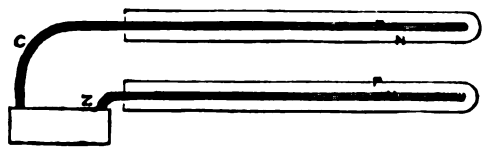
Digitized by Google

in intensity as it approaches the farther extremity. The line B shows the induced charge of the opposite kind on the outer surface of the gutta-percha, and forms an exact counterpart to the internal charge, with the exception of being a little less intense; for as it is spread over a greater surface, and only exactly balances the internal wave, its tension will be less in proportion as its surface is greater. As the tension of the statical charge is raised so will the flow of electricity at the further extremity increase; both will arrive at their maximum together: the current will then flow in a regular stream as long as contact with the battery continues. The dotted lines 1 1 and 1′ 1′ are intended to represent the waves after contact has been made a short time, and the lines 2 2 and 2′ 2′ are intended to represent the waves when they have attained their maximum height. In the last case they will be perceived to be more regular.

When the battery has been disconnected from the wire the opposite waves will still continue to unite, but the rate of flow as the tension falls will become slower and slower.

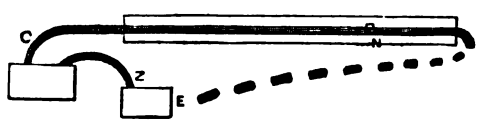
In theory the time which would be occupied by a wire discharging itself completely in this way would be infinite. In practice the wire requires a very appreciable time to charge, and a longer period to discharge. The effect of this is, that if currents are sent at all rapidly one after the other, instead of obtaining a series of distinct impulses at the further extremity, an undulating continuous current is received; and, as to obtain a telegraphic signal the wire has not only to be charged to a certain degree of tension before an appreciable current is received at the further end, but has also to be discharged afterwards before another signal can be sent, the impulses which are obtained through such circuits as these are very sluggish.



The problem to be solved is the best means of reducing the amount of induction, and of mitigating its effects.

Almost the first remedy suggested when this inconvenience was experienced, was to substitute another insulated wire in the place of the earth for a return circuit; for it was argued, that as in this arrangement one wire would be charged positively and the other negatively, they would neutralise one another. This suggestion was put to the test and failed. Since that time the same plan has been revived by several others; a good deal of argument has also been brought forward lately in support of it, and even amongst those who know its practical inutility there would still seem to have been lurking some faith in the capability of the method—in theory at least—to neutralise the effects of induction.

The explanation of its failure, if we are guided by the first principles of the science, appears to me to be very simple, and I expect not only to make it plain that no advantage is to be obtained by the adoption of this method, but that it will increase the retardation.



Let two long gutta-percha covered wires (fig. 7), buried in the earth, be connected, one with the zinc pole and the other with

Fig. 7.

the copper pole of a battery, and let the farther ends of each of these wires be hermetically sealed. The earth from its mass being a perfect conductor, its action it is evident will be the same as if metal tubes in metallic communication with each other surrounded the gutta-percha wires. It is therefore clear that the only retardation to induction will be the thickness of the gutta-percha covering, and the tension of the statical charge will be in accordance with the intensity of the battery. Now consider the case of a similar gutta-percha wire of the same length (fig. 8) as one of these, but in which one pole of the battery is

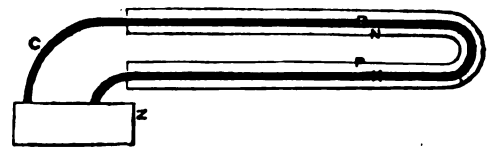


Fig. 8.

connected to the earth and the other to one end of the metallic conductor, and the circuit completed by connecting the further extremity to the earth. It will also receive a statical charge to a certain degree, but the tension of the charge will not, *cæteris paribus*, be dependent upon the intensity of the battery, but upon the resistance which the wire opposes, for it has already been shown that this is the only real insulation between the wire and outer coatings, and that the degree to which statical charge can take place depends on the amount of insulation existing.

Now let the ends of the two wires which are hermetically sealed be connected to each other (fig. 9); the circumstances are

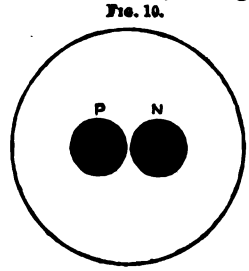
Fig. 9.

quite as favourable for induction as in the wire in which one end was connected with the earth, but there will be twice the resistance; in other words, double the amount of insulation, and consequently a proportionate increase in the amount of induction.

Another view of this matter will perhaps assist to confirm what has just been stated.

It is a well established fact that when a telegraphic circuit is composed of a loop of wire, it will oppose the same resistance as a circuit of double the length where the earth is made use of in the place of a return wire, and this proves that the earth offers no appreciable resistance. If this be the case, what difference can it make whether the battery pole be carried to the end of the wire itself, or through the medium of any length of a perfect conductor, which the earth has been proved to be. Therefore it would appear that the induction which would be manifested in a circuit composed entirely of an insulated conductor, would be the same as that in a circuit of twice the length where one half the circuit is completed by the earth; and the only difference which would exist between the one and the other would be, that in a circuit composed entirely of wire the statical charge will be distributed more uniformly throughout the entire length.

Fig. 10.



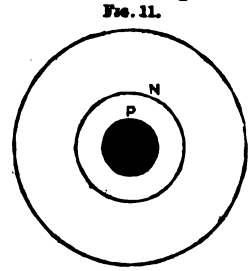


Fig. 11.

"But," says a writer on this subject, "I admit that no advantage would result if two separate wires are used, and which will therefore necessarily be some distance apart from one another, but place the two wires in the middle of a mass of gutta-percha (fig. 10), and so close to each other that they may become virtually the centre of a system, and let the insulating material be of considerable sectional area, then no induction worth naming will take place between the wires and the earth, and the inductive influence of the positive wire will neutralise that of the negative wire."

The fallacy of the proposition will be at once seen if it be carried out more fully. Instead of letting the wires lie side by side, let the one wrap over the other, and be in fact a tube with a thin mass of insulating material between it and the inner wire (fig. 11). They will now become really the centre of the system, and fulfil completely the object desired by the author of this suggestion; but is it not evident that such an arrangement is the fac-simile of a Leyden jar, and will not the conditions be the most favourable that can be conceived for the development of induction?

The only remedy which has been successful in mitigating the effects of induction, is that of throwing into the wire, immediately after a current has been sent, another of the opposite kind: this absorbs and neutralises the preceding wave much more quickly than when the wire is left to discharge itself in the ordinary way. This method however does not reduce the induction, but only mitigates its effects; although in circuits of moderate length its adoption has for practical purposes completely removed the inconveniences arising from the induced charge.

There are only two ways of reducing induction, the one is to

Digitized by Google

increase the thickness of the insulating material, and so render the conditions less favourable for its development, and thus approach the conditions of a suspended circuit, where the induction having to take place through a considerable space of air—a dielectric of very low specific inductive capacity—there is but little accumulation of statical charge, and consequently the impetus is almost entirely directed forward, and scarcely diverted laterally to any appreciable extent.

In gutta-percha covered wires, when the insulating material is increased in size, it has been shown that the full effect of the increased thickness is not obtained, owing to the outer surface increasing at the same time.

There is also another quality possessed by resinous substances, and probably by gutta-percha, worthy of consideration. It is the property of absorbing a charge in the mass of the substance, instead of its being confined entirely to the surface; the tendency of this will be to still further reduce the advantage of an increased thickness of insulating material.

A reference to first principles will make this clearer. All bodies insulate to a certain extent, and the only difference between a so-called conductor and insulator that would appear to exist is a difference of degree; and if a charged body is brought into the neighbourhood of an insulated conductor induction will take place through it in the same way as through a dielectric; but owing to the particles of conducting substances possessing the property of readily communicating their forces one to another, the inductive force developed at the further extremity will, within certain limits, be scarcely affected by the length of the conductor through which induction is taking place. The absorption of a charge within the substance of the dielectric is an approach to this condition, but its practical moment when gutta-percha is the insulating substance has to be determined by experiment.

Lessening the induction by reducing the resistance has next to be considered.

The first thing obviously will be to obtain a metal of the highest specific conducting power, for could the sectional area be diminished without increasing the resistance, the induction would be reduced proportionately to the decrease in the surface. The next will be to increase the sectional area of the conductor, and although this involves increased surface, yet there will be a gain; for when the diameter of a wire is enlarged the surface over which the amount of induction extends does not increase in the same ratio as the sectional area which determines the resistance opposed by a conductor. To make this clearer, let four cables ranged side by side be employed as one conductor.

Such an arrangement will possess four times the sectional area and oppose only one-fourth the resistance; in other words, the same tension of current will force through four times the dynamic quantity of electricity that would be generated through the single cable when used alone. Signals would not however be transmitted more rapidly through the four cables than through the one; for although the conducting power has been increased, four times the surface has been quadrupled also, which will just counterbalance the lessened resistance: but merge the four into one, the external inductive surface will then be halved, whilst the sectional area will remain the same as before, and there will be only half the induction manifested.

It therefore follows when a wire is enlarged, that as the sectional area increases as the square whilst the surface increases only in regular proportionals, the relative balance of forces in favour of rapidity of conduction will in a submarine conductor of a given size be twice the amount of that in a wire of half the diameter.

I would now attempt an explanation of how it happened that an actual retardation was observed in some of the experiments with the Atlantic cable when a conductor of enlarged sectional area was employed; and on this head I would again quote from my remarks on a former occasion:—

"In the experiments to ascertain whether any advantage would result from the use of an increased sectional area of metallic conductor, recourse was had to joining the cables side by side, the increased inductive surface which such an arrangement involved having possibly been overlooked. This will account not only for an increased speed not having been obtained, but for an actual retardation having been noticed. Electro-magnetic induction coils do not create electricity, they simply offer a ready means of converting electricity of low tension and considerable dynamic quantity into electricity of very high tension and small dynamic quantity. The quantity evolved by them is always smaller in proportion as the intensity is greater. Both cannot readily be obtained together, and if a very high intensity is required, the quantity must be sacrificed unless the size of the apparatus is immensely increased. This difficulty has evidently been appreciated, as the induction coils used by the Atlantic Telegraph Company are of large size and great length, so as to obtain high tension with an appreciable dynamic quantity. Nevertheless, there is little doubt but that the quantity evolved even by these machines, when compared with that generated from voltaic batteries, is small. This being the case, on giving the current a larger number of channels to rush into, there is not enough electricity to fill the wires, consequently the tension of the current will be very much lowered. The effect of this will be that a longer time will elapse before the tension of the wire will be raised sufficiently high at the further extremity to render itself apparent on the instrument. To obtain under such conditions the same speed with four cables as would be obtained with one alone, it would be necessary to employ four of these induction coils ranged side by side, and worked with four times the battery surface, so as to generate four times the dynamic quantity of electricity. When qualified with these conditions, under which no doubt the experiments were tried, the reasoning contained in the Atlantic Telegraph Company's pamphlet, given in an earlier portion of this paper, is correct. It is precisely a case of having four Leyden arrangements to charge instead of one. A telegraph cable is in fact a Leyden arrangement, which has to be charged to a certain degree of saturation before signals are obtained. The degree to which it has to be charged statically depends upon the extent of inductive surface compared to the conductibility of the metallic core. In a circuit where the conductibility of the metallic core is very great, compared with the inductive surface of the insulating material, no high degree of statical charge can take place, and signals will pass quickly. The opposite effect will be noticed in a circuit where the inductive surface is very large compared with the conductibility of the metallic core. The wire will then have to be statically charged very highly before a perceptible current will flow from the further extremity, and signals will be obtained proportionately more slowly."*

The reason why signals are found to pass when magneto-electric induced currents are employed in place of voltaic ones arises, I believe, not from any specific difference between them, but simply from the tension of the induced currents being very much greater than any voltaic ones which have been employed.

On this head I will say nothing further here, but would refer those who may take an interest in it to my paper of a former occasion, where I have fully entered into this subject, and also attempted an explanation of how it has happened that in the experiments with voltaic currents of varying intensities, no difference of speed has as yet been observed.

The amount of retardation which will be experienced in submarine circuits possessing conductors of varying resistance, and insulated with different thicknesses of insulating material, it appears to me can, comparative speaking, be readily determined by actual experiment.

I have for a long time been engaged in designing an apparatus for this purpose, and at the time I arranged to give this paper I fully expected to have had the apparatus completed by this time, and to have been able to have laid it before you on this occasion; and though I regret not being able to do this, yet I feel I have sufficiently advanced to warrant my explaining the principles of its construction.

The principles upon which it is based are: that a body which offers the same resistance as another without reference to its substance or length may, as far as conducting power is concerned, be considered electrically the same. If we make use of a substance or metal of any inferior specific conducting capacity to that of the metal employed in submarine circuits, and also of greatly diminished sectional area, the same resistance as that offered by the very longest circuits can be obtained in a very small compass; and such an arrangement will, as far as simple conducting power is concerned, fairly represent a long submarine circuit.

The induction which manifests itself in submarine circuits can also be obtained if the conditions for its development are as favourable as they are in submarine conductors.

The apparatus consists, 1st, of a series of resistances, the values of which are known; 2nd, of a series of induction plates,

* *Vide* 'The Atlantic Telegraph.'

Digitized by Google

the values of which when compared with a given surface of a gutta-percha coated wire are also known; 3rd, a mechanical arrangement to accurately measure minute periods of time.

By a combination of the resistances and the induction plates, a conductor, which will fairly represent a submarine circuit, will be obtained.

The resistance can be diminished or increased, and the inductive surface can be doubled or halved at pleasure, and thus circuits with conductors of varying lengths and sectional area, and different thicknesses of insulating material be imitated, and the law which governs the retardation in the transmission of telegraphic signals determined by direct experiment.

It may be argued that as the inductive surface in a telegraphic circuit is uniformly spread throughout a series of induction plates will not present the same conditions, but it is evident that they may be divided throughout also, and although they will not then precisely represent what is actually the case, the result will approximate very closely to those obtained from a submarine conductor.

Perhaps it would have been prudent not to have called attention to an apparatus before its completion. I have done so however because I have felt it was due from me to endeavour at least to point out how some of the important problems involved in submarine telegraphic communications between distant stations may be resolved.

The chief deductions from what has been brought forward in this paper are:—1st. That the metallic core of a submarine cable should be composed of a conductor of the highest specific conducting capacity. 2nd. That a decrease in the retardation which is caused by the induction that takes place in submarine circuits can only be obtained by increasing the thickness of the insulating material, but that it will be better to do this by enlarging the sectional area of the conductor as much as is practicable.

In designing a cable there are many considerations besides those of its simple electrical qualifications which have to be entertained. The object to be obtained is the best result with the most economical investment of money. Are the proportions which were adopted in the Atlantic cable the best to ensure this?

The weight of the conducting coil in this cable is about 63 lb. to the mile, the value of which, speaking roughly, would I suppose be about as many shillings. When served with gutta-percha the value was raised to £40 per mile. The iron sheathing and getting the cable on board brought its value up to £100 per mile. The expenditure however did not cease here; there was the hire of ships, salaries of staff, &c. In this cable therefore only four per cent. at the outside was invested in the conductor upon which the transmission of the messages depended.

If the views which I have brought forward are correct, a conductor of double the diameter would only produce half the amount of retarding force of one of half the size. Such a conductor at the very outside would not cost more than £16 per mile, and the increased expenditure in serving such a conductor with gutta-percha, and giving it an iron sheathing, would not, comparatively speaking, be very large; the expenses of the staff and the hire of the ships would be about the same in both cases; the latter would be perhaps increased slightly, but not to any material amount.

There are a great many other points which should be entertained in such a paper as this, but the paper has already run out to such a length that I will not trespass any further on your patience: and in conclusion I would only add, that if the ventilation of the subject, through the medium of this communication, should tend in any way to the progress of electric telegraphy, the object of its author will have been obtained.

Discussion.

Mr. C. V. Walker had attended to listen and learn, rather than obtrude his own views upon the meeting; but being called upon, he would offer a few observations. The difference which Mr. Varley remarked between the Leyden jar and a submarine cable, was that which was generally recognised; it was simply a difference of degree as to the relative states of the inner and outer coating. The cable did practically possess all the distinctive character of the Leyden jar, notwithstanding that the inner and outer coatings were connected, as the experiments made with the Atlantic cable illustrated. The experiments worked out in the early part of the paper to determine the law of induction, would be found very clearly laid down by Sir William Snow Harris, in the little book published by Weale. He had shown that the law of induction was inversely as the distance, and directly as the surface. The next clause of the paper referred to "intensity." This term had led to much confusion; moreover, he thought in the present state of electrical science the conditions regarding conduction were far more completely expressed by the formula of Professor Ohm, than by Mr. Varley's diagrams. Another question in connection with submarine cables was the size of the conducting wires. This was a very important one, and he was quite sure they would think he was possessed of very little modesty if he ventured to give judgment upon a matter which, in his opinion, was so entirely a question of experiment that he only wondered the great cable was laid down before this important point had been satisfactorily investigated, so as to put the matter beyond the possibility of question, whether that conducting strand of seven wires was too large or too small. An opportunity occurred to him to try some experiments with seven or eight distinct miles of insulated wires, of different sizes and different thicknesses of gutta-percha insulation. The wires were in lengths of about one mile each, and the results of those experiments were decidedly in favour of a small wire as the conducting medium. There were many points in connection with small wires worthy of consideration, one of which was cheapness, because although the percentage of saving upon a mile of wire was small, yet the saving would be very great in a cable to extend across the Atlantic. The smaller the wire was the greater the insulating power obtained from the same amount of gutta-percha. The alleged advantage of the smaller wire was, that there was a greater resistance in the circuit; but in the pamphlet published by the Atlantic Telegraph Company, the experiments made by Mr. Reid were described, from which it appeared that he sent a signal through 1000 miles of cable with a battery of two plates only, excited by his tongue, so that the resistance to be overcome by that small battery could not have been great. Another point was the return wire, and upon that he considered the whole question of the Atlantic cable turned. What helped them on the one hand hindered them on the other. The effects of the magnetic disturbances of the earth would be obviated by a return wire. If two lines of cable were laid down, and the current passed to Newfoundland by one wire and returned by the other, this inconvenience would be got rid of, but they would have the other inconveniences which Mr. Varley had laid before them. If the two wires formed portions of the same cable they would cause a greater amount of retardation, because one wire would polarise the other. But if two wires were used in the same cable in a somewhat different fashion, namely, if one was laid as the centre wire, and the other carried spirally round it, and the current divided between the two wires, the polarisation would be very much reduced, if not entirely annihilated. Those two wires, however, would act externally upon the outer coating, which would render the advantage nugatory. In his opinion the next Atlantic cable would not be coated with an iron jacket, as the former one had been; but a coating of hemp and other non-conducting materials would be employed. It might be interesting to the meeting to know the time it actually took to send signals through the Atlantic cable. By Whitehouse's induction coil it took 1¾ seconds, whilst the battery current was 6 seconds in its passage through, at least as far as he recollected.

Professor Tyndall would ask, had any particular experiments been made to ascertain the law of, or the benefit to be derived from, thickening the wire? Had experiments been made to determine the law by which retardation was diminished, when the thickness of the gutta-percha coating was increased?

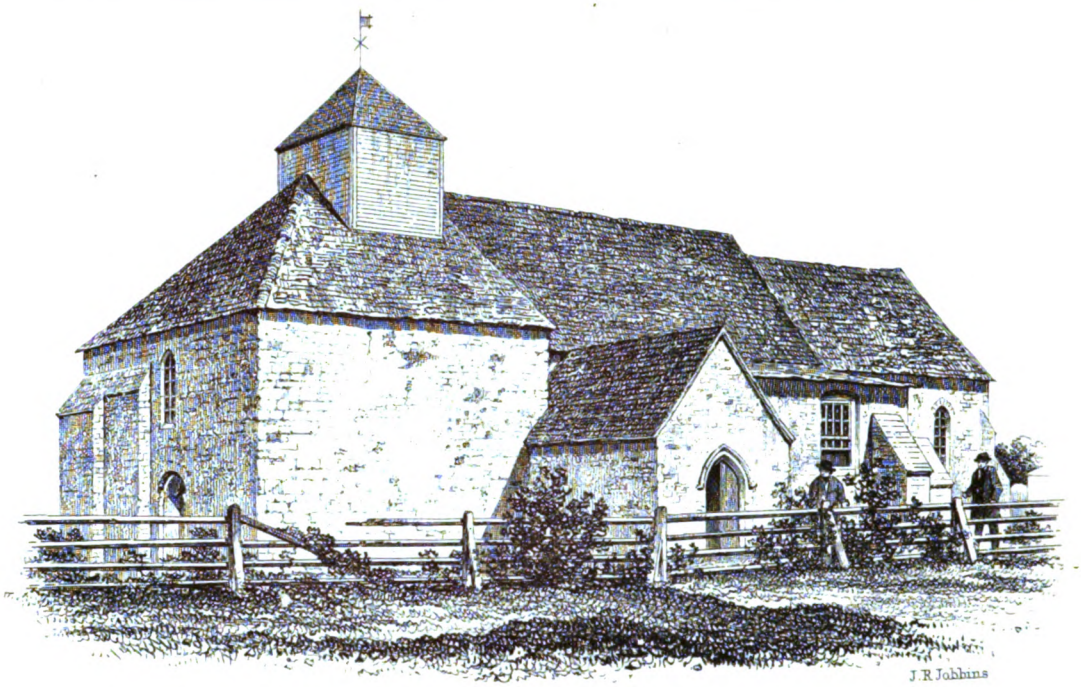
Mr. Cromwell Varley said he could answer some of the questions put by Professor Tyndall. He had consistently recommended to the Electric and International Telegraph Company the use of wires of large diameter, for the last twelve years, as the only means of obviating the difficulties experienced on long circuits in wet weather from leakage, which, with the earlier forms of insulator used, was very great. Since the introduction of submerged wires he had pointed out the advantage that would be gained in such circuits of great length by the use of copper wire of large sectional area. On his recommendation the directors of the above-named company had tried both of these experiments on a large scale. They had erected iron wires of No. 3 wire guage on the London and North-Western Railway, on the Great Western, and the London and North-Western Railways, instead of the usual size (No. 8). The results were such that he had no doubt they would never again, for long circuits (viz., of over 200 miles

Digitized by Google

in length), erect other than thick wires. They had tried thick wire under the sea in their new cable connecting England with Holland. This cable contained four conductors of No. 13 instead of No. 16 wire, and although, for reasons explained further on, the relative speed of this compared with that of the former size was not so great, yet there was a very decided gain in rapidity, together with much stronger and much more uniform and reliable currents. These wires were connected both in England and Holland with a considerable length of overground wire, which latter was much affected by changes of the weather, and the gain in unfavourable weather from using the larger wire was, as predicted, very considerable. He was very much surprised to find Mr. C. V. Walker adhering to, and supporting, views which other well-known electricians had put forward, viz., that increasing the sectional area of the wire did not increase the rapidity of the transmission of electric signals. The experiment, however, had been lately tried in the new Dutch cable, and although the relative speed was not exactly known, because there were many difficulties in the way, yet the fact was established that increasing the sectional area had greatly increased the speed. He had tried to determine the effects of induction, &c. on the speed of the electric wave; not only had the inductive effect to be taken into consideration, but also the absorption of electricity by the surfaces of the dielectric; and these influences were ever changing by heat and by the charging of the wire, to such an extent that approximate results only were obtainable, which, however, were sufficiently near for all practical purposes. The absorption of electricity by the surface of the dielectric required time, and therefore cables of such length and dimensions as would only work slowly suffered more from this absorption than shorter and quicker ones. The retardation of the wave in a cable was caused by the lateral induction absorbing part of the electricity intended to give the signal through the line, and until this charge approached the maximum the current at the distant end would be weak. If two cables were made, the one with an iron and the other with a copper conducting wire inside the gutta-percha, all other things remaining the same, the former would have as much induction as the latter, because this had reference only to the surfaces of the dielectric. As the iron wire would only conduct at one quarter the speed of the copper, it would require, with a given electromotive force, four times as long to transmit a given current. The electricity would require, in the case of the iron wire cable, four times as long to charge the gutta-percha by lateral induction as the copper wire would, consequently such a cable would have only one quarter the speed of the other. Were it possible to compress twice as much copper into the same diameter, and so double the conducting power without increasing the inductive surfaces, the speed would be immediately doubled. This was not possible, and the effect could only be obtained by increasing the sectional area of the wire: increasing this four times, doubled the interior surface of the gutta-percha, which was the chief inductive surface, and, leaving out of consideration for a moment the exterior surface, the conducting power would be quadrupled while the induction was only doubled; hence there would be a gain in speed of from 1 to 2. But there was more still than this gained; first, suppose the diameter of the small wire to be unity, and the thickness of the gutta-percha covering also unity, the exterior surface of the gutta-percha would be 3, and the combined surfaces of the gutta-percha would be $3 + 1 = 4$. In the second case, where the copper wire was doubled in diameter, and quadrupled in weight, there would be two for the inner surface of the gutta-percha, and four only for the outer surface, instead of six,—collectively, six instead of eight. Hence, doubling the diameter more than doubled the speed. The third gain from the large wire was, that, having a higher speed, there was less time for the absorption of electricity, and, consequently, the disturbance and retardation from this cause were less. Having a current of four times the power entering the cable, and the leakage being less in proportion to it, the current received at the distant end would be more than four times as powerful, and much more regular; the apparatus would be less frequently interrupted for adjustment, and would, consequently, work without intermission for a much longer period than the smaller wire. Mr. Walker had alluded to the Atlantic cable, and stated, in proof of the sufficiency of the diameter of the copper wire, the fact that a single element of water battery gave a current perceptible at the other end. He (Mr. Varley) contended that this proved nothing as to its ability to transmit intelligible signals. In an Atlantic cable we must have not only a wire capable of giving currents and signals, but of giving such currents and signals as should overcome the friction and inertia of the apparatus used for indicating them; these currents must be so powerful and constant, that, when the philosopher had left the cable to the ordinary manipulator, the currents should not fluctuate so much as to interrupt the intelligibility of the communications. The current must have such force, that the varying friction of the apparatus should not materially influence the recording of signals. In the Atlantic experiment these difficulties were overcome to a great extent by a most ingenious little instrument,—Professor Thompson's reflecting galvanometer. In this instrument the only friction was that of a single thread from a silk cocoon, supporting a very short magnetic needle only $\frac{1}{4}$ of an inch in length, which carried a small mirror made so light as to weigh only a grain or two. The mirror reflected back through a lens a ray of light, and thus, without impeding its free action or adding to its friction, a long but imponderable arm was added to the needle to magnify its motion. This little needle was rendered more or less nearly astatic, by placing a large magnet under it to neutralise the earth's magnetism; and thus a nearly astatic instrument, sufficiently rapid in action from its small dimensions, sufficiently sensitive by its long imponderable arm (or ray of light), sufficiently free from friction by being suspended from a filament of silk, was obtained, and by it the faint signals through the cable were rendered visible. These signals were watched by a clerk, and recorded by hand on a Bain's printing machine. He (Mr. Cromwell Varley) felt that sufficient credit had not been given to Professor Thompson for this instrument, without which the Atlantic cable would never have transmitted a single message, and the world would not have had this great experiment to guide them, as there would have been no means of ascertaining whether the cable had reached the bottom of the Atlantic without parting. Such an instrument, however, was not calculated to meet the requirements of a commercial undertaking, because the reflected spot of light was difficult to follow with the eye for any length of time, and was often recorded by the manipulator incorrectly. The current must have sufficient force to record itself. With regard to the insulating properties of gutta-percha: when pure and free from moisture he had found it to rank amongst the best dielectrics, but this was not the condition of the gutta-percha used on cables, which appeared to be porous and to contain moisture. When the gutta-percha was sufficiently heated to free it from this, there was great danger of altering its character, and rendering it liable to become brittle and to crack. In the Atlantic cable, even before it had been put under water, the loss of current by leakage was so considerable that less than one-third of the original current only reached the distant end. Were the loss constant in quantity it would not so much matter, but wherever the current escaped through moisture, there was polarisation and ever-varying resistance at the leaky spot. As an example, he would quote one of many similar cases that had come under his notice. In one of the London and Liverpool wires, there was a defect in the Kilsby tunnel, caused by a filament of wood in the gutta-percha, which was wet at this spot. This leak gradually got worse and worse, and sometimes offered a resistance equal to ten miles of the line composing the circuit, and at other times, especially after the continuous passage of a positive current for some length of time, it offered a resistance equal to more than a thousand miles of the circuit. The fault was situated nearly half way, roughly speaking, 100 miles from the end, and when it offered a resistance of only 10 miles, $\frac{1}{11}$ only of the current from London reached Liverpool, assuming the rest of the line perfectly insulated. When the fault from polarisation, &c. offered 1000 miles resistance, the current which reached Liverpool was $\frac{1}{101}$ of that which left London; these fluctuations sometimes took place in a second of time. The formula for such a case was $e = \frac{El}{1+y}$, where e was the current received at the distant end, E the current leaving the original station (London), l the resistance of the leak, and y the resistance of the line between the leak and the receiving station. Now in the former case the current was amply powerful enough to work the instruments, and no inconvenience would have been experienced had the fault remained constant; but on the contrary, it was always varying in force, and to such an extent that it was impossible to work the line, though only 200 miles in length. Thus it would be seen that, leaving out of the question induction, and its consequent diminution of speed, a conductor of sufficient size must be had to cause these leaks to bear only a small proportion to the current transmitted, in order that the

Digitized by Google

received signals might be sufficiently regular and equal in force to record themselves with certainty and ease. Unless these conditions were attended to, the cable as a commercial undertaking would inevitably fail. With regard to the rapidity of conduction of the electric current, his opinion was that the current began to flow from the distant end *immediately* after the near end was connected to the battery. Electricity showed no signs of compressibility or elasticity, and was without inertia. Suppose for a moment that a cable was divided into several portions, each of which was without appreciable resistance, but separated from the next portion by a given resistance,—the first portion, on coming in contact with the battery would be instantly charged, and as instantly would begin charging the next portion, but to a lower degree than itself; this second portion as instantly charged the third portion, to of course a still lower degree; and this the next, and so on to the end. By careful reasoning on the known laws of electricity, he had come to the conclusion that the current began to flow out of the distant end instantly, but so feebly at first that the most delicate instruments failed to show it. Before concluding he would draw attention to the unhappily chosen terms "quantity" and "intensity." What in England was generally understood by quantity, was in Germany termed intensity, or I. What in England was termed intensity, or tension, was the electro-motive force; in other words the $I = \frac{E}{R}$, where I represents the power of the current to decompose a given quantity of an electrolyte, E the electro-motive force of the current, and R the resistance of the circuit. These terms had unfortunately led many into error, more especially the word intensity.



Mr. C. W. Siemens agreed with much that had been said in the paper. He was decidedly in favour of a large conductor of the very best specific conducting power; and had maintained from the first that the conductor of the Atlantic cable was totally inadequate. When he read a paper last year before this society, he had expressed the laws by which the proportion of an electric cable should be regulated for a given length by a simple formula; and he thought that a mathematical expression properly explained was preferable to an explanation in words only, even for a popular assembly like the present, because it combined all the elements to be taken into consideration. He did not agree with Mr. Varley that an electric wave, on entering a submerged conductor at one end, presented itself in however slight a degree instantaneously at the other. The laws of induction and conduction, as he understood them, were directly opposed to such an assumption; and in his own experience he had certainly never observed any indication of it. The line expressing the relative amount of charge at different points of the electric wave in the conductor was expressed not by a dynamical curve, as Mr. Varley had shown it, but by a straight line, terminating abruptly upon the horizontal line which represented the conductor. Another portion of the paper dealt with the complete metallic circuit in submarine conductors, which it was generally understood had been first proposed by his (Mr. Siemens') brother. Mr. Siemens could not agree with the views expressed by Mr. Varley, and by several others who had lately written in the scientific journals upon this subject. Some of them seemed to lose sight entirely of the most essential condition, namely, that the two conductors were to be imbedded in the same insulating medium. His brother had never for a moment assumed, as seemed to be supposed, that lateral induction between the two conductors constituting the circuit would be obviated. On the contrary, it would be rather increased, on account of the greater resistance of the metallic circuit. But it was maintained that the charge between the conductors and the larger surface of the sheathing would be nearly entirely obviated; that the working of one metallic circuit in a multiple cable (which his brother had chiefly in view) would not disturb the electrical equilibrium of the other conductors; that the losses by leakage would be reduced, enabling him also to reduce the area of the conductor, and thereby also the lateral induction between them; that the metallic circuit was not affected by magnetic storms; and finally that considerable advantage could be obtained by the mutual acceleration of the positive and negative currents by Volta induction. So long as a single conductor could satisfy the public demand for messages, the advantages of a metallic return wire would probably not warrant the additional expense, but wherever several conductors became necessary the advantage of working through metallic circuits would be very great. Mr. Varley's illustration of surrounding the one conductor by the other in the form of a tube did not meet the case, because the tubular conductor possessed the very condition which it was intended to avoid, namely, an extended inductive surface both against the inner conductor and the outer sheathing. Mr. Siemens had only one other point to remark upon, and that was of an historical nature. Mr. Varley had stated that Mr. W. Siemens had first employed gutta-percha coated wire in Prussia in 1850, where he had observed the phenomena of induction also. It was however in 1847 when the first gutta-percha coated line wire was laid down successfully near Berlin; and he (Mr. Siemens) exhibited specimens of it, and explained the phenomena of charge which had been observed, before this society in 1848. He might also observe that the statements which had been circulated, that the gutta-percha coated wire as first prepared in Prussia had proved an entire failure, were very unfair towards his brother. These wires had been coated in the same manner as they were at the present day, although it must be admitted that the quality of the gutta-percha employed was very inferior. These lines had however done good service for four or five years, when they began to fail; some of them had however lasted much longer, and some—covered with lead—were actually in use to the present day. He did not think that a much more favourable result had since been obtained elsewhere.

Mr. Leonard Wray said he would make but a few brief remarks upon some of the points under discussion. The best diameter for the conductors of electric telegraph cables was so very much discussed, and so very much disputed, that he would only present to the notice of the society one very singular and significant fact bearing upon the question. When telegraph wires were first introduced into India, Sir W. O'Shaughnessy and his staff were sadly annoyed by the continual breaking of their wires, caused by the very large birds alighting upon them. To remedy this nuisance, that gentleman employed very thick, strong wires, which the birds could not injure; and this great increase in the size of the wires brought out the remarkable fact that no insulation whatever was necessary at the posts, around which they were simply wound. This deserved, he thought, to be recorded in such a discussion as the present. Another subject to which he would refer was that of insulation. Now the substance almost universally employed as an insulating material was gutta-percha; but they were told, and many of them knew it as a fact, that gutta-percha absorbed no inconsiderable quantity of electricity,—indeed, that it became to a certain extent saturated with it. Such being the case, it must be evident that gutta-percha was by no means a perfect insulator; for he held it as an axiom, that no really good and perfect insulator would absorb electricity. The greater the quantity of electricity absorbed by the insulating material used, the greater would be the retardation of the current. Hitherto then a substance had been employed which was very far from perfect, and all calculations had been based upon its known insulating properties; but if they had a superior—a very much more perfect insulating material,—would it not be possible to construct cables with a far less quantity of that material than gutta-percha? He thought so, and he moreover believed that such an insulating material as he had spoken of would probably be soon discovered.

Mr. S. A. Varley said he had but little to reply to, as no attempt had been made to refute the views he had brought forward. He was unable to follow Mr. C. V. Walker throughout, and he did not clearly see the direction in which his views tended. Mr. Walker appeared to object to the statement made, that there was a difference between an ordinary Leyden jar and a submarine circuit; yet he admitted that the conductor united the inner and outer coatings of a submarine wire when regarded as a Leyden arrangement, and that the resistance it opposed was the only thing which prevented the free flow from one to the other. Now he (Mr. Varley) thought this was a most important admission, for upon it depended the reason why a large wire conducted more rapidly than a smaller one, and this was no longer a theory, but an ascertained fact. If there were no difference between a submarine wire and an ordinary Leyden jar, and if a submarine circuit had to be charged statically to saturation before signals passed, as was stated to be the case by the advocates of the small wire system, then it would be clear that as the greater the sectional area, the larger the Leyden arrangement would be, there would be more retardations with larger conductors, as more electricity would be required to charge them. He maintained that,

JOSEPH MESSENGER, ARCHT.

Digitized by Google

in practice, a submarine circuit was not charged to saturation; the degree to which it was charged statically depended upon the relative balance between the conditions which favoured induction and conduction; if the conditions, as had been stated in the paper, favoured conduction, there would be less statical charge, and a greater proportion of the electrical impulse would be directed forward, and signals would be obtained more quickly. Mr. Siemens, when considering the question of the complete metallic circuit *versus* the earth for one-half of it, objected to the fairness of the diagram in which one of the conductors was made into a tube. This diagram was introduced, as was stated in the paper, as an exaggeration, simply to shew the fallacy of the principle; and although, as was stated by Mr. Siemens, the wires would not when side by side present as much surface to induction as an ordinary circuit, yet it must be borne in mind that there would be just twice the resistance of that which would be opposed when the earth was employed for one-half of the circuit, and this would more than counterbalance the lessened surface exposed to induction. He agreed generally with the remarks made by Mr. Wray. There was no doubt that with large conductors imperfect insulation was less felt, but the result in Sir W. O'Shaughnessy's case was probably not altogether due to the size of the conductor, for it must be remembered that the climate was very hot and dry. As a practical fact, he (Mr. Varley) would state that when in the Crimea they never obtained what telegraphists termed a "perfect earth." In the submarine circuit between Varna and Constantinople, contact with the earth was made by connecting a wire to the iron sheathing of a piece of the cable, more than a quarter of a mile in length, which was buried in the earth, and passed through the British Embassy grounds, yet, notwithstanding this extensive surface, in hot weather he found the earth, to use a telegraphic expression, very far from "perfect," and he remedied this by carrying a wire out into the Bosphorus.

HOUGHAM CHURCH, KENT.

(*With an Engraving.*)

This church, dedicated to St. Lawrence, appears to have been built at different periods during the eleventh and twelfth centuries. The walls, chiefly of flint, vary from three to five feet in thickness. The south wall of the nave is undoubtedly the most ancient portion of the edifice, and contains a plain semicircular arch, without ornament or moulding. The arch of the tower is Anglo-Saxon, and of a later date, while the west doorway is Norman; the chancel arch unfortunately no longer exists. The windows are Early English lancets, splaying widely inwards with a hood round the arch; the chancel and north aisle have handsome triple lights at the east end, but in the former they have been closed up. From the appearance of the ground outside it would seem that the north aisle was once prolonged to an equal extent with the chancel, instead of terminating as at present with the nave; this, however, is mere conjecture. The doorway belonging to a rood-screen, and one corbel, are visible in the interior, but simplicity of design and the absence of elaborate ornament constitute the principal features of the building. In these particulars and in the pattern of the king-posts, as well as its general aspect, the interior of this church much resembles that of St. Peter ad Vincula in the Tower of London. The church contains two curious monuments: one to Sir William Hanington, governor of Dover Castle in the reign of Henry VIII.; the other to the family of Nepueu.

The tower, which contains three fine-toned bells, one of them bearing the date of 1634, has been twice lowered, at what date is not exactly known, nor what was the form of its summit. It is about to be rebuilt with a broach, as represented in our engraving, through the munificence of Steriker Finnis, Esq., from designs by Mr. Messenger, of Folkestone. The west and south walls are to be faced afresh in black flint, dressed with quoins of Kentish rag; for the windows and doorways Caen stone will be employed. The interior below the ceiling of the belfry will be thrown open to the nave, and furnished with seats for the children of the parochial school. At the same time the nave is to be restored by subscription, new lights being inserted in the windows, and the stonework, which is much dilapidated, cleaned and repaired throughout. In addition, a brick drain 3 feet in depth will be carried round the building, to preserve it from the damp caused by the accumulation of earth. The total restoration will cost about £500, and is to be commenced immediately.

ON THE RECENT IMPROVEMENTS IN PARIS.*

By Edward l'Anson.

Although Paris is well known to most of us, it has occurred to me that a general account of the great works which have recently been carried out in that city may still be interesting. Much has been done since the cessation of Napoleon Buonaparte's wars to improve the principal towns throughout Europe, In London, for instance, immense and thickly populated districts have sprung up; but Paris has changed in another manner, and on all sides of it buildings of importance for their magnitude, and of the highest interest as works of art, have been erected. Thirty years ago the magnificent Place Louis XV. was a vast plain of mud in winter and of shifting sand in summer; and the ground now occupied by the new works of the Tuileries and of the Louvre was encumbered with irregular streets of closely packed houses, booths, and mean shops. The colossal works begun by Napoleon I.—the Arc de l'Etoile and the church of the Madeleine—were still surrounded by scaffolding; and the massive Fountain of the Elephant on the Place de la Bastille, a project since abandoned, was only a model in plaster. Some great works however had been done; the Pantheon, some of the bridges, the column on the Place Vendôme, and the Rue de Rivoli, had been commenced. With these exceptions Paris could not then have materially changed in aspect since the time of Louis XIV. Scaffolding still masked these works in 1830, when Louis Philippe became king, by whom after a time the completion of the public monuments was taken in hand, and measures I believe were contemplated for extensive municipal improvements. Despite some incongruities he had a very grand town to deal with, containing features which marked it as a monumental city as well as a great metropolis. Among the works undertaken by him was the completion of the Arc de l'Etoile, which had been commenced in 1806, after the battle of Austerlitz. The work was confided to M. Blouet, and vigorously carried on till its completion in 1836, at the cost of £417,812. The central archway is 90 French feet high by 45 feet wide; the total height of the monument is 152 (162 English) feet, and the breadth and depth are respectively 137 (148) feet by 68 (72) feet. The whole is impressive chiefly on account of its colossal proportions, and the mass and solidity of its parts. In addition to some noble colossal sculpture, it is covered with the names of the warriors who accompanied Napoleon Buonaparte in his various campaigns, and of the battles in which they were triumphant. On reading them the beholder is impressed with the conviction that the names graven on a monument so grand and durable will defy both the destructive power of man and the slow decay of ages, and pass down in honour to the remotest time.

The church of the Madeleine was finished under Louis Philippe by the architects Vignon and Huvé. This building is also of great dimensions, being 328 English feet in length by 128 feet in breadth. The cost amounted to £523,160. The podium supporting the columns, which are nearly 50 feet high, rises 12 feet 9 inches above the pavement. The general plan is that of a peripteral temple, with an octastyle portico. The effect of the exterior is imposing, but it is far from being a refined work of art,—the mouldings and the proportions of the various parts being generally coarse and commonplace. The frieze is decorated with sculpture; but the usual right line at the angle being broken by the continuation of the enrichment, a singularly weak and disconnected appearance is given to the profile of the entablature when seen anglewise. The figures placed in the niches between the columns round the cella are but indifferent works, but the detail of the doors and architrave of the principal entrance is of exquisite beauty. The flowing ornament on the architrave is of thoroughly French renaissance character, executed with delicacy and breadth hardly attained by the cinque-cento artists; and it is moreover a remarkably fine specimen of casting. The doors and architrave, which are I believe of bronze, were designed by Triquetti, and cast by Richard Eck and Durand. The doors are only inferior in size to those of St. Peter's at Rome. The interior is to my mind more satisfactory than the exterior, though it is not in congruity with it, as it consists of three square compartments, each covered by a dome with openings for light. This plan is not that to which we are accustomed in a Christian church,—it is neither basilican nor cathedral; nor does it, as I have said, correspond with the external features of the building.

* Paper read at the Royal Institute of British Architects.

Digitized by Google

The effect however is rich and grand, and some of the minutiæ are beautiful,—as the metal railings to the chapels, the baptismal font, and the organ case.

One of the first works of the reign of Louis Philippe was the great column of the Place de Juillet, built as its name implies in commemoration of the three days of July 1830. It consists of a column of bronze, raised on a plinth of masonry, a bronze figure crowns the whole, and brings the total height to 160 feet English. The total weight of bronze used amounted to very nearly 407,000 lb.

The Ecole des Beaux Arts, begun in 1832 by Debret, was carried on by Duban. It contains one of the best modern frescoes, or rather wall paintings, by Paul De la Roche, for which he received £3200. The building cost £140,600. The Conservatoire des Arts et Métiers, for which in 1846 a sum of £57,648 was voted, was commenced under the direction of Lèon Vaudoyer, architect. The church of Notre Dame de Lorette, begun in 1823 by Lebas, was completed; but the beautiful fresco decorations of the interior have been added more recently. The total cost of this building is said to have been about 1,800,000 francs.* One year later the still larger church of St. Vincent de Paul was begun from designs by MM. Lepère and Hittorf: it is remarkable for the introduction of polychromatic and profuse mural decoration, of stained glass windows, &c., at a cost of 256,300 francs. The enlargement of the Palais du Luxembourg was carried out at a cost of £120,000. The character of the exterior of the old part by De Brosse was studiously preserved by the architect, M. Gisors. In 1836 the municipality commenced the embellishment of the Place de la Concorde, and of the Champs Elysées. In 1836 the Luxor obelisk was also erected in the Place de la Concorde, having been transported from Egypt and fixed at a total expense stated to be about two millions of francs. In 1844 the Fontaine Molière was erected from designs by Visconti; and subsequently an elegant fountain was erected on the Place Louvois. In 1845, very important works, although not absolutely in Paris, namely, considerable additions to the lunatic asylum at Charenton, were completed by M. Gilbert, architect, at a cost of £132,800. About this time M. Hittorf erected in the Champs Elysees a circus peculiarly well suited to its purpose. I may also mention the elegant façade of a small theatre on the Boulevard du Temple, now the Théâtre Historique, but then the Théâtre Montpensier.

Another work begun by Louis Philippe is the church of Sainte Clotilde, erected in memory of his youngest daughter. He also built on the spot where his eldest son the Duke of Orleans met his melancholy death, a small chapel dedicated to St. Ferdinand. The architects employed were Messrs. Lefranc and Fontaine, who erected a work very inferior to anything, I think, our revived mediæval tastes would have erected even at that time. It is however principally remarkable for the scenic effect of the interior, produced by the skilful grouping of sculpture and painting, and the management of the light: amongst the sculpture is a representation of a kneeling angel, the work of his deceased sister Marie, who little thought when she wrought it on whose tomb it would be placed.

The fortifications of Paris, begun in 1841, are said to have cost £5,650,000. Ten distinct forts are included in the circuit of the walls. In 1848 the mairie of the third arrondissement was begun, and in 1851 the mairie of the eleventh arrondissement was built. In 1850 the fine building of the Bibliothèque Sainte Geneviève was completed, after being in progress about six years. M. Labrouste was the architect; the cost exclusive of architect's charges was 1,569,000 francs. About the same time the very fine and original building, the Timbre Imperial, was completed, at a cost of 1,298,000 francs.

Louis Napoleon, soon after his election as Emperor in 1852, turned his attention to the public works, and since that date the progress of building in Paris has been beyond all precedent, even of the times of Imperial Rome.

I will now proceed to notice briefly the buildings commenced or built during the last six years. Among the early works of Louis Napoleon was the tomb of the Emperor Napoleon I., designed by Visconti, and erected under the dome of the Invalides. It is much enriched with appropriate sculpture, and cost £360,000.

In the early part of 1852, so great was the impulse given to public works, that the following were in progress:—the completion of the tomb of Napoleon Buonaparte; the Hospital du Nord, Clos St. Lazare; the Nouveau Ministère des Affaires Etrangères, begun in 1845, completed a year or two later, at a total cost of £200,000; the works at the Tuileries; the interior decoration of the Hôtel de Ville, and of the church of St. Eustache; the restoration of Notre Dame; the enlargement of the Polytechnic School; the continuation of the Rue de Rivoli to the Rue St. Antoine; the restoration of the Pont Neuf; the completion of the Quai Conti and part of the Quai Malaquais; the station of the Chemin-de-fer de l'Ouest; the new entrance to the Luxembourg gardens; the embellishment of the Champs Elysées; the enlargement of the railway station, Place de l'Europe; the enlargement and decoration of the Palais de Justice; the construction of a mairie for the fourth arrondissement; infantry barracks, Rue Notre Dame des Victoires; the works of the Halle Centrale; the enlargement of the Rue Montmartre, Mathurins, Saint Jacques, Sainte Avoye, De la Harpe, and others; the formation of the Rue des Ecoles; the transferring of the Garde Meuble to the Ile des Cygnes; the completion and decoration of the church of Ste. Clotilde; the Place Belle Chasse; the continuation of the works at the Louvre, and at the Chemin-de-fer de Ceinture; several kilometres of sewers; with the improvement of various hospitals and prisons. In the same year, 1852, the library of the Conservatoire des Arts et Metiers was opened; and it was decided to erect a Crystal Palace in the Champs Elysées, a work accomplished in the year 1855*; the Boulevard de Strasbourg, leading from the railway station to the general line of boulevards, was opened, the length being nearly 1093 yards and the breadth 105 feet; the restoration of the Louvre and its reunion with the Tuileries were begun; the mairie of the third arrondissement, begun in 1848, was finished; and the Jews' hospital was opened.

In 1853, the decoration of the chief apartments in the Hôtel de Ville was completed,; the Jews' hospital, by A. Thierry, was completed at a cost of 400,000 francs; the Palais Royal was entirely restored for occupation by Prince Jerome and Prince Napoleon Buonaparte; the works at Notre Dame were recommenced; extensive works and additions at the Bank of France were commenced; the east works at the Docks Napoleon† were partially finished; the Hospital Lariboisière, begun under Louis Philippe, containing 612 beds, M. Panthier architect, (cost eight million francs) was opened; the iron pipes to convey the water from the reservoir at Chaillot were being laid in the Bois de Boulogne, the lake of nearly ten acres area was almost finished; an iron inclosure was erected at the Hôtel des Invalides, with two new lodges, and the façade of the church was repaired.

In 1854, the works at the Caserne des Petits Pères were recommenced; extensive restoration and repairs of the exterior and interior were begun at the Palais de Justice, the houses which surrounded the building on the west and on the south having been removed; the bridge of Austerlitz, built of iron in 1830, being much out of repair, was rebuilt of masonry in the space of three months, at a cost of £38,000; and the beautiful building, the Cirque Napoleon, was erected by M. Hittorf, in the short space of nine months, at a cost of £27,000.

In 1855 a new municipal building, covering a superfices of 1500 metres was commenced, at an estimated cost of 627,043 francs, by M. Baltard, architect. The works and additions at the Bank of France were terminated; the additions by M. Gabriel Cretin, architect, costing £80,000, and covering a space of 9750 feet; and the restoration of the tower of St. Jacques was completed at a cost of £40,000, in addition to £10,000 for purchasing it. In 1856, the removal of the sheds and buildings surrounding the Palais des Thermes was in progress; the municipality voted the funds for reconstructing the prefecture of police, under Messrs. Gilbert and Diet; the Gothic church of Sainte Eugenie, M. Boileau, architect, was completed; the pavilions of the new Louvre were covered with scaffolding, newly erected, in order to execute further decorations; the covered ways of the Halle Centrale were finished; the vast space comprised between the Place du Louvre, St. Germain l'Auxerrois, the Quai de l'Ecole, the Rue de l'Arbre Sec, and des fossés St. Germain, was cleared away and laid out; the buildings for the Manutention Militaire were finished; the new wing of the Ecole Militaire was in progress; the Pont de Jena was decorated with four equestrian statues; the decoration of the Pont des Invalides was completed; and the buildings about the church of Saint Eustache had been entirely

* The French metre = 3·28 English feet. The Paris foot = 1·066 English foot. 1,000,000 francs = £40,000.

* The surface utilised, including all annexed buildings, was computed to amount to 124,804 metres. The area of the building in Hyde-park was about 72,000 metres.

† The works are still in progress; during the last twelve years a sum has been expended on them of 22,000,000 francs.

Digitized by Google

removed. In 1857, the church of Sainte Clotilde, M. Gau architect, begun in 1846, was completed; the garden round the Ruine des Thermes and Hôtel de Cluny was inclosed by an iron railing; and the additional works at the Hôtel de la Monnaie, built in 1768, were finished. The following works were in progress:—the Boulevard de Sevastopol, which then extended from the Strasbourg station to the Rue d'Ecole de la Madeleine; the Boulevard du Prince Eugene, between the Barrière Poissonière and the Boulevard du Temple; and the demolitions on the left bank of the Seine for the boulevard from that of Sevastopol to the Jardin des Plantes; the vast Caserne du Chateau d'Eau on the Boulevard St. Martin; the picturesque promenade or square of the Quartier du Temple; and the works of the new Louvre were completed. The Fontaine du Palmier was removed bodily, and placed centrally upon the Boulevard de Sevastopol. Very extensive restorations and some new works were in progress at the Bibliothèque Impériale, giving it quite a new character, and reviving a style of architecture with red brick facings and stone dressings, which seems at present rather in vogue in Paris, and which M. Labrouste, the architect to these restorations, has successfully applied in an hotel built for M. Achille Fould. The demolition of the old and construction of the new bridge of St. Michel; and also a temporary bridge undertaken, like the removal of the Fontaine du Palmier, as part of the works of the Boulevard de Sevastopol. In 1857, the church of Sainte Eugene, M. Boileau, architect, was completed. It is built of stone and iron, and exemplifies the great difficulty of satisfactorily combining these materials. The mullions and trefoils of the windows are meagre, and yet not sharp; the effect of the internal columns is poor and without elegance, and the interior generally recalls to mind the interior of a railway station rather than of an ecclesiastical building. The internal light is however well managed, as is also the iron construction of the roof. In the same year the south façade of Notre Dame was entirely restored, the apse had been repaired, and the restoration of the north façade was in progress; the restoration of the roof and the upper part of the Sainte Chapelle externally were finished, and the works were proceeding in the interior; the churches at Villette and Vaugirard had been built, and that at Belleville was in progress; the hospice founded by the Empress, for the reception of poor girls, near the Barrière du Trône, was finished, M. Hittorf architect; the two Hôtels des Invalides Civils, one in the Bois de Vincennes for convalescents, the other in the forest of Vesinet for mutilated workmen, were finished; the Chambre des Notaires was removed to make room for the Boulevard de Sevastopol, and rebuilt on the Place du Châtelet; the Pont des Invalides, of four arches, situated on the site of the suspension bridge, built in 1829, was finished, at a cost of £32,000; and the Pont de l'Alma, of two flat arches, commenced in 1836, was completed.

In 1858, the Boulevard de Sevastopol was opened; the remodelling of the gardens of the Tuileries, a work I believe still in progress, was commenced; the bridge of the Legion of Honour was commenced; the column on the Place de Breteuil was inaugurated, and the Pont du Change demolished; the great barracks at the Chateau d'Eau opened; and the Hospice des Ménages, Rue de Sèvres (proposed to be rebuilt at Issy), removed. Amongst public works now contemplated I find the removal of the great hospitals; the formation of an acqueduct from near Epernay to Paris, at a cost of upwards of £428,000; the formation of a new system of sewerage, at an estimated expense of £140,000; a central tower to the church of Notre Dame; and the removal of the institution of Sainte Perine at Chaillot. The remarkable building called the Halle Centrale deserves a special notice: it comprises ten different compartments in two sections, separated by a boulevard 30 metres wide; the first section occupying 20,000 and the second 10,000 superficial metres. Cellars extend under the whole, which it was intended should be connected with the railways entering Paris, by means of underground railways on the line of boulevards de Strasbourg and du Centre; but this project has been abandoned. Iron, cast and wrought, glass, and brick, are the materials used. The arcades of the front measure six metres in width; the lower part is inclosed with brickwork; above is open glass work, and the upper part has fixed glass work. The employment of cast-iron is here quite legitimate and pleasing in effect. The columns are light and elegant, interfering neither with space, light, nor air, more than is consistent with solidity, in which respect the whole composition is wanting neither in reality nor in appearance. In November 1857, the works of the first part were on the point of being completed, the large tables of white marble being placed in the fish market. The expense of obtaining the land and houses for the Halle Centrale was estimated at 9,141,020 francs, and it required the demolition of 106 properties, occupying a space of 13,262 metres. The construction, with the compensation and the enlargement of the adjoining streets, cost £1,572,000; of which the houses pulled down cost £1,080,000. I must also refer to those essentially modern works, the railway stations, one of which —the Strasburg station—appears to be a model for such buildings. The others are the Rouen railway station, covering a space of 43,000 metres; the Chemin du Nord, covering 44,000 metres; the Lyons, covering 60,000 metres; the Orléans, covering 46,000 metres; the Sceaux and Orsay, covering 9000 metres; and the Chemin de l'Ouest station, covering 24,000 metres. The last named has an iron roof 120 metres long and 30 metres span, the total weight of which is 31,795,588 lbs. The Strasburg railway station in the Faubourg Poissonnière, the work of M. Lermet, engineer, and of M. Duquesney, architect, was commenced in 1847, and finished in 1852, at the cost of the state. It covers 53,000 metres.

	Francs.
The cost for the ground	6,000,000
Earthwork and works of art	1,900,000
The station	2,900,000
Total ...	10,800,000

The length of the façade is 165 feet. The convenient arrangement of the place in front (which is also found in most stations in Paris) deserves especial mention. A spacious court yard, surrounded with iron railings, affords ample room for carriages both coming and going. The building, as a work of art, is of the highest order, and its purpose and use are at once apparent. The roof of the station is very ingeniously and beautifully constructed; it is not perhaps so grand and simple as that of the Great Northern Railway in London, nor so fanciful as that of the Great Western, but it is certainly not inferior in merit to either.

I may also mention, as one of the most characteristic features of Paris, the number of trees which line the great thoroughfares of the boulevards and surround some of the public buildings. Their green colour forms a great relief to the general hue of the masonry; it diversifies the prospect by pleasing masses of light and shade contrasting with the severer lines of the architecture, and gives freshness, coolness, and pleasing variety. In the particular of trees much has been lately done, and instead of waiting for that slow growth by which they would increase, noble trees of twenty years at the very least are planted; thus, round the Bourse I last year noticed that all the old ones which had flourished but ill in the locality, had been replaced by stately trees of ample size, and that in order to preserve them until their roots should get firm hold in the soil, they were swaddled round with woollen bandages, metal hopper-shaped receivers being placed at the upper part of the stem to receive and distribute the water applied to the trunk, kept in a constant state of moisture by means of the woollen wrapper. The new Boulevard de Sevastopol is planted thus with fine full-grown trees, and especial care has been taken with those round the Fontaine du Palmier. The subject of trees leads me also to notice the Bois de Boulogne, and the great works which have there been carried out. This park, which was formerly in a thoroughly neglected condition, was about 1853 handed over to the town on condition that improvements should be made. The first operation was to conduct the necessary water supply to form the decorative lakes. The pump at Chaillot furnishes the supply from the Seine by means of a tube 40c. (16 in.) diameter and 3740 yards long, there are also branch pipes in all directions for watering plants, the roads, trees, &c. In 1854 at least 6200 metres of these smaller pipes had been laid, at a cost of £4000; one lake contains 30,000 cubic metres of water, and the other and larger one, covering an area of 110,000 metres, holds 150,000 cubic metres of water. The level of one lake is considerably above that of the other, so that a waterfall of very good effect is managed on the rocky sides which line the lower one, and for three or four hours during the time of promenade there is a very considerable fall of water. There are many ornamental buildings, lodges, and Swiss cottages. The turf and road are beautifully kept; and the plants and shrubs, many of them of rare kinds, are in excellent order.

Having given a sketch of the several buildings erected of late years in Paris, it may be interesting to record the cost of some of them, this I have already done to some extent, but I will now quote the following:—

Digitized by Google

		Francs.
The Jewish church, by M. Thierry		234,294
Jews' hospital, same architect ...	Ground 65,000	
	Building 96,492	
		161,492
Cost of building, about 80 fr. the square metre.		
Mairie, third arrondissement		389,379
New fourriere or pound for the police		207,752
140 francs the metre.		
No. 60, Boulevard de Strasbourg, private house ...		203,332
651 francs the metre, probably including land.		
New wing, lunatic asylum, Charenton		3,320,000

As more detailed examples, I give the expenses of three buildings —namely, the Circus by Hittorf, the Colonne de Juillet, and a house, Place St. George.

The cost of the circus built by M. Hittorf, on the Boulevard des Filles du Calvaire, was—

	Francs.		Francs.
Masonry ...	194,000	Painted windows	2,500
Carpentry ...	58,000	Furniture ...	20,000
Ironmongery ...	62,500	Lustres and gas...	42,000
Founder ...	15,000	Decorative painting	6,500
Joiner	93,000	Historical painting	10,000
Carving	37,500	Statuary ...	20,000
Stoves	8,000		
Paving and asphalte	16,500		644,000
Stucco work ...	2,000	Design and direction	32,000
Painting and gilding	24,500		
Ornamental sculpture	16,000	Total	676,000
Bronze ornaments	16,000	or	£27,040

The total surface covered by construction being about 1900 metres, the cost per metre amounts to about 350 francs.

The Colonne de Juillet was estimated to cost 1,172,000 francs. The heavier parts of the bronze work was paid for at the rate of 3 fr. 75 c. the kilogramme, and the lighter parts at the rate of 4 fr. 25 c.

The house No. 26, Place St. George, built in 1853, and occupying a space of 1307 square metres, cost 564,000 francs, being at the rate of 448 fr. 80 c. a metre for the ground. The building covers 823 square metres, being at the rate of 237 fr. 35 c. a metre. The cost of the works under the several heads was as follows:

	Francs.		Francs.
Masonry	150,000	Stoves	4,000
Carpentry ...	40,000	Sculpture... ...	13,000
Joiner	50,000	Carton pierre ...	3,500
Ironmonger, smith, and founder ...	33,000	Pavement ...	4,000
Covering & plumber	10,000		534,000
Painting & glazing	18,000	Interest on outlay, and architect's commission ...	30,000
Gilding	8,000		
Paperhanging ...	2,500		
Internal mirrors ...	11,000	Total	564,000
Plate glass externally	7,000	or	£22,560

The income is said on a moderate scale of letting, varying from 900 francs for a fourth floor towards the Rue Laferriere, to 6200 francs for a first floor on the Place St. George, with stabling for two horses, to have realised 39,500 francs, or at about the rate of 7 per cent. on the outlay.

Together with the great public buildings recently erected, and more particularly the junction of the Louvre and the Tuileries, the most important public works which distinguish the era of Napoleon III. are the very striking improvements which have been made in some of the public thoroughfares of Paris, and which in fact give a perfectly new character to a great part of the town. The most remarkable if not the most important is the eastward continuation of the Rue de Rivoli, from the extremity of the garden of the Tuileries to the Place du Louvre, a length of 1300 metres; and numerous cross streets running north and south have been carried out at the same time.

Up to the end of the year 1857 the works on the Rue de Rivoli had cost £4,800,000, and caused the demolition of 800 houses. As part of this work may be also mentioned the square of St. Jacques, and the Avenue Victoria in front of the Hôtel de Ville, at the back of which is now being built, as a pendant to Saint Germain l'Auxerrois, a mairie for the fourth arrondissement. This square occupies a superfices of 6000 metres. The trees and shrubs are of new, rare, and valuable kinds, and were obtained from the first nurseries of Paris, Angers, and Nantes. After the Rue de Rivoli the most important new street is the Boulevard de Sevastopol, commencing at the Strasburg station and extending thence to the Boulevard St. Denis, and passing between the Rue St. Martin and the Rue St. Denis; it then assumes the distinctive name of Boulevard de Sevastopol, and continues until it reaches the Seine at the Place du Châtelet. Up to this point the expense is said to have been about £320,000. It is intended to carry this boulevard across the Ile de la Cité, and on the other side of the Seine from the Quai St. Michel up to the Hôtel de Cluny. According to the indication furnished by a recent map, it would appear that the work will be continued as far as the end of the Boulevard de Mont Parnasse; its length from the Strasburg station to the Barrière d'Enfer is 6000 metres. An offset from the Boulevard de Sevastopol is the Rue des Ecoles, leading to the Halle aux Vins; it was commenced in 1857; the assumed cost of this street is five million francs. On the north side of the Seine, from the newly constructed Caserne of the Chateau d'Eau as a centre, three streets are contemplated: the Boulevard du Nord to the Barrière Poissonnière; the second to the Barrière du Trône; and the third to connect the Halle Centrale with the Faubourg du Temple. A number of new streets have been formed in the quarter between the Rue Saint Lazare, Rue de Clichy, and Rue des Martyrs, a part occupied a few years ago by gardens and occasional houses. In 1847 a new street was opened in the immediate vicinity of the Bank, in which the fine building of the Timbre Imperial was erected, as also the mairie of the third arrondissement. A new street has I believe been begun from the Place Malesherbes to the Place de Laborde; other streets have I know been formed, particularly towards the Champs Elysées in the neighbourhood of the Elysee Bourbon. Among important projected works may be mentioned a place by M. Hittorf at the Arc de l'Etoile, the Avenue of Neuilly being enlarged to 180 metres. Turning again to the south side of the river, we find a new boulevard running between the Boulevard de Sevastopol and the Quai St. Bernard; the enlargement of the Rue Four St. Germain; the rectification of the Place St. Marguerite and du Carrefour de la Croix Rouge. The expense of the work was valued at £88,800. The Boulevard St. Marie to be made in three sections, from the Rue Royale to the Boulevard de l'Hôpital. Another improvement will be the widening of the Rue Mouffetard; besides which I see two other great lines of street are traced. I have now only mentioned the most recent streets of Paris or those in immediate contemplation; but there are other works of the last thirty years, such as the annexation of the Ile des Cygnes to the adjoining land, the Boulevard Mazas, and the Rue Lafayette, which are of very considerable importance.

In order to form these new streets, the law under which expropriation, that is compulsory sale, takes place, was passed as it now stands on the 3rd of May, 1841. It has been completed or supplemented by several regulative ordinances and by a decree of the Pouvoir Executif, having all the force of law. The expropriation takes place on the report of local commissioners, and the compensation is assessed by a jury who sit as judges of the value.

THE FRENCH EXHIBITION

Attracts this year, as usual, a large number of visitors. The subjects are for the most part not of a class suited for our special notice, but it may be remarked that as a collection it will maintain the prestige of former seasons. Perhaps the most popular name in the catalogue is that of Madlle. Rosa Bonheur (19, 20, 21), who has three small pictures, each good in its way, especially the former. It is evident that animal painting is more her *forte* than foliage or verdure. A very large picture in her more usual style forms one of the chief attractions of the gallery; it is by Brion, and numbered (31). The title, "Early Morning on the Rhine," gives little idea of the scene depicted, which is a group of individuals and cattle gliding down the river on a floating raft. The composition of the whole is excellent, and the perspective foreshortening admirably preserved. We may also mention, as another picture of this class, Constant Troyon's "Country Fair in France (147), which is boldly treated, and characteristic.

Some exquisite studies by Bida (13, 14, 15, 16), cannot fail to arrest the eye. The first of these is the property of H.I.M. the Empress Eugenie, and represents "Egyptian Recruits removed from their Village." Eastern incidents appear to be favourites with those artists who do not confine themselves to *genre* productions. Thus we have, in (12), a large and beautiful view near Cairo, with a herd of cattle returning home; (63) is a kindred theme, "Caravan Crossing the Desert"—one of Theodore Frere's numerous and masterly contributions. Two others by the same

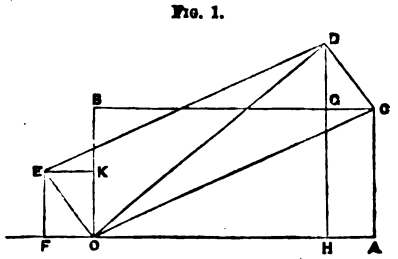
Digitized by Google

hand are (65, 66), depicting Egyptian life in "coffee-houses," while (67) renews our acquaintance with the pyramids of Gyzeh, and (69) with the Temple of Karnac. Almost the only really classical work is a small one by Couture (41), the subject of which is the "Decadence of Rome," illustrating a scene of luxury and frivolity. Perhaps the most masterly and touching picture of its kind is by M. Gallait (74), portraying the "Brussels Archers paying the last respects to the Counts Egmont and Horn," in which every part is rendered with painful accuracy. Among productions of another kind may be mentioned (30) "Rembrandt in his Studio," which for its minuteness of detail is worthy of a place among the old Dutch or Flemish masters. The four pictures (apparently serial) by E. P. Frere (57, 58, 59, 60), and entitled, the Toilet, the Breakfast, the Artizan's Family, and the Cut Finger, which are, each and all, charming little gems;—the "Evening Prayer" (75), which reading might be exchanged for "a study of reflected lights;"—(172) "the Young Artist," by Florent Willems;—"the Last Prayer" (143), N. Tassaert;—a pretty pastoral landscape (94), "Near Haarlem, Holland," by Lambinet;—and the two important works by Henry Leys (108, 109), representing Wiesseling, the carpenter of Antwerp, secretly expounding the Scriptures in the early days of the Reformation; and a "Scene from the Siege of Antwerp," in which a lady is shown interceding for the preservation of a church. (174 and 175) are familiar views from Venice, in which more than ordinary attention has been paid to the architectural detail: they represent the "Place St. Marc," and the well-known palaces which line the Grand Canal at Venice.

THE PARALLELOGRAM OF FORCES.

By Arthur Cohen, B.A., Magd. Coll. Cam.

Almost all those proofs of the parallelogram of forces which are not founded on dynamical principles involve either the solution of a functional equation, or the assumption of some mechanical principle extraneous to the consideration of the equilibrium of an isolated point or particle,—such as, for instance, the principle that the point of application of a force may be transferred to any point in the direction of the force. I propose then in the first place to give a proof which neither involves the solution of a functional equation nor the unnecessary assumption of any mechanical principle; and in the second place to show how the problem may be reduced to the solution of an extremely simple functional equation.



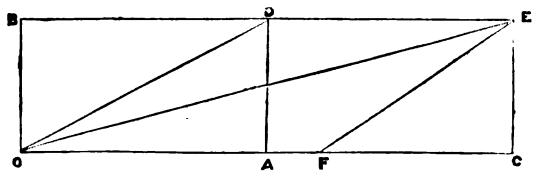
It is easily shown that the only difficulty in proving the parallelogram of forces lies in finding the direction of the resultant of two forces at right angles to one another, and that the angle which such resultant makes with either of the component forces depends solely on the ratio of the magnitude of the two component forces.

If then P and Q be two forces at right angles to one another, and if $\tan(\alpha)=\frac{Q}{P}$, then the direction of the resultant depends only on $\frac{Q}{P}$ or on α. Let then the system of forces P and Q, for which $\alpha=\tan^{-1}\left(\frac{Q}{P}\right)$ be called "a system (α)"

It is clear from the above that if the law of the parallelogram of forces is true of *one* system (α), it is true of *every* system (α). I proceed to show that if the law is true of a system (α) and of a system (β), it is true of a system $(\alpha+\beta)$.

Draw OA, OB at right angles to one another, to represent a system of forces (α) fig. 1; and completing the parallelogram OBCA,

Fig. 1.



draw OC and OE at right angles to one another, to represent system of forces (β). Complete the parallelogram OCDE, draw OD, and draw DGH and EF perpendicular on OA, and OA produced. Since by hypothesis the law is true of forces OA, OB, and of forces OC and OE, OC represents the resultant of forces OA and OB, and OD represents the resultant of forces OC and OE.

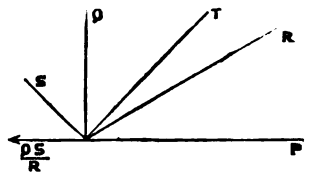
Draw EK perpendicular on OB, then it is evident that OF and OK represent a system of forces (α), and therefore OE represents the resultant of the forces OK and OF. Therefore the resultant of forces OE and OC or OD is the resultant of forces represented by OB+OK and OA−OF, or by HD and OH. But forces OH and HD represent a system $(\alpha+\beta)$; therefore the law of the parallelogram of forces is true of a system $(\alpha+\beta)$. *Q.E.D.*

Secondly, I will show that if the law is true of a system (α), it is true of a system $\left(\frac{\alpha}{2}\right)$

Draw OA, OB to represent a system of forces (α); complete the rectangle OADB: draw OD, and draw OE, bisecting angle DOA and meeting BD produced in E. Draw EF parallel to OD to meet OA produced in F, and draw EC parallel to OB to meet OA produced in C. Since angles DOE and EOA are by

Fig. 2.

construction equal to one another, therefore angle DOE=DEO, therefore OD=DE=OF, and it is clear that FC=OA; therefore the resultant of the forces OB and OC is the resultant of forces OB, OA and OF, or of OD and OF; and since OD=OF, it is evident that OE bisecting the angle DOE is the direction of the resultant of OF and OF. Therefore the resultant of OB and OC is represented in direction (and therefore, as may be easily shown, also in magnitude) by OE. Therefore the law is true of the system $\left(\frac{\alpha}{2}\right)$, which is represented by OB and OC. *(Q.E.D.)*



Combining this and the preceding proposition together, it follows that if the law is true of a system (α), it is true of a system $\left(\frac{m\alpha}{2^n}\right)$, whatever integers m and n may be. Now θ, whatever θ may be, may be made equal to or as nearly equal to $\frac{m\alpha}{2^n}$ as we please, by taking n sufficiently large; and we may thence prove by the ordinary *reductio ad absurdam* that the laws of the parallelogram of forces is true of any system (θ).

I will now give another proof of the same proposition by means of a functional equation.

Let P and Q represent a system (α), so that therefore $\tan(\alpha)=\frac{Q}{P}$, and let the resultant R make with P an angle θ. Assume $\theta=F(\alpha)$.

Apply a force S at right angles to R (fig. 3). Then if we suppose a force $\frac{QS}{R}$ to act in direction opposite to P, and a force $\frac{PS}{R}$ to act in direction of Q, it is clear that these two forces having for their ratio $\frac{Q}{P}$ form a system (α),

Fig. 3.

and therefore the direction of their resultant will make with the force Q the same angle that R makes with P; therefore such resultant will be at right angles to R, or S will be that resultant.

Let T be the resultant of S and R, or of $Q+\frac{PS}{R}$ and $P-\frac{QS}{R}$

Digitized by Google

Let T make with R and P angles ϕ and ψ respectively. Let also $\tan(\beta)=\frac{S}{R}$; $\tan(\gamma)=\frac{Q+\frac{PS}{R}}{P-\frac{QS}{R}}$. Then $\theta=F(\alpha)$; $\phi=F(\beta)$; $\psi=F(\gamma)$ and $\psi=\theta+\phi$. Now $\tan(\gamma)=\frac{\frac{Q}{P}+\frac{S}{R}}{1-\frac{Q}{P}\cdot\frac{S}{R}}=\tan(\alpha+\beta)$. Therefore $\gamma=\alpha+\beta$.

Therefore $\psi=F(\gamma)=F(\alpha+\beta)=\theta+\phi=F(\alpha)+F(\beta)$. Therefore $F(\alpha+\beta)=F(\alpha)+F(\beta)$ ... ... (1)

Differentiate this equation first with respect to (α), then with respect to (β), and we obtain $F'(\alpha)=F'(\beta)$; $\therefore F'(\alpha)$ is constant; $\therefore F(\alpha)=A\alpha+B$, A and B being arbitrary constants. Substituting in (1) we find B=0; and since when the forces are equal $\alpha=\frac{\pi}{4}$ and the direction of the resultant bisects the angle between the two equal forces; therefore $F\left(\frac{\pi}{4}\right)=\frac{\pi}{4}$. Therefore A=1, and therefore $F(\alpha)=\alpha$ or $\theta=\alpha$; therefore the resultant is in the direction of the diagonal of the rectangle on the two component forces.

VARIOUS MATTERS CONNECTED WITH ST. PAUL'S CATHEDRAL.*

By F. C. Penrose.

This paper will, I fear, be greatly wanting in unity, as I shall have to enter on different subjects while carrying out the purpose I have in view of tracing rapidly the history of our magnificent Cathedral since it passed out of the master hands of Sir Christopher Wren down to the present time; and then of inviting your consideration of some topics which may have influence on its history for the future. In accomplishing my task, I must claim your indulgence if I am obliged to introduce matters in which I have a personal responsibility. All present are, no doubt, familiar with the history of the commencement, and the general progress of the building during the reigns of Charles II., James II., William and Mary, and Anne. The great architect's task, while steering through the difficulties opposed to him, was no easy one: even during Anne's time he was very shamefully treated,† and continually thwarted by the commissioners appointed to administer the funds, &c.; but after the accession of George I. in 1714, Wren, being then eighty-two years of age, endured for four years continued annoyances from intriguing persons, favourites of the new dynasty, and was finally dismissed from the office of surveyor—still unimpaired in mind, and even sufficiently strong in body to superintend the works; and an ignorant person, named Benson, was installed in his place—a man of such incapacity, that after one year's trial he was ejected. At this time it would appear that almost the only parts of the external structure not completed were the statues on the pedestals, respecting which Wren wrote, Oct. 28, 1717, "The pedestals for the statues I have already laid in the building, which now stand naked for want of their *acroteria*." The balustrade above the general entablature was not, as you are aware, designed by him; and it is probable that it was not executed until after his dismissal. Still it is presumable that when the commissioners insisted on it he may have made the drawings, though under protest, for fear of his design being still more interfered with, if put into such hands as Benson's. So far as the execution is concerned, these late works were worse done, and have given more trouble to keep in repair than any other parts of the structure.

Wren having replied to the commissioners Oct. 28, 1717, protesting against the balustrade, was dismissed April 26, 1718, from his office of surveyor. We may just pause to reflect on the misfortune of political intrigue interfering with architectural appointments, and to indulge the wish that, instead of Benson being made surveyor, Wren's own pupil, Hawksmoor, had been commissioned to assist him; or Gibbs, who has shown in the tower of St. Clement Danes (added to Sir Christopher's church), that he well knew how to combine his own work with that of his great master. The addition, however, of the balustrade over the main cornice, and the omission of the vases on the piers of the balustrade over the colonnade of the dome, are but slight matters in the general aspect of the Cathedral; and we may indeed be thankful that in its integrity the external design, as executed, displays the intentions of Sir Christopher Wren. The building cost in round numbers £750,000, and the works were in hand during the period of forty-four years under his actual superintendence.

A longer period of the great architect's presiding care could hardly have been hoped for; but had the funds exceeded the moderate average of £17,000 a-year, some portions of the work might doubtless have proceeded more rapidly, and his views for the embellishment of the interior might have been carried out more or less perfectly. We are not acquainted in detail with these views, but we know that mosaic work and marble decoration entered largely into them, and we cannot doubt that the whole interior would have corresponded in magnificence with the exterior.

It is impossible to say how far Sir James Thornhill acted in concert with Wren, when painting the cupola of the dome. All that can be stated is, that in the year 1711 the latter writes despondingly about it. "As for painting the cupola, your lordships (the Archbishop and the Bishop of London) know that it has been long in consideration; that I have no power left me concerning it, and that it is not resolved in what manner to do it, or whether at all." This was written in 1711, Sir Christopher Wren being eighty years old. Again, the decoration by Thornhill is quite different from the coffered arrangement of Wren's first model, and from that shown in an early print. On the other hand, Thornhill seems to have been on friendly terms with Wren; for he was employed on his works at Greenwich, and at his college of All Souls, Oxford.

However, considering the barocco style of Thornhill's decoration, I think Sir Christopher's wishes could hardly have been consulted, and we may be thankful that more, such as is shown in Gwyn's section, was not done; for, however naked the interior may appear at present, it does not shock by reason of any tawdry effect; and should the public subscriptions, now invited for the purpose of carrying out a suitable embellishment in accordance with the views of Sir Christopher Wren, flow in with sufficient spirit, it will be possible to ensure a vastly superior effect by following such examples as St. Peter's, and Sta. Maria Maggiore, instead of the fashion of the beginning of the eighteenth century.

To proceed with the history of the building. There seems to have been little done after Sir Christopher left it, till towards the end of the last century, when, under the surveyorship of R. Mylne, apprehension was felt for the safety of the fabric, arising from settlements chiefly apparent in the north and south transepts; and large iron ties were introduced into the walls at the level answering to the triforium of Gothic cathedrals. So far as I can judge, these ties have either arrested the threatened injury, or, the cause of it, viz., the compression of the substratum, having arrived at its maximum, there are no present grounds for apprehension. Should, however, any deep cuttings, *e. g.* for a sewer, be formed in the immediate neighbourhood (one was actually commenced in 1831, which would have passed twenty feet below the level of the foundation, and only fifty feet distant, but was fortunately stopped by Mr. Cockerell's vigilant resistance), there would again be cause for alarm. At present, owing to Wren's admirable precautions, and the care taken of the fabric by such surveyors as Mr. Mylne and Mr Cockerell (care, it is to be hoped, which will never be wanting when necessary), the fabric is in a remarkably sound condition, and the small amount of displacement of the stones, visible here and there, is no more than is inevitable in so solid and lofty a structure founded on the London clay.

There does not seem to have been anything done towards the embellishment of the interior, except a pulpit by Mr. Mylne, and an alteration in the front of the organ screen (making, perhaps, rather too much of the original modest panel dedicated to Wren's memory, "Lector si monumentum requiris circumspice,"—an inscription which has again given place to an expansion of the organ itself) until the year 1821, when Mr. Cockerell superintended the restoration of the decayed gilding and decorative painting at the east end, and at the same time most effectually renovated the ball and the "cross of gold that shines over city and river."

* Paper read at the Royal Institute of British Architects.

† In a curious cotemporary pamphlet—'Frauds and Abuses in St. Paul's'—he, with the master workman and others under his charge, was attacked in a most unjust and unscrupulous manner.

Digitized by Google

During the first twenty years of the present century, however, the walls of the interior have been appropriated to the reception of monuments, good, bad, and indifferent; which, while they certainly add interest to the cathedral, seem even to enhance the cold aspect of its architecture. An opportunity now offers itself, in the Wellington monument, to combine more colour with the composition, which will, I trust, not be altogether thrown away. The paintings of the cupola having become nearly black and obliterated in many places, have been restored. I had the pleasure of bringing this subject before you in 1852. The zeal of Mr. Parris in undertaking, and his energy, courage, and skill in carrying out this extensive work, are worthy of very great praise. The simple and effective contrivances, his own designs, for supporting himself in his eyrie in the air were well worthy of attention; and the adoption of them will greatly facilitate the execution of whatever may hereafter be done in the way of embellishment to the other vaulted portions of the interior. If however the present more ambitious views,—perhaps rather dreams—dreams that, nevertheless, I will hope may work in the direction of their own fulfilment,—had been entertained at that time, it is probable that Sir James Thornhill's work, which, whatever its merits, must be pronounced only second-rate, would hardly have been followed and restored so scrupulously.

Besides the restoration of the paintings, the only important work executed in or about the cathedral within the last few years, until the recent opening of the dome area for divine service, is the tomb of the Duke of Wellington, and the arrangement of the two adjacent sepulchral chambers containing this and the tomb of Nelson. The tomb of the latter is placed under the centre of the dome, surrounded by eight Doric columns, whose bases were hidden by the floor of the crypt having been raised, for some unknown reason, nearly 2 feet above its original level. The bases having been found on excavating, the pavement was lowered, and the columns restored to their original appearance. The vaulted covering over this part was found to be pierced by a number of lead pipes in the haunches of the groins; the object of these pipes is evident when we remember that, for many years after the rest of the church was finished, the central portion was open to the sky.

The sarcophagus of the Duke of Wellington is composed of schorl porphyry from Luxulian, near St. Blazey, on the Treffry estate in Cornwall. Previously to the adoption of this, considerable time was occupied in endeavouring to obtain from Ireland a suitable material. The Clenony marble from quarries on the banks of the Shannon, near Banagher, King's County, Ireland, was particularly examined for that purpose. Blocks of sufficient size could have been obtained, but difficulties in the undertaking and transport made it necessary to abandon the project. The Cornish material was pointed out by Mr. Warrington Smyth, one of the professors in the Institution of Practical Geology, and Inspector of Mines to the Duchy of Cornwall. The sarcophagus rests upon a basement of granite from the Cheesewring in Cornwall. The name and date are cut upon the side panels of the lower or principal block, and the elliptical bosses at the ends are each inscribed with a cross. In the design the great desire has been that extreme simplicity and solidity should prevail, but that by a careful adjustment of the proportions any effect of rudeness should be obviated. If this combination of ideas has been impressed upon the tomb, the result is chiefly due to the assistance given me by Mr. Cockerell. The length of the sarcophagus is 10 ft. 3 in., the breadth 5 ft. 1½ in., and the height about 6 ft. 6 in. It was cut out of a single stone which was just of sufficient size. After it had been scabbled into the general form, a small steam engine was erected on the spot to saw it in two, and afterwards to rub and polish it. The work of sawing the piece in two lasted day and night, with scarcely any intermission, 42 days. The whole operation took nearly two years. It was finally sent to London by the Rev. E. J. Treffry, and was received at the end of January last year. The amount paid for it on delivery was £1100. I estimated the weight of the larger stone, including a timber frame on which it was moved, at 8 tons, and that of the smaller stone at 6 tons. The sarcophagus was lowered into the crypt through one of the windows on an inclined plane. As soon as it reached the floor, the stage was taken down and reconstructed so as to elevate it to the proper height for rolling it on a level upon another short stage erected over the base of the tomb. For these stages light timbers and frequent props were preferred to heavier framing, as more convenient for re-adjustment. The greater portion was of 6 in. by 6 in. and 5 in. by 5 in. die square timber. The general calculation for the bearings was that the load should be equal to one-third of the breaking weight, and the result showed that it was everywhere amply sufficient, as there were no deflections of any large amount. From watching the behaviour of the timber under this strain, I am inclined to think that trusting two-fifths of the breaking weight would not have incurred any danger, but I should not be inclined to advise a smaller margin. In considering these proportions it must be borne in mind, that the condition of a mass moving very gradually and smoothly is the most favourable to the strength of the material, as subject neither to the increasing deflection resulting from too great a permanent load, nor to the danger from concussion resulting from weight in more rapid motion. The bottom and principal stone was lowered by means of two crabs from a jib, supported by trussed framing independently of the stage. The upper stone, which offered no convenience for inserting the lewis, was slung by two straps passing round horns or ears left on each side, which were afterwards worked to a square shape after the manner of the Greek masons. The ceremony of shutting down the lid of the sarcophagus upon the venerable remains enclosed within it, took place April 15, last year, in the presence of the Duke of Wellington, Lord J. Manners, first Commissioner of Her Majesty's Works, and the Dean of St. Paul's. Mr. Mallcott was the mason. The cost of lowering and fixing amounted to about £120, including the timber stages, and making good the window through which it was lowered.

To return to what more particularly affects the Cathedral itself. It is assuredly a fact of great importance, that during the last few months the great central area of the Cathedral has been opened for evening services, by carrying out at last a plan which the Dean and Chapter have been desirous of achieving for the last eight years, but which recent movements in the church put into their hands the means of effecting. These services have answered to an extent which has given great satisfaction to those engaged in it. It would appear that Sir Christopher Wren from the very first must have contemplated such a use of the interior. Even before the Fire of London, we find him engaged in a plan for forming a large central space in the old Cathedral, by removing the tower which had become dangerous; and we are told he advocated the plan expressly for the purpose of its receiving a large congregation. Again, in the model of his single order, a design preserved till lately in the Cathedral, but now at the Kensington Museum, it is quite evident that the great central space must have been the part intended for the congregation, so that the present use of the dome area is strictly in accordance with his intentions. It may be justly affirmed that it has not hitherto been used. It has, no doubt, two or three times in the century been the scene of great public memorials, thanksgivings, and funerals. And once every year it has been turned into a sort of amphitheatre for the exhibition of 4000 charity children; certainly a remarkable spectacle, but not sufficient to satisfy the full purpose of such a building. It therefore seems a matter of great satisfaction that the present evening services have been commenced, at which upwards of 3000 persons are arranged in great comfort; and it is remarkable how well, on the whole, the voice of the preacher is heard. The pulpit is raised about 7 feet, and a preacher with a good and clear delivery, speaking slowly but not very loud, can be heard by the whole congregation, the most distant part being upwards of 120 feet. With respect to the fittings for receiving the congregation, doubtless in the present commencement there is much that is temporary, and cannot fail to have a mean, unsatisfactory appearance. But should sufficient funds be available, these will be gradually removed; and when handsome marble screens or other suitable inclosures take the place of the present rough barriers, ample opportunity being given to the eye of the spectator to traverse in every direction, there can be very little doubt that the appearance of solemnity from the hallowed use of the place, as well as the scale given by the furniture, will render the interior of the Cathedral very much grander than it was before. Indeed has it not become so already, while much is confessedly incomplete? To admit of these services, the Cathedral has been warmed by Messrs. Goldsworthy, Gurney, and Co., who are also engaged in warming the Houses of Parliament. In the crypt which underlies the whole church thirteen large stoves have been placed; and the air in the crypt is warmed to a temperature of about 66°. There are twenty-three openings formed in the pavement of the Cathedral, each

Digitized by Google

about 4 feet diameter, by means of which a constant circulation is produced; some being made upcasts, others downcasts, by means of a winsail, so that the warm air of the crypt rises by some of these openings into the church, and by others the air having been cooled by contact with the walls, roof, and windows of the church, descends to the floor of the crypt, and thus the circulation is kept up. The flues of the stoves are carried up in the external walls of the Cathedral without any injury to the building, owing to the foresight of Sir Christopher Wren, who has everywhere provided for the due examination of the gutters and downpipes by carrying a passage in all cases under the gutters: the downpipes being carried in shafts each about 2 ft. 3 in. square formed in the hollow of the external walls, and iron steps left in the angles of these shafts. The stoves, without being forced, consume about one chaldron of coke per day; the effect is, that instead of a temperature of about 45° Fahrenheit, which we should probably have had (in a severer winter than the present at this time it would have been about 42°) we have a temperature of 57°, which rises about 2° during the time of service; and if the weather were much colder, the same temperature could, I believe, be maintained, but at a larger expenditure of fuel. All the apertures in the floor of the Cathedral are outside the part were the congregation is assembled, so that the stream of heated air which the congregation throws up is replaced by air moderately warmed, and the draughts, inevitable in so large a building, are deprived of their chilling effects, while they are greatly moderated in force. The whole expense of the apparatus, including mason and bricklayers' work, was about £1250. The floor is covered with Kamptulicon floor-cloth, composed of India rubber and cork, excepting the centre (60 feet) where Manilla matting has been used, with a view to its more ready removal if occasion should arise. To confine the sound of the preacher's voice, the space for the congregation is enclosed on six sides of the octagon by screens of American cloth (known as sham leather). Where the screens are placed, it is desirable, should these services become permanent, that marble screens or cancelli should be adopted, of which a good example is seen in the Duomo at Verona. Almost the whole of the congregation is seated on rush bottom chairs of a very strong description, made by Mr. Skull of High Wycombe. The cost of each was 3s. 4d. delivered. As nearly as possible, 1 ft. in 8 lateral, by 2 ft. 9 in longitudinal space is allowed. The gangways are reduced to a very small space, it having been found that persons are otherwise apt to stand in them, and interfere very much with the rest of the congregation. The chairs not offering so solid a resistance as pews to the congregation in entering and going out, it seems that this reduction of the gangways can be managed without any great inconvenience. The result appears to justify the use of chairs even in point of accommodation; and they certainly do not in any way interfere with the architecture of the Cathedral.

Light is obtained chiefly from a corona of about 800 gas jets, placed round the Whispering Gallery: it is sufficiently strong to render moderately small print easily legible by the congregation. The form of the sounding board is, I think, a novelty, but I am led to believe that it is an approach to the true form for the purpose. The first Sunday, when the Bishop of London preached, his fine clear and distinct voice was very much confused by the echo from the dome. It therefore became necessary to put up a sounding board to stop the inconvenience. Flat sounding boards have been most commonly tried, but they are now generally discarded. A parabolic sounding board behind the preacher has been used with a certain effect, but the advantage is limited to those in the direction of the axis of the curve; and in these cases, action and reaction being equal, the preacher can sometimes hear the criticisms of his audience, if any should be uttered tolerably loud in the proper direction. Besides which, a shell of this description would have had little effect in stopping the objectionable echoes. To meet these difficulties a curve was selected, which has the property of distributing uniformly in every direction so much of the preacher's voice as can be advantageously reflected. The figure is hyperbolic, the axis being perpendicular over the preacher. The diameter is 10 feet, and so much of the voice it receives is reflected as if it came from a point about four feet above the preacher.

It would be interesting to know, but I am not aware that sufficient experiments have been made to ascertain, what amount of sound is reflected from a given material. The harder the material, obviously the better the result. In this case, hard organ-pipe metal has been used. I observed a marked increase of audibility of the voice at a place where the assistance of the reflected sound is obtained over a point equidistant from the pulpit, but too high to receive the reflected wave from the sounding board.

The total cost of these fittings, with other expenses incidental to making the building available for the services, was about £3000.

Up to this time no serious expense has been incurred, except re-glazing the windows of the drum of the dome, and re-gilding the parts originally gilt. Messrs. Powell are engaged upon the windows: the glass chosen is of a very simple character, after a pattern in one of Palladio's churches at Venice; it being felt necessary that these windows should admit all the light possible consistent with its not being too glaring. A richer description of ornamental glass may however be used in other parts, especially in the windows at the east end, and in the great windows at the ends of the nave and transepts. But the embellishment of the church ought not to be confined to or even consist mainly in glass. The chief indications of Sir Christopher Wren's wishes as to the embellishment of the cathedral are drawn from a note in the 'Parentalia.' We read in page 291, "In the aisles the lesser cupolas are both ways cut in semicircular sections, and altogether make a graceful geometrical form, distinguished by circular wreaths, which is the horizontal section of the cupola; for the hemisphere may be cut all manner of ways into circular sections; and the arches and wreaths being of stone carved, the spandrels between are of sound brick invested with stucco of cockleshell lime, and which, having large planes between the stone ribs, are capable of further ornaments of painting if required. The inside of the whole cupola is painted and richly decorated by an eminent English artist, Sir James Thornhill, containing in eight compartments the histories of St. Paul. In the crown of the vault, as in the Pantheon, is a circular opening, by which not only the lantern transmits light, but the inside ornaments of the painted and gilded cone display a new and agreeable scene."

In a note to the last paragraph we find the following information:—"The judgment of the surveyor was originally, instead of painting in the manner it is now performed, to have beautified the inside of the cupola with the more durable ornament of *Mosaic* work as is nobly executed in the cupola of St. Peter's in Rome, which strikes the eye of the beholder with a most magnificent and splendid appearance, and which without the least decay of colours is as lasting as marble or the building itself. For this purpose he had projected to have procured from Italy four of the most eminent artists in that profession. But as this art was a great novelty in England, and not generally apprehended, it did not receive the encouragement it deserved. It was imagined also the expense would prove too great, and the time very long in the execution; but though these and all objections were fully answered, yet this excellent design was no further pursued. The painting and gilding of the architecture of the east end of the church over the communion table was intended only to serve the present occasion till such time as materials could have been procured for a magnificent design of an altar, consisting of four pillars wreathed of the richest Greek marbles, supporting a canopy hemispherical, with proper decorations of architecture and sculpture, for which the respective drawings and a model were prepared. Information and particular descriptions of certain blocks of marble were once sent to the Rt. Rev. Dr. Compton, Bishop of London, from a Levantine merchant in Holland, and communicated to the surveyor, but unluckily the colours and the scantling did not answer his purpose, so it rested in expectance of a fitter opportunity; else probably this curious and stately design had been finished at the same time with the main fabric."

A baldachino over the communion table we do not perhaps require, but that is no reason why coloured marbles should not be introduced: we know we can have them both from abroad and from our own country, and they may be most advantageously applied in the panels; and why should we despair of carrying out the desires of Sir Christopher Wren in respect to the mosaic decoration? There is no difficulty—the island of Murano in Venice still produces the material, not inferior to the ancient, even if our own manufacturers do not surpass or equal it. I know that Messrs. Powell are striving to produce this beautiful manufacture: the method is understood,—certainly it is slow,—but there is no mystery about it. I cannot conceive that there ought to be any insuperable difficulty in making this magnificent

interior of Wren's Cathedral brilliant with this forcible but quiet manner of colouring; and the cost of the undertaking cannot be beyond what might fairly be hoped to be contributed in London, many of whose merchant princes could singly do it without impoverishing themselves. I believe that £7000 or £8000 expended in mosaics, would go far to make the drum of the cupola all that could be desired in point of ornament. This would be a commencement, which, if successful, (I do not for an instant question its success,) would most likely lead the way to greater things; a school of workers would have been formed, and the noble spandrils of the eight arches of the dome, and the hemispherical vaults through which the vaults of the aisles are pierced with so much beauty, would offer fit places for more elaborate designs and subjects from Scripture history. This accomplished, there would still be work to do; but by the time thus much should have been done, there would be materials enough collected to form the subject of another paper to be submitted to the consideration of the members of this Institute

ON THE BURNING OF WELSH STEAM COAL IN LOCOMOTIVE ENGINES.*

By J. Tomlinson.

The use of coal in locomotive engines having become almost the rule, the writer offers the following results of a series of trials he has made with the steam coals of South Wales, in locomotive engines upon the Taff Vale Railway, in comparison with the best descriptions of coke to be had in the same district; as there has hitherto been a difficulty in the use of that description of coal for such a purpose almost amounting to prohibition, from the fact that in all previous trials a failure has resulted from the burning of the firebars. This failure of the Welsh steam coal in locomotive engines has been hitherto attributed to the firebars becoming clinkered over; but the results of the trials described in the following paper appear to show that the failure has arisen from an entirely different cause, and one that can be completely obviated.

The writer was originally driven to the use of coal alone for carrying on the traffic of the Taff Vale Railway in January 1858, in consequence of the continued strike of the colliers in the Rhondda Valley, where the coking coal is obtained. Previous to that time little or no coal had been used in locomotives, owing to the good quality and low price of the coke; and from the idea that coal could not economically compete with coke for the heavy work of this line, and also from the known difficulties to be overcome in its employment. The transition from coke to coal being sudden and unprepared for, it became necessary to watch the matter closely, so as to determine which of the various descriptions of coal would answer the purpose best, and to arrange its treatment; more especially as at the outset, from the various qualities of coal that had to be used, the firebars were continually being burnt out, and seldom could be made to last two days without passing through the hands of a smith to be separated and straightened; even then several bars a day were totally destroyed in each engine, some engines having had two entire new sets a day to run 100 miles. After careful consideration of the subject it was decided to use only one description of coal; the preference was then given to the steam coal over the bituminous, as being more pure in its composition, and smokeless; and after attentive observation and trials the Aberdare Four Feet Vein coal was chosen. With this coal it was found that the least damage was done to the firebars, and the best result obtained by working the engine with a very thin fire, say not exceeding 9 inches with a moderate load, and slightly thicker as the load increased, not however exceeding 15 inches in any case. In working with a light train or down hill with a loaded train, it was found advantageous to keep even a more shallow fire than 9 inches; for the blast being very light (as little or no traction is required down hill on this railway), the supply of steam could not be kept up unless the air were admitted with little difficulty; it is however necessary to be prepared in case of being stopped, and therefore a bright fire was a desideratum which could not be obtained unless it were kept thin.

The injury to the firebars was however still a great item, notwithstanding all the care that could be bestowed on them; for it is difficult to get a number of men to attend implicitly to rules which give them more trouble than they have previously been accustomed to. The writer therefore was induced to try an experiment by covering up the entire surface of the bars with small pieces of firebrick, not exceeding 3 inches cube, and putting the fire on them, so as to prevent the direct action of the fire on the iron of the bars; and it was found that from the clean nature of the coal no bad result took place in the generation of steam, while the bars now received little or no injury. Figs. 1 and 2, Plate XVI., are a longitudinal and transverse section of a locomotive firebox, showing a layer of broken pieces of firebrick on the bars. This plan has consequently been generally adopted, but with the partial substitution of clinker from stationary engines instead of firebrick alone. It has completely obviated the difficulty of the bars being burnt, and a set of bars will now last on an average four months, running about 100 miles a day. It is also attended with a beneficial result; for the small coal, instead of passing directly into the ashpan unconsumed; adheres partially to the red-hot brick and clinker, and is consumed; and notwithstanding that the Welsh steam coal falls readily to small, and has little if any binding property, the engines can run 100 miles without cleaning out the ashpan. Another description of coal containing a larger percentage of ash has also been tried for getting up steam and making the first fire to start with, which clinkering slightly on the bars most effectually protected them from burning: the use of this coal was however limited to 5 cwt. per day for each engine.

To place the engine more out of the control of the men, the plan was adopted which had been in use on other engines, of perforating the shield of the firedoor and drilling five or six 2 inch holes in the door itself, as shown in Figs. 3 and 4, so as to admit a little air above the fire; this was found useful not only in assisting combustion but also in preventing the blast from lifting the small particles of coal and thereby choking the tubes.

Having so far succeeded in efficiently working the traffic entirely with coal, and finding the engines were working the trains with a smaller weight of fuel than they had previously done, the writer was disinclined to return to coke without good reason, after the experience he had had. A series of experiments was therefore made to test the commercial value of each description of fuel. The first series of experiments was made with an engine working the regular mineral trains, with Aberdare Four Feet coal and Rhondda Valley best coke: the second series, with the same coal and coke, with a special train of 35 loaded coal wagons weighing 269 tons, run at the regular speeds of the ordinary trains of about 11½ miles per hour: the third series, with various fuels, with a special train of 40 loaded coal wagons weighing 314 tons, run at a speed of 20 miles per hour up the hill and 12 miles down (12 miles per hour being the limit down hill with loaded trains): and the fourth series, with bastard steam coal and Aberdare Nine Feet coal: the former of these has a larger percentage of ash and more bituminous property, the only objection to its use being the smoke: it does not burn the bars, and is fully as economical as the pure steam coal.

The whole series of experiments were made with the same engine and by the same engineman. The engine is of the following dimensions: cylinders 16 inches diameter and 24 inches stroke; six wheels coupled, 4 ft. 6 in. diameter; firebox 3 ft. 6 in. square by 4 ft. 10 in. high; 156 tubes, 13 ft. 3 in. long by 2 inches diameter, and No. 11 to No. 14 wire gauge thickness; safety valves loaded to a pressure of 110 lb. per square inch.

The following table gives the general results of the whole of the experiments, showing the quantity of fuel consumed per ton per mile, the quantity of water evaporated per lb. of fuel, and the average speed of the train during running:—

Description of Fuel.	Fuel consumed per ton per mile.	Water evaporated per lb. of fuel.	Speed in running Miles per hour.
	lb.	lb.	miles.
Coal—Aberdare Four Feet Vein	·127	7·63	11·5

The results in the consumption of fuel showing in all cases slightly in favour of the coal, they may fairly be considered equal; and as the abuse of the engine when burning coal is more easily detected than when using coke, this forms a further advantage in favour of coal. The preference may also be given to coal over coke for the freedom in generating steam, which will allow the blast pipe to be of larger dimensions than when burning coke. This has been clearly shown, as the engines are now maintaining steam at 100 to 110 lb. per square inch with coal, with the same sized blast pipes as were used previously for 80 lb. with coke; and the firebars have also been placed closer together, the air spaces being reduced from 1 inch to ⅝ inch. Hence the writer thinks it may be concluded that the Welsh smokeless coal may be economically used in substitution for coke; and that where failures have taken place previously, they are to be attributed to the very great heating power of the coal; and that the difficulty with firebars has resulted not from clinker, but from the absence of a proper protection for the iron of the bars, so that with heavy firing the heat has struck downwards and fused the bars themselves.

Nearly all the engines on the Taff Vale Railway are now burning Welsh steam coal entirely; they take with each train a load of eighty empty wagons averaging 3¼ tons each or 260 tons total, up an average rising gradient of 1 in 309, at from 13 to 14 miles per hour without any inconvenience.

The composition of the Aberdare Four Feet Vein, the coal now in use in these engines, is

Carbon	90·25
Hydrogen	4·12
Oxygen	2·25
Nitrogen, &c.	2·13
Ash...	1·25
	100·00

It is therefore practically coke, and requires only proper treatment for substitution in the place of coke. Another great advantage in the use of this coal over all others in locomotive engines is its almost entire freedom from smoke, thus rendering any plan of smoke-burning unnecessary, not even a steam jet being required when the engine is standing.

The advantage of slow speed is so distinctly shown in the results obtained that the writer considers this point is worthy of more attention than it usually receives on railways; for a slow speed not only economises the quantity of fuel consumed by diminishing the resistance of the train, but also increases the evaporative duty obtained from it.

Discussion.

Mr. TOMLINSON explained that the firebrick was merely broken up into small pieces of about 3 inches cube, and thrown in roughly with a shovel in a single layer over the grate, so as to cover the firebars; it was found to last a long time, and in one special trial that he had made to ascertain its durability the fire was not dropped for six days, the engine running continuously 100 miles per day, and at the end of that time the firebrick still remained as an efficient protection for the grate bars. The thickness of the fire was an important point: it might be 9 or 10 inches thick at the sides, where the absorbing surfaces of the firebox kept down the temperature; but should be as thin as possible in the centre, so that the bars could just be seen through it, for the bars would go down in the centre in spite of all precautions, unless the fire was kept very thin, on account of the intense heat. By the experiments the injurious effect of increased speed was remarkably shown, not only in increased consumption of fuel, but also in diminished evaporative duty of the fuel, which was reduced about 10 per cent. by an increase of speed of 5½ miles per hour, or about 50 per cent. In the trial that he had made of Newcastle coal, he had found that the bituminous Newcastle coal demanded very different circumstances for its economical consumption, requiring a much greater supply of air; it consequently received imperfect treatment in ordinary locomotive fireboxes, where no provision was made for an extra supply of air beyond that admitted through the grate; so that the evaporative duty obtained in the trial was only 5¼ lbs. of water per lb. of fuel.

The results of the trials in consumption per ton per mile were not always thoroughly reliable as a means of comparison, on account of the great fluctuation in the weight of trains down, some being as much as 700 or 800 tons down hill, which would materially affect the result; the fall was nearly uniform from one end of the line to the other, amounting to 409 feet in 24 miles, or an average gradient of 1 in 309. The coke cost 12*s.* 6*d.* per ton and the coal 6*s.* 8*d.* per ton in the wagons upon the railway; so that the cost of fuel when coal was used was little more than half of that with coke, as the consumption was about the same in quantity to do the same work.

Mr. R. LAYBOURN said he had made some trials of burning Welsh coal in locomotives on the Monmouthshire Railway, about eighteen months ago, with coal from Nixon's Deep Duffryn seam, the same seam of coal as the Aberdare Four Feet Vein, but found the bars came down in the way described: this was obviated by using inferior coke for lighting the fire, which formed a portion of clinker over the bars that served to protect them; by this means he succeeded in using the coal. He had made a series of experiments, which led him to the adoption of a considerable proportion of coal mixed with the coke for the locomotives on the Monmouthshire Railways. In the half-year ending December 1855, and previously, coke alone had been used, at an average rate in that half-year of 40 lb. per mile for all the trains, passenger and goods, costing 3·12*d.* per mile of the trains for fuel. In the following half-year to June 1856, a quantity of coal was mixed with the coke; and in the next half-year to December 1856 this was increased to an average of 22·73 lb. of coal per mile and 17·85 lb. of coke, making a total consumption of 40·58 lb. per mile, at a cost of 2·56*d.* per mile of the trains for fuel. The proportion of coal was then further increased, and the results were—

In the half-year ending	Coal.	Coke.	Total Consumption.	Cost of Fuel.
June 1857	39·25 lb.	5·60 lb.	44·85 lb. per mile.	2·09*d.* per mile.
Dec. 1857	39·71	5·20	44·91 —	2·13 —
June 1858	34·15	7·21	41·36 —	2·10 —

He had not tried fire-brick, but by getting up the fires with inferior coke a clinker was formed over the grate, which was found to answer the purpose of protecting the bars.

Mr. TOMLINSON said that the weights given in the tabular statement of experiments were those of the trains alone, independent of the engine and tender, which would add about 45 tons, the engine being about 29 tons weight and the tender 16 tons.

Mr. B. FOTHERGILL had been engaged recently in experiments on this subject, and he agreed entirely with the statements in the paper, as to the efficiency of coal for locomotives in place of coke; and that the quantity of coal required was not greater to do the same work, if suitable provision was made for its proper combustion. His experiments had been made with the partially bituminous coal of Lancashire and Yorkshire; and he had also made one trial with the Welsh smokeless coal in a locomotive engine, but it was impracticable to complete that trial in consequence of the firebars melting down upon the trip, so as to stop the engine after having run only a short distance. It was not from defect of the coal that this stoppage of the trial took place, but entirely from the melting of the firebars; and it was evident that without some provision for protecting the bars from melting, the Welsh smokeless coal could not be employed in locomotives. In two trials he had made, the cost of fuel for taking the same train over the same distance of 96 miles was found to be with coke at 11*s.* 6*d.* per ton, 22*s.* 3*d.*; with coal at 5*s.* 3*d.* per ton, 9*s.* 5*d.*; showing a saving of 57 per cent. in the cost of fuel consumed when coal was used. Locomotive engines using coal might always be made to burn their smoke satisfactorily. A point of great importance was the relative durability of the boiler tubes and firebox with coal and with coke; and after the practicability of using coal with great economy in cost of fuel had been established, this became a serious question in deciding whether to go on making coal-burning engines instead of coke engines. It had been feared at first that there would be a loss from more rapid destruction of the brass tubes and copper firebox with coal than with coke; and he had been recently engaged in an investigation of the subject on the London and South Western Railway, where coal-burning engines had been worked for a long time, for the purpose of ascertaining the real lifetime of the tubes under the two circumstances. The result was found to be that in twenty-six coke-burning engines the average duration of a set of brass tubes was 94,518 miles, varying from 65,000 to 127,000 miles, according to their quality and the description of coke used. But in several engines running with half coal and half coke, the tubes had run 154,955 miles, and were still in good working condition; and in one of these engines the

Digitized by Google

tubes after 137,676 miles' work were not half worn out, and were reduced in thickness only from No. 13 to No. 16 wire gauge, or from ·095 to ·065 inch. From the results of this investigation he was satisfied that the ordinary wear of the tubes was caused mainly by the cutting and abrading action of the hard particles of coke drawn rapidly through the tubes, and was not entirely a chemical action as had been at first supposed; and consequently the comparative softness of the particles of coal greatly reduced this cause of wear. This was illustrated by the wear that ordinarily took place in the fireboxes of coke engines, in which the roof and upper portion were reduced only $\frac{1}{32}$ inch in thickness, whilst under the firedoor and at the lower part of the sides, where exposed to the continued wear of the hard pieces of coke, the thickness became reduced $\frac{1}{8}$ inch in the same time. He was satisfied that the durability both of tubes and fireboxes would prove much greater with coal alone; and that there was no ground to fear more chemical action from sulphur with coal than with coke.

Mr. Tomlinson said that the quantity of sulphur in the Welsh steam coal was very small, and was included in the 2·13 per cent. of nitrogen, &c.; in the Four Feet Vein the proportion of sulphur seldom exceeded from 1 to 1½ per cent., and was never more than 2 per cent.

Mr. W. G. Craig said he was satisfied that the tubes had a much greater durability with coal than with coke. For the purpose of burning coal he had used a firegrate constructed with each alternate bar raised 1 inch above the others, making a kind of hollow fire, leaving spaces for air to enter under the fuel; the bars were not found so liable to burn in that arrangement as with a level grate, being protected by a greater supply of air on their top surface; a set of bars now lasted several weeks with coal, instead of only one week as before when they were all level.

Mr. J. Fenton observed that the low evaporative duty obtained from the Newcastle coal, when burnt without consuming the smoke, showed the great importance of ensuring a sufficient supply of air for bituminous coal, and a considerable larger quantity than was required for a coke fire.

Mr. W. Smith remarked that he had seen a construction of cast-iron channelled firebars by Mr. Gray, in an application of which every alternate bar was raised about 1½ inch above the rest: sloping notches or channels were made across the top edges of the bars, to afford an increased area for supply of air; several sets were at work in London, burning coal, and they appeared to answer satisfactorily, giving an increased supply of air, and lasting longer than the ordinary bars from the greater cooling effect of the air.

Mr. Tomlinson said he had tried a set of Mr. Gray's firebars for a stationary engine grate under a large Cornish boiler, but had not found there was much advantage over a set of thin cast-iron bars which he had tried in a companion boiler of the same description; the latter bars were 3½ inches deep by ¾ inch thick at top and ½ inch at bottom, with ¼ inch spaces. In both boilers the firedoors were perforated in the same manner as the locomotive firedoor, and provided with sliding shutters to close the air holes; there was also a damper below the fire to shut up all close when the incline was not being worked. He thought that in practice the channels across the bars were more frequently filled with dust than clear, and hence the absence of any good effect resulting from them. The bars that he used for locomotives were wrought iron, 4½ inches deep by ⅞ inch thick at top and $\frac{5}{16}$ inch at bottom, and ⅜ inch spaces when new. In some engines the same set had lasted five months when burning about 45 lbs. of coal per mile and running about 500 miles per week: their average duration was about three months, which was gradually increasing.

Mr. R. Laybourn observed that an important consideration in the matter was the great variation in the quality of coal obtained in different districts, so that a special plan had to be arranged on each different railway to suit the coal to be used there. He had made trial of a plan of firegrate by Mr. Jeffreys, of the Shrewsbury and Hereford Railway, in which the bars were laid flatways on the side instead of the edge, with air spaces between, and partly overlapping one another, forming a gradually sloping surface from each side of the firebox down towards the centre; this arrangement proved successful in admitting a larger supply of air, and he found it effective in burning the bituminous coal.

Mr. Maudslay observed that this was similar to Mr. Crampton's firegate, that was used on the French railways, except that in the latter the bars were laid transversely instead of longitudinally in the firebox, forming a surface sloping down from the firedoor towards the tube plate.

Mr. E. A. Cowper observed that in Mr. Gray's plan of firebars that had been referred to, the general arrangement he believed was to have ½-inch bars and ½-inch air spaces, giving 50 per cent. area of opening in plan for the admission of air; but the effective area was increased to 60 or 70 per cent. by cutting sloping notches in the top edges of the bars, so that portions of the top surface of the bars were cut away. He did not know what were the results of their working, but thought the use of very thin bars fully answered the purpose required; he usually employed bars only ½ inch thick at top and ¼ inch at bottom, with ⅜-inch spaces.

Mr. Tomlinson said that a set of Mr. Gray's firebars had been tried for some time in the "Iron Duke" locomotive engine on the Great Western Railway; but he did not think any plan of stepped grate would be suitable for burning the Welsh coal, for he found that if any one of the ordinary bars was accidentally left standing up above the others, from the notch in the firebar-frame not being cleaned out, it was sure to get burnt more than the rest.

Mr. E. A. Cowper had heard that a plan had recently been tried in some locomotives on the Great Western Railway, for tipping up the entire firegrate upon a centre bearing, so as to allow of laying the fresh fuel on the bars, and then covering it over with the red fire when the grate was tipped back again sharply.

Mr. R. Laybourn believed that was Mr. Jeffreys' plan, and was intended as a mode of making cast-iron bars suitable for locomotive firegrates: this was effected by never disturbing the cast-iron bars on their bed, and they were never removed until worn out; but when the fire had to be dropped the whole frame was tipped over on a centre bearing, allowing the fuel to drop out. This plan gave great economy in the cost of maintenance of firebars, as cast-iron was used instead of wrought-iron bars; and the bars were preserved from injury by avoiding the handling of them whilst hot, which was liable to bend or break them.

Mr. J. Fernie said an arrangement of ridged firebars had been tried for a stationary engine boiler at Derby, on Mr. Chanter's plan, in which the top of the bars was ridged or serrated, and every alternate bar was moved longitudinally about 1 or 1½ inch backwards and forwards, the intermediate bars remaining stationary; the alternate bars were moved by a transverse shaft provided with a lever, which was moved occasionally by the stoker. These had been in use about two years, and were found to answer the purpose satisfactorily; the ridges on the bars served to keep the fire gently stirred, preventing clinkers from adhering to the bars.

Mr. W. G. Craig observed that for burning coal it was requisite to have the bars rather close together and very thin, considerably more so than with coke; and the object he had in view in using a grate with the alternate bars raised above the others was to admit more air under the fuel, making a kind of hollow fire, to prevent the bars from burning. The firebars he used were ⅞ inch thick at top and ½ inch at bottom, with ¾ to ⅞ inch air spaces, and when placed alternately raised they could be brought still closer.

Mr. J. E. Clift inquired whether a pan of water had been tried under the firegrate, to prevent the bars being burnt; that plan was frequently used in stationary engines with good results, and by this means he had had firebars in constant use for two years with intense coal fires under gas retorts, without the bars burning away. There was constantly a supply of water under the firegrate, and the steam rising from it served to keep the bars continually protected and cool.

Mr. Tomlinson said he had tried a jet of water from the boiler kept continually running under the firegrate of a locomotive during the whole trip, but it did not serve to protect the bars from burning; he had not tried a pan of water, but with the jet there was so much water constantly supplied as to keep the ashpan full of steam, and he thought the effect would be the same as in the use of a pan of water.

Mr. C. W. Siemens observed that the efficiency of the water below the firegrate would depend a good deal upon the quantity of ashes falling from the fire; if the ashes fell easily they would keep up a supply of steam from the ashpan and preserve the bars from injury; but if much clinker were formed on the firegrate, the water-pan would not answer, as there would not be steam enough to keep the bars cool.

DESCRIPTION OF A DIRECT-ACTING EXPANSIVE STEAM ENGINE.*

By Thos. T. Chellingworth.

The very general use of high-pressure non-condensing steam engines makes the economy of their working and construction a matter of considerable importance. There are many cases in which circumstances will not admit of the use of a condenser, such as the absence of a good supply of water without deep wells and expensive apparatus for lifting; or where the work to be done or the capital available will not admit of the expense of a condensing engine. In any of these cases it becomes a most important consideration that economy in the first outlay, which is a frequent reason for the use of a non-condensing engine, should be combined with economy in the working also. The economy obtained with a single slide valve, by giving an additional lap and cutting off the steam at an earlier part of the stroke, can be carried only to a moderate extent, and the use of a separate cut-off valve is found necessary to obtain the full advantages of expansion.

With the view of obtaining simplicity and economy of construction, the writer has endeavoured in the engine described in the present paper, with a single cylinder and a simple slide valve and without any additional valve gearing, to cut off the steam at an early portion of the stroke after having been admitted at a high pressure, and to expand it very nearly down to the atmospheric pressure. The steam is first admitted to the top of the piston, and after having made about two-thirds or three-fourths of the down-stroke, it is cut off and expanded to the bottom of the stroke; the same steam is then admitted to the under side of the piston and expands through the whole of the return stroke; being in fact used in the same manner as if it were cut off at about one-third of the single stroke of a cylinder double the length. In order to obtain this result it is necessary to have a piston with two different areas, the steam being first admitted on to the smaller area and then expanded on to the larger one.

The construction of the engine is shown in figs. 1, 2, Plate XVI. Fig. 1 shows a front elevation, and fig. 2 a longitudinal section. The cylinder A is bolted to the base-plate and also to the standard B by snugs at the back. The piston C is cast in one piece and bored out to receive the end of the trunk D, being secured to it by the bolt E, which also forms the eye for attaching the connecting rod F. The piston is dished and fits into the cylinder cover, leaving only a small space between, the stuffing box projecting inwards; this shortens the height of the engine while it admits of the piston being lightened. The steam ports G and H are placed next to each other; and the exhaust port I, underneath, instead of between them, as in the ordinary construction; the valve K is an ordinary D slide worked by an eccentric and rod; figs. 3 and 4 show the extreme positions of the slide valve. In starting, a difficulty would be caused by a partial vacuum being formed by condensation of the steam before the lower part of the cylinder gets heated; this is obviated by the starting valve L, consisting of a small conical plug which is drawn back by a screw, and opens from the steam chest into the top port G, by means of which the engine is easily started at any point of the stroke.

In this engine the steam is first admitted through the top port G, and acts on the annular space round the trunk D, being cut off and expanding in proportion to the lap of the valve: then in the return stroke the two steam ports G and H are thrown into communication with each other by the inside of the same slide valve, as in fig. 4, and the same pressure acts on both sides of the piston, the return stroke being made by the unbalanced pressure of the expanding steam acting upon the area of the trunk; and during this up-stroke there is no back pressure from exhaust. Fig. 5 shows the indicator diagram taken from this engine, the full line being the diagram from the upper side of the piston and the dotted line from the under side, the bottom line of the one and the top line of the other being necessarily identical; the speed of the engine was 60 revolutions per minute.

The engine as described is working at the writer's works at Westbromwich, and an engine of similar construction at Mr. Dowler's works in Birmingham; in the latter engine the connecting rod, instead of working direct on the crank, is connected to the end of a beam, the present cylinder being in the place of one of the ordinary construction, which has been removed.

* Paper read at the Institution of Mechanical Engineers.

In the Discussion which followed, Mr. Chellingworth said that the engine was about 4 horse power, and worked with 40 lb. steam in the boiler; and it had been eight months at work. He showed the piston and trunk taken out of the engine; the piston had been working at present without packing, with merely a groove turned round the centre to receive a packing ring, the groove being supplied with oil by two small holes from the centre of the piston; the piston was found to work well and steam tight, having a great length to serve as a guide. The consumption had been 21 cwt. of engine slack during a six days' trial of ten hours per day.

Mr. Clift said he had seen the engine at work and had seen the indicator diagrams taken; it worked very satisfactorily, the up and down strokes being nearly uniform, and it ran steadily at a high speed; it was simply a means of carrying the principle of expansion much further in small engines than was usual, with a simple, compact, and very economical construction; and he had no doubt it would be found an efficient engine.

Mr. W. Smith observed that the general arrangement of the engine appeared to be the same as had been adopted in several previous plans of trunk engines, and he did not see any novelty or special advantage in the one now shown; he thought the cylinder should have a steam jacket if it was intended to be economical in working.

Mr. Chellingworth said the only object had been to get a simple and convenient expansion engine, giving a considerable degree of expansion with an ordinary single slide valve, cheap in manufacture and economical in working, and suitable for the cases of ordinary small engines, which were generally very imperfect in economy of steam. A steam jacket had not been used in the present engines, as economy of construction was specially aimed at; but he intended to add a steam jacket where practicable, to prevent the drop of pressure shown in the indicator diagram on letting the steam into the bottom of the cylinder.

Mr. I. Smith remarked that with a flat cut-off slide working on the back of the valve the steam might be readily cut off at any part of the stroke in an ordinary cylinder, by the addition of a simple expansion gear. He had lately seen an engine working at Bolton with a good form of expansion gear of this description, by Mr. Schiele, in which the steam was cut off either very early or later in the stroke as the work to be done required more or less steam, by means of the ordinary governor being connected to the expansion gear, which served to regulate the engine without the intervention of a throttle valve: he had seen the indicator diagrams obtained from the engine, which showed a very high degree of expansion.

Mr. Inshaw said he remembered an engine many years ago, of a similar construction to that described in the paper, in which the trunk was two-thirds the area of the cylinder, and the steam was superheated by means of a firegrate below the cylinder.

THE EXHIBITION OF FEMALE ARTISTS.

The small gallery in the Haymarket, where this—the third—exhibition is now held, is hardly spacious enough for its purpose; so assiduous are our fair practitioners, and so much have they gained in strength as well as numbers. Apart from the motives of mere curiosity which may prompt sundry visitors, there are not a few of the pictures which, besides their intrinsic merit, would otherwise repay examination. Flowers, fruit, and still life appear to be in general the favourite studies; and, as might be expected, these are ordinarily the most successfully handled. We may refer especially to "Wild Flowers" (134); "Spring" (2); "A Study from Nature" (68); "Flowers" (114); "Study in Spring" (167); "Fruit" (218); and "Autumn Fruit" (250); to which are attached the names of Ellen Cantelo, Emma Walter (2), Florence Peel (2), Miss Lance, and Mrs. V. Bartholomew. Some articles of domestic use have been carefully copied in (295); and (235) is a painstaking study of various shells, by Marianne Stone.

(56) Is a very masterly delineation of a Swiss scene, as is an English scene, "Hop-picking at Seven Oaks" (77). An attractive picture, too, is (181), "The Colossi at Sunrise, Thebes," which are invested with becoming stateliness and solemnity. Among the careful "transcripts from nature," (266, 270) must not be overlooked, and others of the same kind will be readily discerned here and there on the walls. (43) "Marie Antoinette at the

Digitized by Google

Conciergerie," by the Hon. Mrs. Monckton Milnes, is a portrait which will be scanned with sympathising interest.

A few drawings, embracing more or less architectural subjects, may be enumerated. A well-known name among contributors of this kind is Miss L. Rayner, who is here an exhibitor of four such pictures—"Christ Church Gateway, Canterbury" (21); Salisbury Cathedral, from Silver-street" (39); the "South Aisle, Westminster Abbey" (120), (scarcely equal to the others); and (229) "Old Houses at Gloucester." There are two other views in Westminster Abbey—one, taken in the "Ambulatory" (74), is by Miss Beale, who is not very happy in indicating Gothic details; the second, on the contrary, is a capital bit of manipulation (110), in which Miss M. Porter reproduces the "Entrance Gates, &c. to Henry VIIth's Chapel." In (7) we have a sunset effect on "Whitby Abbey," in which that venerable ruin is excellently shadowed forth. Rivaulx Abbey, too (62), with its enchanting scenery, finds a skilful limner in Miss M. Stone. Two views of Bamborough Castle (20, 31) are interesting, and nicely coloured. In (30 and 85) Mrs. Higford Burr exhibits two architectural subjects from Verona; the first is a "Tomb in the Pellegrini Church of St. Anastasia," and the second shows the "Pulpit in the Church of St. Fermo," in which a preacher is seen addressing his audience evidently in a strain of impassioned fervour. These drawings are both carefully detailed, as well as being quite artistic in effect. (27) claims our attention as being professedly an architectural subject—"St. Ann's Chapel, Malvern Abbey;" but it is not altogether so successful as could be wished. Nether Hall (97) is better. The "Church of St. Pierre, Caen" (163) is well given; as is the Rue de l'Ecu, Coutance (228). The "View of Fitzroy-square" (111), is careful, but only locally interesting, and the same may be said of (279), "the Old Steyne, Brighton."

INSTITUTION OF CIVIL ENGINEERS.

J. Locke, Esq., M.P., President, in the Chair.

March 29.—The whole of the evening was occupied by the Discussion, commenced at the last meeting, of Mr. Jackson's Paper, "*On the Melbourne Gravitation Water Works.*"

It was remarked that there was a vast number of instances in this country of the collection of water, in a similar manner to that adopted at Melbourne, from drainage areas, generally of a mountainous character, in which the water was received into artificial reservoirs, of sufficient capacity to equalise the irregular rainfall for many years in succession. The present mode of treatment was rather the result of experience than of original reasoning, which for the most part had been erroneous. The method of procedure was this: first, the extent of the drainage area was ascertained; secondly, the amount of rainfall was arrived at by taking an average of a number of years' observations in the neighbourhood; and thirdly, the quantity of rainfall that could be collected into any reservoir which it was practicable to make in the district had to be considered. The capacity of the reservoir should be proportioned to the population to be supplied; and its area was usually about one-twentieth part that of the water-shed. It was almost impossible by means of reservoirs to govern vast floods, and when they occurred an uncertain quantity of water would flow over the waste weirs, and be lost. This loss was usually estimated at 10 per cent., or, with a rainfall of 50 inches, 5 inches. There was also to be deducted the amount lost by evaporation. This, it had been found by experience, might be assessed at 15 inches in this country; so that there could be collected about 30 inches of rainfall. The size of the reservoir to receive and make that quantity available differed in different parts of the country. In Lancashire, where the rainfall was about 48 inches, the reservoir should be capable of storing one hundred and forty days' supply; in Cumberland, where the rainfall amounted to 60 inches, one hundred and twenty days sufficed; but in the eastern parts of England, where the rainfall did not exceed 22 inches, two hundred days' supply should be provided for. As to the amount to be supplied, it was believed that if the waterworks were well managed, and care was taken to prevent waste, 16 gallons per head per diem were sufficient for all sanitary, manufacturing, and domestic purposes; or where the manufactures were in excess, then from 18 to 20 gallons might be allowed. Where the internal fittings, particularly those called sanitary, were not properly looked after, then the waste would cause that amount to be increased from 30 gallons up to 60 gallons per head per diem, and in New York it was reported to be 90 gallons per head per day. The laxity which prevailed as to the internal fittings, leading to this great waste, was alike destructive to the interests of those who supplied the water as well as to those to whom it was supplied; for in many parts of England a scarcity was already beginning to be experienced.

With regard to the particular works under discussion, it was felt that as the rainfall seemed to be less than in England, and the area of the reservoir to be one-fourth that of the water-shed, and as the evaporation from that large surface as well as from the land must, from the statements made in the Paper, nearly approach the whole supply, a want of water was likely soon to arise. There could therefore be little hope of any large quantity of water, adequate to the requirements of the future population, being permanently obtained from the same source. In reference to the fracture of the pipes, 33 inches in diameter, laid through the embankment, it was observed that the same thing had occurred under an embankment, less than 12 feet in height, of a reservoir near Prescot, for the Liverpool water-works.

Fully one-third of the pipes so placed, which were 44 inches diameter, and excellent castings, were broken; and the fractures invariably occurred at the top and bottom. It was remarked that cast-iron in the form of a pipe would stand little external or unequal pressure. If ruptured when in use the water would escape into the embankment, and if it found its way to the back of the puddle the embankment would be torn down and the water in the reservoir be set free. It was not therefore desirable that large pipes should be laid under an embankment where they would be subject to a considerable pressure of earth. It was mentioned incidentally that all plans for conveying the sewage of London through pipes in an embankment, with an unequal pressure of earth upon them, were opposed to experience, and would result in inevitable failure. Then again, the Paper stated that the diameter of the main had been gradually reduced throughout its length from 30 inches at the commencement to 24 inches at the end. For this there was no apparent reason; and although that plan had been adopted in some of the old water-works in England, it had long since been abandoned.

It was observed that when a town was to be supplied with water by surface collection, the first point to be ascertained was the average rainfall over the entire gathering ground, and then the proportion available for storage, which was dependent upon the varying conditions of the rainfall. At Bombay it had been estimated at six-tenths. In the construction of dams for impounding water, it was believed that sufficient attention had not been paid to making them consistent throughout; hence failures arose from their not being watertight. This was to be attributed chiefly to their being raised by the earth being tipped from waggons. At the Edinburgh water-works all waggons were excluded, carts only being allowed, and the banks were formed in layers 6 inches thick, each layer being thoroughly indurated and punned. It was a matter of importance that the best system of constructing dams should be practised, so as to allow of their being made as high as was consistent with safety, as a little extra height added greatly to the capacity of the reservoir. It seemed to be generally admitted that there was great waste in the water supply; for although 20 gallons per head per diem were usually allowed, yet not more than from 5 gallons to 7 gallons per head per diem were used. Opinions were divided as to what became of the difference; whether the loss occurred in the houses or in the mains; but it was thought that the latter was the chief source of waste, and at all events the former could in most cases be checked by the use of meters.

From experiments which have been made with a Dalton's gauge, it was argued that as much as four-fifths of the entire rainfall in this country were lost by evaporation from the surface of the land. This result was corroborated by gauging a neighbouring river, when it was found that the discharge of the river did not much exceed the proportion of rain which percolated through the soil of the gauge.

It was contended that experiments upon a large scale did not show that the amount of evaporation in this country was nearly so high as had been stated; much more rain being impounded year by year than such a statement would lead to the belief. In constructing dams over a loose alluvial bottom it was essential to go below it for a foundation, and with a rocky bottom, seams, fissures, and uprising springs must be especially guarded against. The Holmfirth embankment was said to have been made rotten by a spring in the centre. In one case which was mentioned the springs were collected in a puddled trench, and the water carried into a vertical well of brickwork, rising therein to a level of the adjoining river. It had been a general practice to carry culverts and outlet pipes through the deepest part of embankments; but it was believed that under no circumstances should an outlet pipe be placed in any portion of the 'made' embankment. There should be a vertical shaft or inlet tower, into which the water should be admitted by valves, and the outlet pipe from thence should be made by tunnelling or side cutting in the solid; so that the impounding dam might not be liable to the interference of water.

Allusion was then made to works for conducting and storing water in the east, particularly in India and Asia Minor. It seemed that in many cases the natural springs had been sought out, the water being conducted in earthenware pipes, provided with ventilating shafts, settling wells, wash-out places, and other appliances as perfect as could be devised at this time. The lines of aqueducts for the supply of Constantinople were also described. It was thought that the plan of gathering water, and conveying it through earthenware pipes to a common strong service reservoir was one that might be followed where the springs were tolerably permanent, and in some situations it might be preferable to the use of an impounding reservoir.

Digitized by Google

It was asserted in reference to the enormous waste in the distributing apparatus of towns, that at least two-thirds of the supply to London were lost. Where the supply was regulated by ball-cock the ball was often deliberately unscrewed, and the water run out of the cisterns. Leaky pipes and taps, and especially leaky mains, were likewise the cause of much loss.

With regard to the Melbourne Water-works, it was remarked, that they appeared to be dependent upon the drainage area of 5200 acres. Now, if the statements in the Paper were to be credited, there would seem only to be a rainfall of 6 inches or 7 inches over that area available for the water supply, after deducting the loss by evaporation. This might suffice for 100,000 persons, but as the population of Melbourne was fast increasing, it was almost impossible that a continuous supply could be afforded for many years from this collecting area. It was true that the drainage area of the river Plenty was given as 40,000 acres, which would amply meet the demands of Melbourne for many years to come, but it did not appear that the river had any connexion with the water-works. As to the question of the parallelism of the mains, it was agreed that under certain circumstances, when a main was entirely open as an outlet, and was discharging with its full force, the line of pipes might be tapered. But that was not the condition under which water was sent through pipes for the supply of a town. The pipe was not open at the ends, and the resistance to be overcome was simply that occasioned by the friction of the water moving along the pipe. It was the same throughout, and therefore the parallel figure was the proper one. Towns situated near mountainous districts could not be supplied by streams in a minimum condition, as they were at present appropriated by mill-owners, by bleachers, by paper-makers, by dyers, or by some or all of these trades. This was particularly the case in Lancashire and the West Riding of Yorkshire. If the streams were taken for the water-works, then these parties must still be afforded a regular supply. The reservoirs should be made sufficiently large to equalise all the storms which the country was subject to. Occasionally there might be an excess of downfall, resulting in floods as large as three hundred times the minimum volume, as had been stated; but it must be borne in mind that the minimum volume was about one sixteenth, or even one-twentieth of the mean volume. It had been ascertained, as the result of practice, that generally about one-third of the water utilised was given to the mill-owners and others, and the remaining two-thirds went to supply the inhabitants generally of the town. It had also been found that for a supply of 20 gallons per head per diem reservoirs capable of containing one hundred and forty days' consumption in the north-west of England, and from two hundred to two hundred and twenty days in the north-east of England, were sufficient. Only two instance of complete exhaustion, except where the drainage area was manifestly too small for the population, had been known to take place, and the cause in these cases could be readily explained. They both occurred on the east coast of England: one at Boston, which arose from 40 gallons per head per diem being allowed to be drawn from the reservoir instead of 20 gallons per head per diem; and the other at Newcastle, where the storage was not at the time sufficient, a new drainage area not having come into operation. It had been said that the Liverpool main was too large, not for the amount of water required, which was delivered with the greatest regularity and precision, but because when a pipe of that magnitude burst it usually did a great deal of damage. Repairs were also difficult of execution, the materials being heavy and inconvenient to handle; and if an accident should happen then the supply might be cut off for a day or two. A plan had been submitted to the corporation for two mains, each of 32 inches diameter, instead of one of 44 inches diameter, to be laid 200 yards or 300 yards apart. This it was found would increase the expense by 7000*l.*, and on its being put to the vote, by the corporation, there was a majority of two in favour of one line of pipes.

After the meeting, Mr. SIEMENS (Assoc. Inst. C.E.) exhibited a machine of his invention, manufactured by Messrs. Guest and Chrimes, for joining lead and other pipe, by pressure only. The machine consisted of a strap of wrought-iron in the shape of the letter V, and of three dies, two of which were free to slide upon the inclined planes, while the third was pressed down upon them by means of a screw, passing through a moveable cross-head, embracing the sides of the open trap. The pipes to be joined were placed end to end, and a collar of lead was slipped over them. The collar was then placed between the three dies, and the pressure was applied, by means of a screw-key, until the annular beads or rings projecting from the internal surface of the dies were imbedded into the lead collar. The machine was then removed, and a joint was formed capable of resisting a hydraulic pressure of 1100 feet. The security of the joint was increased by coating the surfaces previously to their being joined with white or red lead. The advantages claimed for this method of joining lead or other pipes over the ordinary plumber's joint were the comparative facility and cheapness of execution, as the cost of a joint of this description was said to be only about one-third or one-fourth that of the plumber's joint. A machine of a similar description was also used for joining telegraph line wires, a specimen of which was likewise exhibited by Mr. Siemens.

April 5.—The first Paper read was, "*On a new system of Axle Boxes, not requiring lubricating, and without liability to heating.*" By ALPHONSE DE BRUSSAUT.

The author first recapitulated the liability to accident arising from inattention to the constant greasing of the ordinary axle-boxes and journals of carriages and of machinery, the inconvenience of accumulating dust and grit on the bearings, and the friction and wear and tear arising from these causes. He then reviewed the numerous inventions and attempts to remedy these evils, showing that none of them had hitherto successfully abolished the necessity for the expensive and uncleanly use of some lubricating matter. He next proceeded to describe the system which he had introduced, and had applied somewhat extensively in France to various classes of machinery in which the use of grease had hitherto been considered indispensable. The new apparatus was described to consist of a series of four, six, eight, or any other convenient number of cylindrical rollers of the length of the journal, retained at certain distances apart from each other, yet still united by elastic bands of vulcanised india-rubber. These rollers, thus united, and placed around the journal, would be set in motion by the pressure of the axle, without the possibility of collision with or friction against each other, or of rubbing upon the surface of the journal or of the bearing, and thus avoiding as much as possible any friction or opposition to the motion of the journal. The action of rolling being thus substituted for sliding, there could not be any abrasion of the substances, and lubricating became unnecessary. The machines so fitted were stated to work with remarkable ease and steadiness, and to be set in motion and the speed to be kept up with considerable facility. No inconvenience had been experienced from the fracture of the elastic bands and shafts, making 450 to 500 revolutions per minute, working perfectly well, without any symptom of heating.

The reasons for this action were stated in a plain and comprehensive manner by showing that in moving a body of an octagonal form along a plane the action must be either by sliding or by rolling; in the former lubrication was necessary, whereas in the latter the presence of any lubricating matter would be prejudicial. Extending the latter principle to the cylindrical form, which was merely a body having an indefinite number of sides, it was evident that by retaining these cylinders apart by means of the elastic bands, so to avoid friction against each other or upon the journal or the bearing surface, a practically perfect rolling motion would be obtained, and it was contended that by M. Brussaut's system the two material results of rapid rotation without heating, and a complete suppression of the use of grease in all journals of machinery were arrived at.

The second paper read was "*On the Permanent Way of the Madras Railway.*" By BRYCE MCMASTER, Assoc. Inst., C.E.

It was remarked that two leading features in the construction of railways in India were, the cheapness of those works entirely dependent upon native labour and the resources of the country, and the expense of those dependent upon England for the supply of materials. Among the latter of these was the permanent way, almost every part of which had as yet to be furnished from England. Thus the portion of the Madras railway from Madras to Arcot, being a length of 65¼ miles, had been constructed for 6000*l.* per mile, of which amount the permanent way alone had cost upwards 3000*l.* per mile. On this portion of the line earthwork for a distance of 25 miles was for a double line, and on the remainder for a single line only. All the bridges and culverts were for a double way. There was only a single line of rails laid throughout.

The permanent way on the portion of the line above indicated, was laid with the double-headed rail, weighing 84 lbs. to the yard, in lengths of 20 feet. The rails were fish-jointed; and six sleepers were used to each rail length. The chairs, wooden trenails, and keys were all of the ordinary construction. West of Arcot the line was laid with rails weighing 65 lb. to the yard. These rails were laid on seven sleepers to the same length of 20 feet. The gauge was 5 ft. 6 in.

The expense of freight from England to Madras, for the first portion of the line was very heavy, owing to all the materials having been sent out during the time of the Russian war. A reduction in these charges, as well as in the weight of the rails, may be expected to diminish the cost of the remaining portion of the line; although the greater distance to which the materials would have to be led, as the work was pushed on into the interior, would add to the cost as the line advanced.

At the commencement of the undertaking tenders were invited in India for the supply of chairs, fishing-plates, bolts, and nuts; but the prices gave no ground for hope that the Indian iron could compete with the English, or that the Indian railways could look for any considerable supply from local sources. But what the country could supply was materials for sleepers, as its forests and jungles afforded a great variety of hard and durable woods well adapted for the purpose. On the Madras railway twenty-eight different kinds of wood had been used; all of which, with few exceptions, had been found to answer well when carefully selected. Although few woods were not attacked by the white ant while lying exposed, and the sap wood in particular was much eaten away, yet in two years after the trains began to run there was not a case known of a sleeper being attacked in the road. The vibration of the passing trains, and the frequent opening out of the ballast by the workmen, seemed suf-

Digitized by Google

ficient to prevent the attacks of this universally destructive insect. Many woods were also liable to the attacks of other insects, which bored holes into them; but the sleepers when covered with ballast appeared to be free from their depredations. Creosoted fir sleepers, sent out from England, were found to be very durable; but their cost at Madras was 8s. 6d. each, or 9s. 6d. each when led fifty miles to the works, while the sleepers procured in the country varied in price from 4s. to 6s. 6d. each. A few thousand half-round Sâl sleepers were kyanised experimentally with corrosive sublimate, at a cost of 6d. per cubic foot; but they were not found to be more durable than those of the same wood when unprepared. In the neighbourhood of Arcot granite blocks were used, but not to any great extent on account of the roughness and rigidity of the road. Near the coast one mile of line was laid with laterite, but the blocks were found to split, and their use was consequently abandoned. Some native-made keys and trenails were used, but the former were not pressed, and although they did very well in wet weather, in the hot season they shrank so much as to be unfit for use. The trenails, which were of teak, answered very well. In laying the road at first the natives were found, as in almost every other kind of work, intelligent and apt when care and patience were taken in their instruction.

The damage to the line from the settlements and slips, from the effects of the monsoons, had been much less than was anticipated, and one monsoon of extraordinary severity having shown all the defects, it was confidently expected that little damage would be done in future; and that the line would be maintained as cheaply as its construction had been inexpensive.

THE INSTITUTION OF FINE ARTS, 316, REGENT STREET.

THE exhibition this year may be pronounced a decided advance upon that of last, though this arises more from its general tone than from individual specialities. This is a fact for congratulation, and one that augurs well, we hope, for the future.

The president, Mr. R. S. Lander, contributes two excellent Scotch pictures: No. 364, "Head of Loch Long," and (397) "Ben Bladach." No. 53 is a large and grand landscape composition, "an October Morning—clearing the ground for winter sowing," by Mr. Peel, who, in (333) "Seeveyholme Leaps, on the Croglin, Cumberland," treats us to another fine piece of English scenery. Mr. Hulme proves himself as delightful a master as ever in the same school: his (80) "in the Meadows, Pyrford, Surrey," and (355) "the Way over the River," are perfect gems of art. Messrs. Herring and Rolfe are fittingly associated in three groups, two of which are farm scenes; one being (105), "the Pet Team"—full of incident; and the other (182), "the Homestead." No. 108, also by the same artists, is named "the Watering-place." Mr. Sidney Percy again lends his valuable aid to the exhibition in three fine pictures: (110) "near Hastings;" (368) a magnificent portrayal of "a Quiet Valley;" and (478) "Passing Shadows." Wild scenery, especially that of hedge and field, has another worthy exponent in Mr. Raven, whose pictures glow with colour and pre-Raphaelite manipulation. Nos. 122 and 126 may be pointed out in illustration of this,—a quality which is preserved also in the other pictures he exhibits.

Passing on in our examination we arrive at a gorgeously finished subject in water-colours (221), a scene from Lucknow,—a figure group,—more truthful, doubtless, than agreeable to look upon. A little farther on is a refreshing little lane scene (232) by Mr. Soper, cleverly touched in; and just beyond, a pleasant couple "Out of Town" (262), and sketching from nature. This latter is by Mr. J. B. Burgess, whose "Hot Chesnut Seller of Spain" (277) is another capital hit. No. 293 shows Mr. Needham's skill in foliage delineation; and No. 331 is devoted to "Beech Wood," which Mr. Leader characterises with praiseworthy skill and patience. No. 306, "Seaside Downs," forms a very good subject for Mr. H. Moore, who also appears to advantage this year in some other pictures. No. 326 is a pathetic scene, "the Last of an Old Comrade,"—two old soldiers are seen watching with saddened thoughts the cutting of an inscription on the tombstone of an old friend: it is painted by Mr. W. Macduff. No. 352 is another subject picture of quite a different kind, in which Mr. Hayllar amusingly indicates, by the mischievousness of a spoilt child, "the Way the Money goes." The Thames, as of old, furnishes an exhaustless theme: No. 372 is one of the many pictures devoted to this subject. No. 398, by Mr. Dell, is a tasteful little bunch of wood flowers. Mr. G. A. Williams presents some very good works, such as (318) "a Mountain Brook," (338) "Repose," and (415) "the Ice-cart," in which the cheerless haziness of a winter atmosphere is very well expressed. No. 457, by Mr. C. J. Lewis, under the title of "Sunday Morning" shows a picturesque old wooden porch to some village church, towards which two children are reverently approaching. One of the most telling landscapes in the collection is No. 459, the work of Mr. E. A. Pettitt, who appears to be a rapid as well as clever artist. In the picture before us, the rich verdure and clear atmosphere of June combine to produce a highly satisfactory bit of colouring, which the artist has felicitously transferred to his canvas. No. 474, "Leading Hay" (A. W. Williams)—a large picture illustrating another every-day scene—is very well given. No. 508 is one of several little cabinet pictures, by Mr. Chaplin, devoted to various kinds of fruit, and charmingly natural.

Among such works as belong more or less to the Pre-Raphaelite school, Mr. Smallfield's will take an honourable position. No. 319 is a larger picture than he ordinarily attempts, but it is throughout very excellently rendered. Showy colours are sufficiently balanced by subdued ones to prevent their becoming too prominent; but striving after excessive contrast seems to be the great aim as well as failing of this school. "Queen for a day" (269), partakes somewhat of this fault, but nevertheless the harmony of colours is very ably maintained. No. 397, "the Popular Song," is a truthful bit of indoor life. Mr. H. S. Marks in (225) gives a highly elaborated pen-and-ink sketch,—subject—"Macbeth's Porter;" and, in (565), gives vent to an irresistibly humorous whim, and calls it "Tooth-ache in the Middle Ages." No. 98 is one of Mr. Rossiter's numerous contributions,—clever, but overlaboured. "Itinerants" (407) is in some respects better; while "Too Hot" (564) is a suitable neighbour to Mr. Marks' "Tooth-ache," just mentioned.

Architectural subjects are here comparatively numerous, but in general do not require much particularising. Two London views by Mr. Sleap (37 and 220) must be pronounced decidedly bad; while another (226), "on the Thames, Millbank," is better. No. 246 "Old Palace Yard," is also pretty good. In (38) Mr. Parrott shews the apse end only of St. Pierre, at Caen; which, though good in its way, is not comparable with the exquisite steeple at the other end. His next picture, "the old Clock Tower, Rouen" (42), is more to our mind, albeit the architecture is none of the purest. Mr. Burnett has two views (43 and 55) at Venice, hardly outlined, and sadly deficient of texture. In the "Ruins at Philæ" (97), he has been more successful. We always welcome Mr. L. J. Wood as a really architectural artist, and though his subjects are generally delineated on too small a scale to convey more than general effects, as much care is taken properly to express the comparative "value" of the several constituent parts. The French edifices which form the subjects of Nos. 93, 94, 95, will be examined with interest. We cannot compliment Mr. Swarbreck's "Interior of the Chapel, Haddon Hall" (156); No. 264, "Remains of Jarrow Abbey," is, however, exceedingly good. This abbey is one of the very earliest architectural ruins in the kingdom. His "Interior of the Lady Chapel, at Rosslyn" (329) is also well shewn. "Teignmouth Castle, Northumberland" (380) is an interior view of the ruins of part of the old priory, now used as a barrack, and a very fine specimen of the "transitional" period of architecture. No. 404 is the last of this artist's contributions, and a worthy pendant to (264). In No. 214, Mr. Rudge has a distant view of that lovely ruin Tintern Abbey: No. 219 is Holyrood Abbey, by Mr. E. Sharpe. No. 286 is a highly interesting picture, by Mr. Gray, of "the Cottage, South Wingfield Manor House, Derbyshire," of which every part is carefully detailed. Nos. 241 and 244 are by Mr. Ernest George: in the former the fine Norman arches in Minster Church, near Ramsgate, are very correctly drawn. The church is altogether one of unusual interest to both antiquarian and architect. Mr. Henshall has two architectural pictures; one (287) shews "part of the Church of St. Jaques, Dieppe," and the other (402), Rouen, from the banks of the Seine. The odd grouping of the buildings in this picture is very noticeable, but there is a monotony about the whole which mars the effect. No. 300, "Evening, at Antwerp" is a pretty distant view of the town, by Mr. H. Williams; it appears however to lack power in the treatment of the foreground. No. 322 "Fetcham Church, Surrey" (G. B. Moore), with its ivy-mantled tower, forms a pretty picture, somewhat we think, out in the perspective; while Mr. Clark's "Dunsfold Church" (373), in the same county, will convey an idea of the exterior of one of the simplest and prettiest rural churches in England. It is throughout of Decorated date; and, owing possibly to its secluded position, has fortunately hitherto escaped any questionable improvement.

REVIEWS.

On Some of the Grounds of Dissatisfaction with Modern Gothic Architecture. A Lecture delivered at the Royal Institution of Great Britain. By EDMUND BECKETT DENISON, M.A., Q.C. London: J. H. and J. Parker. 1859.

Mr. Denison, though by profession linked to another pursuit, is, it need scarcely be remarked, enthusiastically devoted to architecture, especially as it is developed in our own mediæval examples. With these he has to a great extent made himself personally acquainted, and that not in a *dilettanti* sense merely, but historically and analytically. Hence whatever opinions he may venture to propound in connection with Gothic architecture, are sure to carry with them some weight, and to furnish at least materials for deliberation, though that may not always result in acquiescence. The form of *lecture* is the one which he has almost uniformly chosen for his purpose, and it must be allowed to be the best means of popularising the subject, which appears to be Mr. Denison's chief aim. Certain it is, that he is well qualified for such *vivâ voce* proceedings, his addresses being delivered from notes only: hence the apologies we meet with on their publication, that the author has used these notes only as an outline to be filled up, inasmuch as he does not profess to remember accurately what he said.

In the case before us we have a pamphlet of upwards of thirty closely printed pages, containing "a fuller version of the lecture than the usual abstract," and it of course has the advantage of being deliberately penned, and therefore it may be presumed, expresses in the most suitable terms the author's real views. Not by any means an insignificant portion of the address is occupied with purely self-laudatory remarks, which, even supposing them to be in good taste, particularly on such an occasion, are little more than egotisms which have been already printed over and over again. Who does not know that over the new parish church at Doncaster it was Mr. Denison's "lot to exercise an unusual amount of superintendence," and over its neighbour, St. James', which was completed at the same time, "something more than superintendence?" Yet a repetition and amplification of these assertions consitute a large portion of the bulk of this essay; and in other parts the writer goes over the same ground as in his "Lectures on Churchbuilding," which in a former number (April, 1856) we reviewed and quoted from at length, so that the portion which relates to the immediate subject is found to be included in a comparatively small compass. We believe that since Mr Denison's strong and weak points are by this time pretty well known, our readers will prefer hearing what he has to say as much as possible without note or comment, and will themselves perceive where to take it *cum grano salis*, and where to indorse it in its entirety.

By a curious coincidence the House of Commons was engaged on the identical evening when this lecture was delivered, in discussing almost the same theme in connection with the New Government Offices, and this circumstance furnishes Mr. Denison with the subject of his preamble, and which he has turned to account very dexterously.

"One would almost fancy that we were put back a couple of centuries, and listening again to the kind of description which used to be given of the Gothic style by the leaders of the public taste in the days of the Restoration, when all Gothic art was supposed to be dead and buried far too deep for any chance of revival. This is the character which the once celebrated John Evelyn, who was one of the commissioners for rebuilding St. Paul's cathedral, gave in his treatise *On Architecture and Architects* to the style of all the great cathedrals of the world except his own and its prototype at Rome. He calls it 'a certain fantastical and licentious manner of building, introduced by the Goths and Vandals and other barbarous nations, who demolished the glorious Roman empire with its stately and pompous monuments, and filled not Europe only, but Asia and Africa also, with mountains of stone, vast and gigantic buildings indeed, but not worthy of the name of architecture, congestions of dark, heavy, melancholy, and monkish piles, [Lord Palmerston's view of Gothic almost verbatim] without any just proportion, use, or beauty, compared with the truly antient; so as, when we meet with the greatest industry and expensive carving, full of fret and lamentable imagery, sparing neither of pains nor cost, a judicious spectator is rather distracted or quite confounded than touched with that admiration which results from the true and just sympathy, regular proportions, union, and disposition, and from the great and noble manner in which the august and glorious fabrics of the antients were executed;' with more nonsense of the same kind, to which other similar nonsense from other writers of the two last centuries might easily be added.

* * * * *

"I do not mean to 'prove' anything that I am going to say, or to give any reasons for it, except that I have arrived at certain conclusions or opinions from experience and observation, which you can verify for yourselves. I do not mean even to claim the merit of novelty for them. Most of them have been in substance published before, both by myself and by others. But what I have to say about them is, that within the last few months two buildings have been completed [St. George's and St. James' churches, Doncaster], in which these conclusions, or theories, or whatever you please to call them, have been enforced in practice for the first time, I believe, since the fall of Gothic architecture 400 years ago.

"I believe it is no exaggeration to say, that St. George's is universally considered the finest Gothic building of modern times; and as far as its pretensions go, the other is pronounced by most people who have seen it, to be fully equal, and in some respects superior, even to its more magnificent neighbour. Nobody is more sensible than I am of the faults in each of them, notwithstandiug their general success; but there is no building of any age without some faults quite as striking; and whether that be so or not, the conclusions which I have arrived at respecting the common cause of dissatisfaction with modern Gothic building are founded no less upon the defects than upon the beauties which are apparent in these two buildings.

"The first cause which I shall notice is one which few persons can have failed to hear alleged as an excuse for the inferiority of modern to ancient architecture in every style; and that cause is stinginess. But with the exception of a certain class of buildings which I will advert to presently, I believe it would be nearer the truth to say that so far from stinginess accounting for the general failure of modern architecture, there never was a time in the world when money was spent on building in such profusion.

* * * * *

"No doubt in the best Gothic times it was the case that the more elaborate a building was, the handsomer it generally was; and so it ought to be in all times. But so far is it from being so now, that I should almost be inclined to say, that if you wish to make quite certain of a failure in the most essential elements of good building, you had better give out at once that you do not care how much you spend. No doubt that looks like a paradox, and it is not a complimentary one to the present race of architects; nevertheless, I adopt it, not from theory, but from observation, and I believe that if you will use your own observation you will come to much the same conclusion. If it is necessary to account for such a phenomenon, I should attribute it mainly to the existence of one of the most mischievous delusions ever propagated on this subject—that '*ornamentation is the principal part of architecture.*'.....Mind, I am not saying anything so absurd as that arcitecture is not improved by suitable decoration; but I say that, as a bare matter of fact, a great deal of what is universally admired as architecture of a very high order, much finer than the most highly decorated modern building, is almost or altogether independent of both carving and colouring.

* * * * *

"I do not know whether it is owing to the latent or avowed belief in this theory that decoration should be aimed at first and principally, before instead of after all the other conditions of grand building are satisfied, or to pure and simple ignorance and incapacity for observation, that there are hardly any modern buildings which are not deficient in two primary elements of all grand building in any style whatever: I mean massiveness, and depth of shadow, which is the visible evidence of massiveness, besides having a beauty of its own.....The same fault is generally noticeable in the woodwork as in the stone of modern buildings; frequently, and with some architects invariably, it is even worse.....The old builders, who knew how to build stone roofs and wooden roofs, which are stronger now after five centuries than many that were built last year, knew very well that they were using more materials than were requisite for merely satisfying the mechanical conditions. But they knew also that engineering is not architecture, and that science is not art, though it is involved in it, at least in the art of Gothic building, the architecture of pointed arches, and vaults, and buttresses, of open roofs, and tall spires; and why should we not add of domes,—not the low and clumsy Roman or Byzantine dome, incapable of standing on its own base, but the truly scientific and beautiful Indian or Saracenic pointed dome, chiefly built I suppose in horizontal courses, and therefore capable of standing alone, and presenting an outline like a tall Gothic arch standing on its piers, and with a more than Gothic independence of abutment beyond them!

* * * * *

"The next common modern mistake which I have to notice, is another instance of a truth turned into falsehood by exaggerations. You have all heard or seen how St. Peter's at Rome fails, from the magnitude of all its parts and details, in producing the proper impression of its size, and you will see in Mr. Fergusson's and Mr. Garbett's books some strong observations on and illustrations of the same want of subdivision of even the Gothic cathedrals on the continent, into parts of moderate size with a distinct outline to each—an art which was far better understood by the English architects, who knew how to give to our cathedrals an appearance of almost unlimited extent, though they are generally smaller than the foreign ones. Well, all this is perfectly true and right, and it is undoubtedly an architectural blunder to have great size and yet not to get the full effect out of it. But the modern architect interprets this truth to

Digitized by Google

mean, that if you only make plenty of distinct parts in a building or a window, of any size, and put plenty of stages in a buttress, or mouldings in an arch, the eye will be cheated into believing that the building is large, the window a grand one, the buttress high and deep, and the wall thick: precisely the reverse of all which is the fact. The eye is not such a fool: though its owner may not be wise enough to know how he has discovered the cheat, yet he always does discover it—and more; for by a strange but just retribution, buildings designed on this fraudulent principle generally look even smaller than they are; and for this reason: the eye soon perceives that everything within its power of measuring is small and paltry, and therefore the mind instinctively concludes that the whole is, whether it is in fact or not. Of the two mistakes, the old foreign one is immeasurably the best; inasmuch as it is far better that you should find a building to be greater than you thought at first, instead of gradually discovering that the more you see of it the more paltry and mean and good for nothing it is: not that buildings are the only things of which this is true.....I have already alluded to the modern passion for the foreign characteristic of height, and the disposition to sacrifice to it the more English and certainly more useful one of length. I should say of height, as of ornamentation, of course it is a valuable element of architectural effect, but it ought to come last, not first; and I will add, as my own opinion, that it ought very seldom indeed to be the leading characteristic of a large building; for when it is, it is extremely likely to destroy that character which everybody understands by the term Repose, and for which our own long cathedrals seem distinguished above all others in the world. Some of them are undoubtedly too low; but too low for their breadth, not their length; and with our usual discrimination and good taste, breadth is the dimension into which we almost invariably expand now when size is wanted; and thus the length is doubly overpowered..... A still worse fault of the same family is the passion for building high spires on bases about half as wide as the old ones. This vile practice seems to me to concentrate all the bad taste, and pretension, and ignorance of proportion, which will be recorded some day as the characteristic of this age. The architects profess to be reviving the architecture of the thirteenth or fourteenth centuries—'taking that as their starting point' for further development; and yet they seem to have discovered that the builders of Salisbury, and Norwich, and Grantham, and Coventry, and Louth, and Newark, and Lincoln, and Ely, and old Doncaster, and all the towers of the West, knew nothing of their business, and of the proper width for a tower in proportion to its height..

* * * * *

"There is only one more physical cause of the general failure of modern Gothic architecture which I mean to speak of. And on this one I am glad to say that I can agree with Mr. Ruskin as thoroughly as I differ from him about some others, especially his ornamentation theories. The thing I refer to now however is no theory, but a simple matter of observation so plain and obvious that there is very little to say about it, except to desire people to pay no attention to theories of perfect building, but to use their eyes; which, however, is generally the last thing we learn to do. Now everybody who does condescend to learn in that way, will see, the first time he really looks at any old Gothic building in good preservation, and at any new one, that the old one is, as a builder would say, shockingly inferior in the execution of the work. He will see no kind of precision about the joints anywhere; no edge, or *arris* (as the builders call it), is either quite a straight line if it professes to be generally straight, or quite a regular curve if it is curved.....In short, you will see what will strike you as a general carelessness about execution; and usually the inequalities are greater in large work, heavy mouldings, and bold carvings, than in small; or, as Mr. Ruskin well expresses it, 'the execution is always subordinate to the design.' Whereas, the pride of modern work is precision and *finish*, as the masons and clerks of the works will tell you themselves, and probably call your attention to the excellence of their performance in that way, if you give them a chance."

The following is a suggestive paragraph, and it will be seen to bear out our remarks with regard to the author—

"I have described in the book before referred to how I accidentally learnt that 'finishing' is really spoiling, by finding a moulding lying about which seemed to me exactly right, and like an old one, and being told by the man whom I asked how it came to be so, that 'it was not finished.' I have not time to dwell further on this point now, beyond saying that with extreme difficulty, and in spite of resistance which required a very strong hand to put it down, I succeeded in getting most of the work at Doncaster left 'unfinished;' but in that respect also there is just enough done in the usual way to enable anybody to judge of the difference, for the joints of the nave pillars were pointed up as usual, and present their white lines like a band of paint at every joint, and the inside stone work was scraped; whereas the great pillars were not allowed to be touched after they were built, nor any of the outside work or window tracery. At St. James's nothing of the kind was allowed.

* * * * *

"I believe the progress of Gothic architecture, rapid as it has been, would have been more rapid, and at any rate more complete as it went on, but for the impatience which is one of the characteristics of these times. I do not mean merely that kind of impatience which is evinced by those who told the Gothic architects only eighteen years ago, that they must 'be content to lay the foundations of an edifice which future generations shall see completed, and to toil for the recovery of hidden principles and lost harmonies which the master spirit of a succeeding age may awaken into life;' and then, within less than half the time of a single generation, turn round upon the men who have been so toiling, and declare that they can wait no longer; and that they are now convinced that some unknown and scarcely imagined compound of the Classical and Gothic styles is the thing to toil after and harmonize. This particular phase of impatience may not be common, but when we think of the variety of architectural fashions which have now flourished within less time than was occupied by the shortest-lived of all the old Gothic styles, we must come to the conclusion that our architects are either much cleverer than the old ones, or else much more impatient."

The following opens up a much controverted question:—

"A few years ago came in the marble and colour mania, imported principally by Mr. Ruskin from Venice; a magnificent discovery for the architects, but not so certainly for architecture just at present; for the apparently inevitable effect of a rage for colour seems to be that it makes people more careless about form than ever; and no one I think will say that the knowledge of architectural form and proportion is in such a highly advanced state that we can afford to let it take its chance for a few years while we are speculating in some other element of beauty. I am far from objecting to the introduction of marble shafts, or granite pillars, wherever people like to pay for them: but if they fancy that a building otherwise bad, feeble, and in short, ungothic, will be made into a good one, capable of giving lasting satisfaction or pleasure, by putting in a certain quantity of marble instead of stone, they will be mistaken, and will find that the choir of Selby, and the nave of St. Alban's, and fifty other whitewashed churches, are still perversely admired, while all their beautiful colours are despised. *A fortiori*, the same is true of painting; for marble being composed by nature is sure not to be bad in itself, whereas painting has an unlimited capacity for badness in itself, and unfitness for its place besides."

* * * * *

"I am not sure that I know what that imposing, but only plagiarised phrase, 'the architecture of the future' means; and even those who are fondest of using such pieces of cant magniloquence have not always a very distinct apprehension of their own meaning; but I am tolerably certain that if it means a style of architecture which is to last as long as the shortest of the old styles, or to have any chance of being treated with respect, or looked at with satisfaction when the future has become the past, as all the genuine styles of old still are, it must be something very different from what is contemplated by our present seers. Vitruvius, the great authority on the classical styles, is quoted by Evelyn as saying that among the twelve things which an architect ought to know is astrology. I wonder from what signs it is divined that a new architecture, to be celebrated in future ages as the Victorian style (for so it has been already christened by persons who are too impatient even to postpone that ceremony till the usual time), is so near the ascendant now. I cannot help thinking that we are more likely to glide into a new style (if there is ever to be one again deserving the name) by learning first to stand a little more firmly on the old ground, from which most people now agree that we must take our start, before we are in such a hurry to take it. If the new style is to be a composite one, it is not very likely to be developed except by men who show by their works that they are thoroughly master of the others from which it is to be compounded. We are a little too ready to assume that a knowledge of dates and facts and measures, and all the history of architecture, (which is probably greater now than ever,) is a proof of a practical mastery of principles; but knowledge is not necessarily power, in spite of competitive examinations."

"The last cause of dissatisfaction with modern Gothic building which I have to notice is of just the opposite kind to that of impatient running after novelties, whether 'antiquated novelties,' or novelties of invention, which I have been complaining of just now. It is too often forgotten that architecture is not archæology, nor ecclesiology either; and many foolish things are set down to the credit or discredit of Gothic architecture, which it has nothing in the world to do with, except that somebody has chosen to embody his own antiquarian or ecclesiastical fancies in a Gothic building. I fully appreciate the obligations of Gothic architecture to the archæologists, who saved many a fine building from being burnt into mortar like the greater part of that most beautiful of ruins, St. Mary's Abbey, at York, at a time when almost everybody thought, as Lord Palmerston and his adherents still do, that Gothic architecture was a relic of barbarism. And the modern advance of architecture in the only style which has advanced is undoubtedly due in a great degree to the ecclesiologists. But for all that we cannot afford to let either of them be our masters. Architecture is the art of erecting new buildings for use and beauty; even Mr. Ruskin, with all his love of decoration, puts use and fitness for its purpose as the first condition to be satisfied by a building, though of course not the only one. Archæology (so far as it relates to our business) deals with the preserving of old buildings; a very good, but a very different thing; and ecclesiology is obviously more different still; and at any rate it has nothing to do with civil architecture, about which the fight happens to be just now; for our opponents say that we have carried the ecclesiastical and eleemosynary

Digitized by Google

position, even the Protestant Dissenters having now joined us in it; the Romanists alone seem to be discovering that the architecture of Rome after all suits their purposes the best, and it is remarkable that their modern Gothic buildings are seldom among the best specimens; there are many better dissenting chapels.

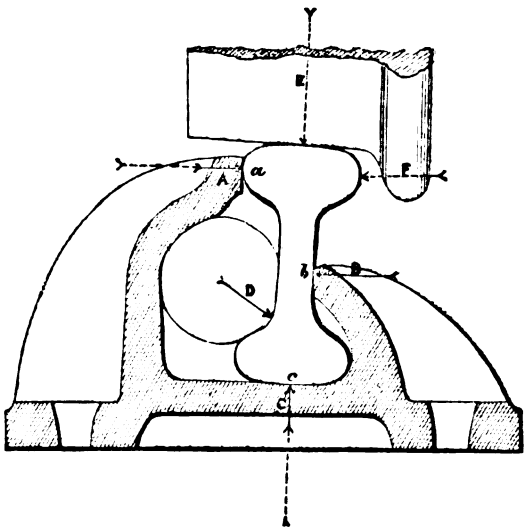
"I think therefore that everybody who feels interested in the progress of architecture ought to resist all attempts to overwhelm and choke it by either ecclesiastical or antiquarian pedantry."

The Literary and Educational Year Book for 1859.
London: Kent & Co.

The multiplicity of books of a similar nature to that mentioned above is a proof of their usefulness and ready sale. Indeed, no class of work is so welcome on a library table as a compendious book of reference, one which just answers the purpose of assisting the memory, or giving current information on a variety of subjects in the fewest possible words. The volume now before us presents an aggregate of statistical and other items such as we feel assured have rarely if ever been before collected. Some of the titles are worth enumerating, as they will serve to explain the peculiar recommendations of this 'Year Book.' There is a list of important works published during the past twelvemonth,—a list of new editions of standard works,—of American and foreign books generally;—titles of papers in the quarterly reviews;—new maps and engravings;—newspapers, English and foreign;—metropolitan periodicals and publishers;—a variety of information relative to our universities and the several colleges and schools in the kingdom;—also lists of members of the different learned, scientific, and artistic societies of the metropolis, with a summary of their proceedings, &c. &c. Some excellent hints are given too on the formation of mechanics' institutes, and itinerary libraries, and an abstract of the law of copyright in different countries,—the whole comprised in a half-crown volume, the size of an ordinary quarterly review. It may be imagined that, as this is the first volume that has been issued, it will be found not altogether perfect. This is modestly apologised for in the preface, and the editor requests that, to render it more perfect in future, any corrections or additional information will be supplied by "lecturers, editors, secretaries of public societies, the proprietors or teachers of grammar and other first-class schools. For our own part, in dipping pretty freely into its contents, we have been astonished at its general accuracy and fullness: the principal drawback being that the latest particulars have not been in every case ascertained; and, this being so essential a point, the conductors will do well to pay it special attention in forthcoming volumes.

RAILWAY CHAIR AND FASTENINGS.

Robt. H. Bow, C.E., *Patentee, Edinburgh.*



The mode of action of this chair is as follows:—The rail is maintained in its proper position by being made to bear against the three resisting points or surfaces of the chair *a*, *b*, and *c*. The pressures which the rail exerts against these points are brought into play by a fourth pressure D, arising from the action of a key, wedge, screw, or other fastener.

The pressure D, from the key, wedge, or screw, becomes resolved into a vertical pressure C, which serves to hold the rail down in the chair, and into a horizontal pressure, which is balanced by that at *a* acting round the point *b* as a fulcrum.

The additional pressures to which the rail may be subjected by the action of the wheel, may approximately be represented by the dotted lines E and F. But these can only augment the previously existing two pressures C and A, as indicated in the figure, so that the compression of the wedge or other fastener is of a constant character, and need be of but small amount compared with that which the key in the common chair has to withstand.

The chair at present in most general use is objectionable, in making the steady motion and safety of the train depend too much upon the presence and condition of the wooden key. The key in it is absolutely necessary for the maintenance of the rail in an erect position against the action of the flange of the wheel. Many chairs are so designed that they require the inner jaw to fit the lower shoulder of the rail with great accuracy, in order that the rail may be held steadily down in the chair; and when, in the course of time, the top of the rail becomes worn out, and the rail turned, the chair can no longer keep the rail down in its seat; such a misfit could not but lead to much injury being done both to rolling stock and permanent way, as, whenever a train passed rapidly along, severe blows would be interchanged between rail and chair.

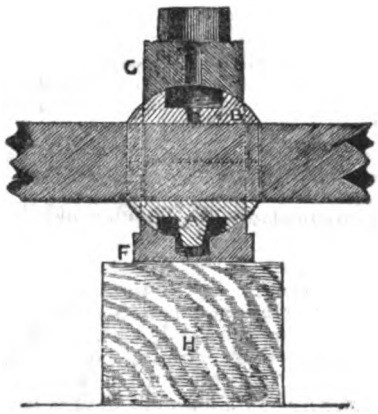
The patentee states that in this chair the rail withstands the pressures from the wheel without the aid of the key; the actual use of the key in it being to keep the rail constantly pressed against its bearings *a*, *b*, and *c*, so as to prevent any rattle from vibration. And no serious evil could arise from the absence even of several adjacent keys, since the general action of the pressures from the wheels could not upset or bend the rail, as would be the case with the common chair.

In the common arrangement the key soon becomes loose from the alternating wet and dry condition of the wood; and from the occasional blows and severe compressions to which it is subjected. The first of these causes is got rid of by using keys thoroughly saturated with creosote; the second remains in the common chair, but does not exist in the form herein described. The usual frequent inspection and adjustment of the keys is thus rendered unnecessary.

When necessary to invert the rail in this chair, it would fit equally well in its new position; it would sit a little lower, but this would not affect its inclination or steadiness, and the height of the outer jaw of the chair is originally made so low as to keep it well out of the way of the wheels. These advantages are not gained by the sacrifice of any good property of the old chair; the rail can still be dropped in from above; the key is still on the outside; and simplicity and cheapness are still leading characteristics.

When used as a joint-chair, the new form possesses the following advantage:—In the common joint-chair, the meeting ends of the rails may get out of line; horizontally by one end working further into the soft substance of the key than the other, and vertically from bad fitting of the inner jaw. In this chair the ends of the rails are held in perfect line, by each being pressed against the common bearing surfaces *a* and *c*.

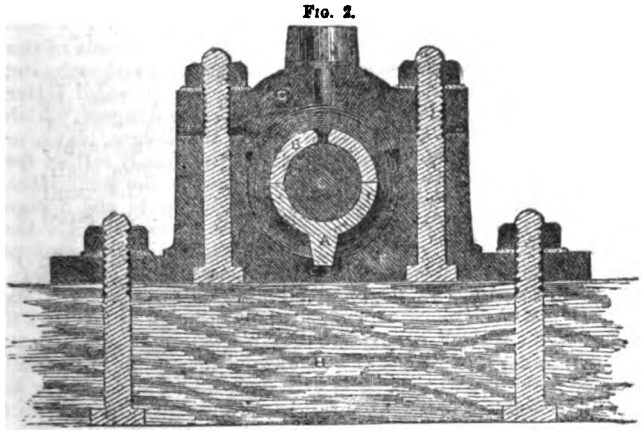
When the employment of a wooden key is objected to, as for use in India, the pressure D may be produced by means of an iron key, wedge, or screw. When a screw is used it may be tapped through the jaw of the chair, and bear against a bent piece of steel, 3 or 4 inches long; or it may work through a nut let into the chair, and bedded on an elastic washer. In this description of the chair its application to rails of the most frequently used shape has alone been considered; but the same method of fastening the rail is applicable to many other forms of section.



SELF-ADJUSTING SPHERICAL BEARING.

The Spherical Self-Adjusting Bearing shown in the accompanying illustrations has been patented by Messrs. Wallis and Haslam, engineers, Basingstoke. It is composed of four parts,—the seat or block, the upper and lower brass, and the cap. Fig. 1 is a cross section, and fig. 2 a sectional elevation. The seat or block F, and the cap G, are turned internally in such a manner, that when put together their interior surfaces form a spherical cavity, with a portion removed on each side of the block, leaving

Digitized by Google



openings through which the shaft or spindle passes out, surrounded by the brasses in which it revolves; and the upper and lower brass B and A, after being bored in the usual manner for the reception of the shaft, are turned externally to the form of a sphere of the same diameter as the cavity in the block, so that on their being placed in the said cavity, and the cap adjusted over them in its place, they form a universal joint, which will turn freely in any direction within certain limits. On the under side

Fig. 1.

of the lower brass A, is cast a nipple, which descends into a socket E, bored in the bottom of the block to receive it. This socket is considerably larger than the nipple, and will therefore

Fig. 2.

allow sufficient motion for the brasses to adjust themselves to the position of the shaft, while, at the same time, it prevents their rotating along with it, which they might otherwise be liable to do. The brasses, as shown in the engravings, are lightened in weight by having a channel cast round them at right angles to the shaft, which does not, however, interfere with their self-adjusting properties. They are also constructed with a short lengthening portion, or nose, at each end of the brasses, for collared journals, or in cases where unusual steadiness is required. The part claimed by the patentees is the application of the ball and socket joint to shaft or axle bearings of any description. These bearings may be applied with advantage to railway carriage axles, as their self-adjusting properties will allow the wheel to rise or fall with the inequalities of the rail without in the least affecting the relative position of the axle journal and the brass in which it revolves. They are also particularly useful in cases where shafts or spindles run at a high speed, or from any cause are liable to heat or wear crossways in the bearings, as they instantly adjust themselves to the slightest variation in the line of direction of the shaft, while at the same time they are quite as steady in work as the ordinary description of bearings.

The three successful competitors in the Manchester Assize Courts competition are—first, Mr. Alfred Waterhouse, Manchester; second, Mr. Thomas Allom, London; and third, Mr John Robinson, London, to whom the premiums of £250, £150, and £100 respectively have been awarded.

OUR METROPOLITAN RAILWAY BRIDGES.

TO THE EDITOR OF THE CIVIL ENGINEER AND ARCHITECT'S JOURNAL.

Railways are a great necessity of the times, but art-progress also is usually and truly considered an attribute of the age, which now indorses the idea that useful things can possess beauty as well as utility. Looking at it in this way, one is at a loss to understand how it has come to pass that the ugly railway arches we see crossing our great public streets have been allowed to be erected, and our eyes and taste offended by the bald and inelegant structures reared across our paths; this offence against good taste being by no means a matter of necessity, for these arches or viaducts might with a very moderate outlay have been—indeed, might yet be—rendered an ornament to the streets. Such an arch as that which crosses the Westminster Bridge-road might have been Gothicised and rendered ornamental by panelling the parapet of the bridge, making the spandrels of ornamental character and finishing them off with ornamental corbels. In some cases it would be a great convenience if an additional ornamental parapet were provided outside the railway parapet, for foot-passengers to cross the thoroughfare, reached by light iron staircases.

Doubtless the railway companies will say that they ought not to have this additional expense thrown upon them, but I think the Londoners have the right to reply, that whilst these companies can afford to build elegant and expensive stations at places of much less importance than this metropolis, and erect ornamental bridges in remote corners of private parks for the possible delectation of the owner, the railway bridges or viaducts crossing main streets of a great town should be designed with the view to produce an agreeable architectural effect, as well as answer all the required useful purposes.

Now that we have several metropolitan railway projects on the *tapis*, it is worthy of consideration whether something could not be done in this matter; and it is to be hoped that the Metropolitan Board and all whom it may concern will take order herein.

MEGALOPOLIS.

SUPERHEATED STEAM.*

THE idea of working engines by superheated steam, and the immense saving of fuel and increase of power it would effect, was, we believe, first started many years ago by Mr. Howard, and subsequently by Dr. Haycraft. At a later period the matter was again taken up by an American enginer (Mr. Wetherhead) who, however, only superheated a portion of the steam and mixed it with common steam in its way to the cylinders. The success which attended even this partial application of the process again revived the idea and encouraged other engineers to turn their attention to the subject. The result of these renewed efforts is, that several methods of securing the great economy to be effected by superheating the steam are now under trial.

As to the various proposed methods of superheating steam, it may be briefly explained that the conditions required to be fulfilled are perfect simplicity of arrangement with ready control over the apparatus; that it should be so placed as not to be liable to accidental injury in the engine-room; and that the heat employed for superheating the steam should be waste heat, which has already done its duty in the boilers and is passing away. All these conditions have been most satisfactorily fulfilled by Mr. Penn in the new engines on board the Valetta. The Valetta was for many years the mail-boat between Marseilles, Malta, and Constantinople. While thus employed she had Penn's engines of 400 horse-power.

Mr. Penn, at the repeated request of Mr. Allen, the managing director of the Peninsular and Oriental Company, undertook to apply to them the principle of superheating, to which his attention had many years before been seriously directed by Dr. Haycraft. His method of doing this is to place in the smoke-box of the boiler, through which the hot air from the furnace first passes, as large a number of small pipes as is consistent with allowing a free draught from the furnaces, Through these all the steam from the boilers passes in its way to the cylinders. By this plan an immense heating surface in the pipes is secured, the steam is in a subdivided form, so as to be readily acted on, and the waste heat from the furnace is utilised at the point where

* Abridged from the *Times*. For account of previous experiments with superheated steam, see proceedings of British Association, *ante*, vol. xxi. page 365.

Digitized by Google

its intensity is greatest, and where the greatest conveniences exist for applying the apparatus. By the means of three ordinary stop-valves the whole contrivance can be shut in or off from the engines at pleasure. In ordinary engines steam leaves the boilers at about 250°, but declines from this temperature in its way to the engines to 230°, undergoing from condensation a still greater and more serious diminution of heat in the cylinders. From these causes, and also from the immense quantity of waste heat which escapes through the smoke-box and up the funnels, there has always been a theoretical loss of steam power amounting to 40 per cent. as compared with the coal consumed. It is this loss of power and waste of heat which the superheating process is intended to prevent, and which will allow a reduction of from 28 to 30 per cent. on the fuel now consumed. By the superheating process the steam is raised in passing along the pipes in the smoke-box (where the heat is about 650°) from a temperature of 250° to 350°, and so enters the cylinders at 100° in excess of the temperature due to its pressure. This extra heat is, of course, rapidly communicated to the metals, and prevents the condensation in the cylinders or other parts of the engines which would otherwise, of course, take place. A smaller amount of cold water is required to condense the steam at this high temperature of 350° than when at the ordinary heat of common steam.

At the measured mile at the Lower Hope, near the Nore, the result of repeated runs gave an average speed of nearly 14½ knots per hour, thus realising with engines of 260 horse-power, and a small consumption of fuel, the same rate of speed as had been gained with her previous engines of 400 horse-power, and a consumption of 75 tons of coals per day. The superheating apparatus evidently effected a most important saving in fuel, but until an average of many days' working can be obtained, it would be difficult to estimate the exact amount economised. The thermometer during the trial indicated in the steam pipes an addition to the ordinary temperature of 100°, which Mr. Penn believes to be enough for all practical purposes of superheating. Even when making from 33 to 34 revolutions per minute, and driving the vessel against a strong head wind and tide, it was impossible to consume all the steam generated, which was blowing off from both boilers all the trip.

THE ARCHITECTURAL MUSEUM.

(SOUTH KENSINGTON MUSEUM).

Prizes to Art-Students and Artist-Workmen, 1859.

Prizes for Wood Carving.—The Committee of the Architectural Museum offer to Artist-Workmen two Prizes of £5 5*s.* and £3 3*s.*, as First and Second Prizes, for the most meritorious specimens of carving in Wood, being the enrichment of a hollow moulding, not less than 18 inches long and 7 inches wide, either in naturally or conventionally rendered foliage, with or without animal life. The work may be executed in either hard or soft wood as the workman pleases.

Prizes for Coloured Decoration.—A Prize of Five Guineas is offered by the Committee of the Ecclesiological Society (of London), through the Committee of the Architectural Museum, for the competitor who shall show himself most successful in Colouring, according to his own judgment, a cast from a panel (one of eight) from the side of a tomb in the Church of San Giovanni, Verona. It contains a draped female figure, surrounded with foliage on a flat ground in low relief, and inclosed in a narrow border. Mr. Beresford-Hope, M.P., will give Three Guineas in one or more extra prizes if any works appear deserving of being so rewarded. This being specifically a colour prize, the same cast for competitive coloration is proposed to all the competitors. The candidate may adopt that medium for applying his colours which he prefers, but he is expected to treat the panel as forming a portion of an architectural composition, and not as a cabinet piece. The original is in marble.

Casts from this panel will be supplied on application to the honorary secretary of the Architectural Museum at 5*s.* each at the Museum, or by payment of 2*s.* extra for packing and case. Duplicate casts will be allowed. The Committee of the Ecclesiological Society will themselves adjudicate.

General Conditions.—All specimens sent in competition for the prizes must be deposited in the Architectural Museum, free of cost, by the 1st of December, 1859, with the competitor's name and address, and those of his employer (if any) attached. They will remain the property of the competitor or his employer, and will be exhibited in the Architectural Museum for one month before the prizes are awarded, and also until after the day of presentation if thought desirable. The specimens must be removed at the expense of the respective competitors. The prizes will not be awarded unless there appear sufficient merit in any of the specimens to entitle them to such distinction: but certificates of merit, in addition to the prizes, will be given in such cases as the judges may consider deserving.

GEO. GILBERT SCOTT, A.R.A., Treasurer.
March, 1859. JOSEPH CLARKE, F.S.A., Hon. Sec.

(13, Stratford-place, W., where communications should be addressed.)

Patent Law for India.—The law granting patent rights in the Indian territories having passed the legislative council in India, has received the assent of the crown, but has not yet been promulgated in India. By it British patentees will be enabled to obtain patent rights in that country, provided they make the proper application within twelve months from the date of the British patent.

The National Wallace Monument.—The acting secretary of the Wallace committee, Dr. Rogers, of Stirling, has recently issued details for the guidance of architects intending to compete, from which we obtain the following particulars:—The monument is to be erected on the Abbey Craig, near Stirling. The Abbey Craig, is situated in the midst of a level plain, bounded by ranges of hills at various distances. In the directions of east, south and west, the Craig may be seen at a distance of twenty miles. From the site of the proposed Monument are seen the battlefields of Stirling Bridge, Bannockburn, Sauchieburn, Falkirk, and the district of Sheriffmuir. The funds for the monument at the disposal of the committee are £4000, but designs may be prepared which would cost £1000 more. There are three excellent quarries in the vicinity, one of trap or greenstone at the Craig's north-eastern base; a second at Bridge-of-Allan, in the old red sandstone, one mile distant; and a third of pure white freestone, at Bannockburn, at the distance of four miles. There is a railway station at Causewayhead, within a few hundred yards of the Craig. Designs, plans, or models, and specifications, with estimate, must be sent in by the 1st of June next, with a sealed letter bearing a motto and the name and address of the designer, which letter will be opened only in the event of the designs, plans, or models bearing the corresponding motto being finally settled for adoption, premium, or honourable mention by the committee. In the event of the committee giving a preference to any design which it may be afterwards found cannot be carried out for the estimate given, it shall not be obligatory on the committee to adopt it. The plans and elevations to be drawn on a scale of 2 in. to 10 ft., and be tinted in Indian ink only; no coloured drawings will be received. A small elevation on a scale of 2½ inches to 100 feet to be shown on the Craig, enlarged to the same scale, must accompany each design, plan, or model. The successful competitor to furnish plans and specifications, and give such superintendence as may be requisite for carrying his plans fully into execution, for which a commission to be allowed of 5 per cent. on the outlay. First premium, 50 guineas; second, 25 guineas. Should the designer of the first be employed to carry out the design, his premium to be transferred to the next best, and the 25 guineas to the third in merit. Dr. Rogers will, on application, supply intending competitors with a topographical outline of Abbey Craig and the adjacent hills.

Bourton, Warwickshire.—The alterations at the Church of Bourton, near Rugby, have been recently completed. A north aisle has been added, and separated from the nave by arches of early character, corresponding with those on the opposite side; the north transept has been rebuilt from the foundations, and suitable decorated windows have been inserted. A small recessed porch, gabled flush with the aisle wall, serves as a means of communication with this transept, which is used chiefly as a mortuary chapel for the Shuckburgh family, and contains an interesting Gothic monument against its south wall. Some new seating of plain but substantial character takes the place of some very objectionable pews. The works have been executed, under contract, by Mr. Parnell, of Rugby, the outlay being about £600.

A colossal statue of Victory has just been placed in the garden of Apsley House. It is stated that it will form part of the monument to be erected in St. Paul's Cathedral to the memory of the late Duke of Wellington, as proposed by Baron Marochetti.

Iron Bridge for India.—Tenders are invited for the iron superstructure of the Jumna Bridge by the directors of the East India Railway Company.

MEMORIAL GATEWAY, LODGE, AND LICH HOUSE, NEW CEMETERY, BRIGHTON.

ROBT. WHEELER, ARCHT.

Digitized by Google

THE NEW CEMETERY AT BRIGHTON.

(With an Engraving.)

THE new parochial cemetery at Brighton, situate on the Lewes road, about three-quarters of a mile from the town, was established in 1857. A site containing 19 acres having been presented to the parish by the late Marquess of Bristol, it was decided, that as an expression of gratitude a memorial gateway should be erected at the entrance to the cemetery. The burial board having advertised for designs for the chapels, lodge, and gateway, about twenty sets were forwarded for approval;—those by Mr. Robert Wheeler, of Bedford-chambers, Southampton-street, Strand, were adopted, and ultimately erected under his superintendence. Our engraving shows the Memorial Gateway, Lodge, and Lich-house; the gateway forming the central feature, is built of flint and Caen stone; the niche above the archway contains a statue of the late marquess, and on either side are carved panels containing respectively the arms of the Bristol family and of the town of Brighton.

THE DEPARTMENT OF PRACTICAL ART AT THE ARCHITECTURAL EXHIBITION.

ARRANGEMENTS having been made for an exhibition to be exclusively devoted to objects of a practical bearing upon architecture and building, and which will be opened in the Conduit-street Galleries immediately upon the close of that which now occupies its space, there is less occasion to regret the comparatively scanty show which the department of building materials, patents, inventions, manufactures, &c. contributes to the Architectural Exhibition. We have reason however to know that this deficiency is to be attributed to the very limited space then at the disposal of the committee for such purposes, and that many who had intended to exhibit, and were even making preparations expressly with that view, found every inch of ground pre-occupied when they forwarded their applications. Some of the present exhibitors will retain their places during the next exhibition, and new names have already been handed in: we may consequently anticipate that the forthcoming collection will prove, not only interesting and profitable to all parties concerned, but varied and extensive. Meanwhile, as our examination of the specimens of this class now on view has furnished comments for our note-book, we proceed to transcribe them for the consideration of our readers.

In the North Lobby will be found the chief part of the collection in question, and the first-named in the catalogue is the "London Parquetry Company," who exhibit specimens of panels and moulded decorations of various kinds, including ornamental ceilings, in marquetry and other designs, inlaid with hard woods of various colours, thus admitting of the application of either simple or elaborate kind. We notice also some "patent *waterproof* veneered panelling and wall-decorations," by means of which it is stated that the dampest wall or ceiling can be finished immediately after it has been plastered or cemented. The principal advantages of this system are:—1. The introduction of wainscot, walnut, mahogany, maple, and other fancy woods, as internal decoration, instead of ordinary pine, painted or varnished. 2. Its adaptability to any degree of ornament and to any style of decoration, being capable of application in panels of unlimited dimensions without visible joints, and, if necessary, without any joints at all. 3. It thoroughly resists the effect of any dampness that may arise from the walls, and offers no combustible material in case of fire. 4. It cannot by any means shrink or warp, nor is it liable to crack; and finally, the price for even the simplest design, in fine figured woods, scarcely exceeds *one-half* that of the old-fashioned solid panelling in plain oak, and is cheaper in proportion as it is more ornamental.

There are also some portions of "parquet floors" prepared by this company, suitable for dwelling-rooms or public buildings, and executed in wainscot, walnut, birch, maple, and tulip-wood. These patterns are all *plated* with ¼ inch hard woods upon inch ground work, and require no intermediate floor on the joists. The experience of this company enables them to recommend this system in preference to the "solid" inlaid floors originally introduced by them into this country, though in exceptional cases these are still executed by them without any extra cost.

The adjoining space (2) is occupied by "Encaustic Tiles, &c.," manufactured by Messrs. Minton, Hollins and Co., illustrated in a variety of ways, such as for paving, wall surfaces, panelling, or merely ornamental. There is a large tile, 12 inches square, inlaid with the royal arms, and a medallion of circular form, manufactured for the Capitol at Washington, and ornamented with a figure of Peace. The Patent Architectural Pottery Company, Poole, are also, as heretofore, exhibitors in this material, as Messrs. Maw and Co., to whom we shall have occasion again to refer.

Mediæval metal-work is, as heretofore, worthily represented by "divers cunning craftsmen." The names of Messrs. Hardman and of Messrs. Hart are guarantees for excellence in this department; and Messrs. Johnson and Co., who have a stand in the large gallery, have made great advances this year. We miss, however, Mr. Skidmore's tasteful ornamental work, and also Mr. Potter's. Messrs. Cottam and Co. send several works in metal, which are exhibited in (13); one of these is a handsome Jacobœan gate of large dimensions.

That beautiful material, serpentine marble, again attracts by its charming qualities of colour, veining, and admirable polish. No material, English or Foreign, equals this stone in brilliancy of colour, or in elegance of appearance; and the lower beds of the Signal-staff quarry, near the Lizard, are now realising the predictions of Sir Henry de la Beche, who indicated this as a particularly promising locality. All marbles having carbonate of lime for their base are acted upon immediately by grease and ordinary acids; but serpentine is an igneous rock, and, having a different composition, resists not only the application of grease, but also of sulphuric and muriatic acids. The Lizard company state that "Serpentine is no less fit for external ornament than internal decoration, as it is proved to be more durable than granite, and to retain under all conditions of the atmosphere its polish, which is produced by friction." As examples of its application, we have before us a chimney-piece, some vases (large and small), a tazza, chess table, two balusters, and a specimen of paving (cube pattern).

Messrs. Hobbs, Ashley and Co. have in (6) a great variety of locks, from the simplest to the most complicated construction. Among these are specimens of what they term their "Patent Economic Self-adjusting Mortice and Rim Lock furniture," suitable for locks and latches of all descriptions, and easily applied.

The next case (7) contains articles of a similar kind, forwarded by Messrs. Pugh and Co. These are all well finished, and more than usually tasteful. Some very handsome door-knobs in particular will be observed, and in great variety of material and pattern.

Messrs. Charles Botten and Son, and Messrs. Hayward, Tyler, and Co. exhibit improvements in water-closets (Nos. 8 and 9). "The Patent Regulator" of the former is a vessel containing a diaphragm raised by the action of the closet handle or seat, causing the outer chamber to fill (through the bottom valve) with air, which air, escaping only through a small aperture at the side, prevents the rapid closing of the supply valve, and this escape-hole being enlarged or diminished at will, regulates the flush of water, and dispenses with cisterns, service-boxes, &c. Of their "valve" closet, several are fixed in different parts of the premises. The bottom valve has a glass face, and shuts against vulcanised india-rubber, which experience shows to be the best, soundest, and most durable material to use. They show also a "Patent Slide or Sluice Valve," the peculiarity of which is, that the gun-metal faces can be removed for repair or renewal without taking out the body of the valve, or breaking the joints, or in any way disturbing the mains. In "Howard's Patent Regulating Valve," exhibited by Messrs. Hayward and Co., the simplicity of its construction is its great advantage; it being not liable to get out of order, or to leak; besides which, being entirely unaffected by damp, it may be fixed in the wettest situation without injury. Mr. Jennings, whose show of articles of this class has been usually so large was this year disappointed in his intentions of exhibiting, owing to want of space in the rooms.

No. 10 is called a "Design" by Mr. D. O. Boyd—whose establishment forms part of the ground-floor of the Exhibition galleries —representing his improvements in the construction of smoke and air flues, whereby a separate and effective ventilating flue is provided for each room of a house, without increasing the bulk of the chimney stack, or reducing the sizes of the smoke flues.

Now that brick has become so important a material in an ornamental as well as constructive point of view, it is not to be wondered at that so many modes of its application should be

Digitized by Google

discovered, and that manufacturers should vie with each other in endeavouring to bring it to perfection. In point of colour we have now almost all the varieties that can be wished; but perhaps the red, which is the most sought after for decorative purposes, has hitherto been the least successful. The white is now very fairly accomplished, as may be seen in the Norton Works specimens exhibited (15) by Messrs. Fayle and Co. These white facing bricks, and architectural moulded blocks, approach very near in colour and appearance to stone, and in quality are described as superior to any other facing. (These moulded blocks may be made of any dimensions or pattern). Some of the specimens exhibited are similar to those used at the Middlesex Industrial School, Feltham; and others like those made for Harrow Schools. There are also some good specimens of fire-brick,—tested at the Arsenal at Woolwich,—and also of paving tiles, superior in hardness and durability to Portland stone, and much less in cost. Other specimens of "model bricks" in various forms are supplied (12) by Messrs. Norman, of Burgess Hill, near Hurstpierpoint.

Doulton's stone-ware is too well known to require recommendation; suffice it to say, therefore, that it is not altogether unrepresented here. Mr. Moore's ventilators also are now so generally in use that they need no description. In (14) are a few specimens designed specially to meet the requirements of different kinds of buildings, and with good success.

We have on previous occasions, drawn attention to the marvellous imitations of various woods by Mr. Kershaw; these are grained by a patent process, on painted work; also on deal and bay wood without paint. The specimens this year in (16) are if anything superior to former ones.

No. 17 is a "specimen of bronze work in combination with marble and wood," submitted by Mr. W. Potts, whose endeavours in this line have met with high commendation. The specimens on view are mantel-pieces and sepulchral monuments, constructed with a view to economy, durability, and beauty. As both classes of these works are constructed on the same plan, viz., that of making the architectural fabrics in marble or stone, and adding the sculptural or decorative features either in metal-work (electro deposited in solid copper, and rendered massive by a lining of cement), or by peculiarly beautiful effects in painting on glass, they possess durability in the fullest sense; while, as to cost, it appears that they will vary from about one-third to one-fifth of the expense of such designs in sculptured marble.

A very large space in the East Gallery is occupied by Messrs. Maw and Co.'s Mosaic and Encaustic tile pavements, an extensive series of patterns for which has been designed by Mr. Digby Wyatt with considerable ingenuity and taste. These patterns are here practically worked out, and enough of each is given to convey a true idea of the general effect; the prices also being in every case affixed, ample facilities are afforded for forming a correct judgment in also a business point of view.

Mr. Hart (of 69, Fleet-street) exhibits a little article which has now successfully stood the test of eighteen month's trial; and, now that gas is so generally introduced into buildings of every description, it is one that will probably ensure a large demand. It is styled the "Economising Burner, and Illuminating Power Diffuser," and is a simple contrivance which can be affixed to any gas chandelier, stand or bracket in a few moments. The evil which necessarily arises from the great variation of pressure in the mains is remedied by this apparatus, while it also increases the brilliancy of the light. The current of gas is so regulated that under any circumstances it will permeate with its natural velocity; and, this being attained, all noises caused by overdue pressure are obviated, and at the same time all flickering is prevented.

Messrs. Cox and Son have a handsome stand, in the principal room, devoted to articles of church furniture and decoration. This is a branch of art which they make an exclusive study, we believe, and we can cordially recommend their productions both on the score of correct taste and moderate charges. We have before had occasion to notice their work approvingly; and, now that a new element is introduced by which wood carving is by machinery brought into a roughly-finished state with so much ease, we may expect still more available results.

In the same room also are two solid doors, novel in design, and more especially in decoration. The architectural portions are due to Mr. Waterhouse, of Manchester,—the gentleman who has just carried off the first premium for the new Assize Courts there,—and the design and execution of the decorations to Mr. J. Aspinwall. The "*Drawing*-room door" (367) is in the Italian style, very simple in its treatment, and depending chiefly for effect on its coloured decorations, which are chaste and elegant. The inclosing frame is more architecturally enriched than the other portions, the prevailing colours being red, buff, and green. The surface of the door has three panels, and the enrichments consists of a series of prettily-devised subjects, suggested by portions of Shelley's poem of the "Sensitive Plant." The "*Library* door" (368) is based upon Gothic details, but the modifications, we confess, are not quite to our taste. Nor is the finished colouring so successful as in the other case, though it is far from being devoid of merit. Some conventionally-ornamented panels are of peculiar excellence, and much more in keeping than the diapers, &c. on the architrave jamb and head.

In (262A) M. Desachy exhibits several specimens of his manufacture, called "*Le Stuff*," which is peculiarly suited for internal enrichments, being easily moulded and exceedingly light. One of the practical evidences on view is a portion of the handsome show-room preparing, from the designs of Mr. Owen Jones, for Messrs. Osler, of Oxford-street, the treatment of which is so peculiarly novel as almost to baffle description, at least with any degree of conciseness. Those of our readers, however, who have visited the New Crystal Palace Bazaar have seen the same idea carried out in its fancifully-devised ceiling, and polychrome lights in its interstices. Another specimen in the gallery is a length of one of the front divisions of the Queen's box at Covent Garden Theatre, designed by the architect, Mr. E. M. Barry. This specimen measures 12 feet in length, and is full 3 ft. 6 in. in depth, yet weighs only 87 lb.

Mr. Owen Jones' name appears also in connection with another subject of internal decoration, viz., *paper hangings*, of which a great variety of patterns are to be seen in Messrs. Trumble's specimen book (190). A great many of these have the same geometrical outline, but when printed in various colours, they produce very different effects, as is often observable in paving tiles. The patterns in question are all *on the flat*,—the only correct style of decoration for such purposes.

Our notice of this department of the exhibition must be concluded by a reference to the two or three models on the large marquetry table in the Great Gallery. One is of the church now completing in the Italian style, from the designs of Mr. Tite, at Gerrard's Cross, near Uxbridge, which has at least the attraction of novelty. The model is so contrived as to show all parts of the building, and has been very creditably executed, to a scale of one inch to five feet, by the clerk of the works, Mr. J. Monteath.

A model of the roof over a new chapel on Highgate Hill, and another for contriving two staircases within the same area as would be required for one, will be viewed with interest. The latter scheme in particular is highly ingenious, and one that might frequently be adopted with great advantage.

A model, in cardboard, of Heckington Church, Lincolnshire (369), by Mr. R. J. Johnson, is the only specimen of the kind in the exhibition. Every detail of this exquisite and well-known building is truthfully expressed,—even the subdividings of the mullions and cusping in the windows,—and the whole is an evidence of what persevering industry can accomplish.

ARCHITECTURE AT THE ROYAL ACADEMY.

THE impression conveyed by the aspect of the pictures generally in the Academy exhibition this year,—that it is destitute of leading attractions, and perhaps hardly of average merit taken as a whole,—is certainly correct as regards the Architectural contributions. When however it is remembered that an exhibition of works exclusively of this kind was but recently opened in Conduit-street, and presents a goodly array, we can hardly be surprised if the walls in Trafalgar-square suffer both in point of numbers and choiceness of subjects. True, the half of the North Room is again allotted to architecture; but this, we once more repeat, is but a paltry instalment of the space which it is entitled to claim from an institution bound by its charter to encourage that art equally with those of painting and sculpture. What chance have our delicate drawings (we speak of legitimate architectural works) when, as now, interspersed with and overpowered by a host of gaudy oil paintings. Were the profession as alive to its own interest as it should be, it would not succumb to these repeated indignities, but insisting on its rights, would never rest till it regained the sole possession of an "Architectural Room."

Digitized by Google

Besides the very few oil paintings of architectural subjects which are to be found in the other rooms of the exhibition, we can number in this only between sixty and seventy, while scarcely any, as we have said before, are of superlative merit, or have been contributed by leading men in the profession. With neither of the Barrys, no Cockerell, no Scott, no Donaldson, no Hardwick; Sydney Smirke represented by a single drawing, and David Roberts in less force than usual; the insipid character of the collection may be easily inferred. (1030), "Winchester," gives a faintly distant glimpse of that venerable city, beautiful from any point of observation, and especially the one in question. (1027) shifts us into the neighbouring county, to recal to view that charming bit of mediæval domestic work, the Manor-house at Great Chalfield, Wilts, of which geometrical delineations have been published in one of the supplements to Pugin's 'Examples;' while (1026) transports us to a remote scene, "the Monastery of Smolnoi, on the banks of the Neva, at St. Petersburgh." Netley Abbey is an English ruin, familiar to most tourists in the south, but of which the picture before us (1034) gives but an inadequate idea. There is not much to study in the "Ruins of the villa of the Emperor Commodus, near Rome" (1035); but Mr. Falkener's "Oriental sketches" will invariably repay examination. This gentleman sends no less than five pictures, all in his peculiarly careful style, and illustrating classic remains in Asia Minor. Among these, (1037) the "exterior of the Mosque at Ballat" will be noticed as an example of great *breadth* in composition: some coloured materials and trellis-work enhance the general effect, which is still further heightened by the marble shafts which occur here and there, while the simple dignity of the whole is preserved by the plain comprising arch, unrelieved by moulding or enrichment of any kind. (1058)—in another part of the room, unfortunately—shows the interior of the same mosque; (1086, 1087) represent "the city of Pinara," in Lycia, and "Adalia, the ancient Ataleia," also in Asia Minor. The former of these views is taken from the ruins of the theatre, and includes the lofty rock of the Acropolis, some hundred feet in height, and studded with countless tombs.

(1047), Allsopp's New Brewery, and other buildings, in course of erection at Burton-on-Trent, from the designs of Messrs. Stephenson and Hunt, are on a most extensive scale, but do not appear to possess much architectural pretension. They are shown by a bird's-eye view, unfortunately not accompanied by any plan. "Christ's College, Brecon" (1050), is one of the two excellent drawings contributed by Messrs. Prichard and Seddon, but here again the want of a plan as a key to the arrangement of the buildings is manifest. Under such circumstances criticism is fettered, and the most that can be safely adverted to are the strictly architectural features. In the present case, though there is no great display made, the disposition of the several masses is happily balanced. It may be worth reconsidering (inasmuch as the design is to be modified previous to execution), whether the windows generally are not susceptible of improvement: there is variety, but hardly of the right kind. The design for remodelling "Eatington Park, Warwickshire" (1109), by the same architects, is, in every respect, a contrast to the preceding. The fault here is a redundance of ornament, and that of a very florid kind. Besides the sculptured and carved ornament, the wall surfaces contribute to this effect by the striped and banded work with which they are covered. In the arrangement of this idea of the design considerable taste is shown, as well as in the composition of the principal oriel windows in the two gables. A showy columnar arcade-screen, which stretches on each side of a somewhat fussy entrance-porch, all across the centre of the front, has an unmeaning look, and is the chief drawback in point of detail. The grouping of the whole is exceedingly picturesque.

(1049), "A Design for the Interior of a Chapel" we refer to as a specimen of modern Gothic only slightly removed from the carricatures which Pugin held up *in terrorem* in his memorable 'Contrasts.' Mr. Blackett has consulted the economical movement of the day by using thin walls, which, therefore, luckily will not admit of a proper series of mouldings; moreover, the slender columns which support the arches favour the non-obstructive principle, and are so far also in keeping. Galleries, too, are introduced, but not with satisfactory effect. The best feature is the open timbered roof, which is polygonal, with arched principals springing from corbels.

Mr. Ashpitel's famous picture of ancient Rome finds this year a worthy pendant in his view of the "Modern" city. The spectator is supposed to be among the ruins of the Palace of the Cæsars on the Palatine Mount, and to look across the terraces of the Farnese Gardens upon the Capitol, the Forum, Via Sacra, the Quirinal, the Colosseum, &c. (1052), Mr. Sang's design for decorating the new music hall at Lord Derby's seat at Knowsley, is sufficiently showy and tasteful. By-the-bye, we should have our doubts, from the appearance of the room in this view, as to its good acoustic properties; the succession of domical compartments in the ceiling suggests an adverse opinion. It appears, however, to have been erected expressly for the purpose by Mr. Sydney Smirke. Mr. Sang also exhibits another gorgeous specimen of his art in (1057), the very elegant apartment in Hatfield House known as King James's Room. The ceiling here is flat, and covered with a series of elaborate interlacing panels, such as are not unfrequent in Elizabethan mansions. In (1124) he has yet another work of the same kind, but on a more extended scale: it is to decorate St. George's Hall, at Liverpool. Although we have nothing whatever to urge against Mr. Sang's proposed method of decorating this building, so far as we can make out what is indicated, it is almost needless to observe that the utmost care should be taken that no step so weighty as that now proposed should be resolved on without due consideration. This hall, as a whole, has now no rival among the similar edifices of our country, and it behoves us how we meddle with that purity of architectural detail which constitutes its especial charm.

(1053) Is one of the many new domestic buildings which find representations on these walls, and is, altogether, a very fair specimen. It is in course of erection at Bromley, Kent, from the designs of Mr. E. Ellis, who has turned the simple material of red brick to good account. The two windows, side by side in the gable, mar the otherwise pleasing expression of this design. The "Cartoon for one of a series of painted glass windows to be placed in Southwell Minster," from Mr. O'Connor's designs, occupies the whole of one of the Norman single lights, and illustrates effectively the parable of the Good Samaritan. The "Porch at Ludlow Church, Salop," by Mr. Pedley (1055), is chiefly of Early Geometric date, with subsequent additions; the fabric is now undergoing a thorough repair and restoration.

The "Morning Room" (1061), at Ashbridge (a seat of the Earl of Brownlow), has given Mr. Digby Wyatt an opportunity of indulging in his favourite Renaissance style, and he has certainly availed himself of the resources of that style with considerable ability. Nevertheless, a frequent repetition of such works would not tend to improve our national taste. Decidedly in contrast with this, as regards conception, is its neighbour (1060), Mr. Sydney Smirke's "Interior of a small church proposed to be erected in Yorkshire." This is further described as being in the "Early Christian style," which turns out to be nothing more or less than a simple *basilica*. As a set-off to the tameness of its parts, coloured decoration is lavished throughout; blue and gold being the predominant hues. The columns between nave and aisles are apparently of marble (green), and the pavement is of a rich tesselated pattern. The roof is open, the trusses being of the ordinary king-post construction, such as were common in "early" times.

Mr. Murray exhibits three clever drawings: (1062) the "exterior," and (1100) the "interior" of the proposed Roman Catholic church at Cork, are unfortunately hung quite separate from one another. The former is also too much above the eye to admit of an examination of the details, but the general outline is noble. Internally, the design of the roof, which is open-timbered, is as ingeniously contrived as it is novel. In (1076) and (1113) we have respectively the "interior" and "exterior" of another of the competition designs for the same building, by Mr. J. P. Jones. The difference in appearance of these two designs is every way most striking, while each can point doubtless to orthodox authorities; but in the one case these are altogether English, and in the other they are exclusively foreign. If the one aims at too little effect, the other certainly aims at too much. We leave the question of cost entirely out of the consideration, though in this there would be necessarily a proportionate difference.—Mr. Murray's remaining drawing is (1168) "Design for the proposed National Schools, Leamington," one of the prettiest and most skilfully coloured little pictures in the room.

One of the "Designs for Heigham Church, near Norwich," for which several others are in the Architectural Exhibition, is numbered (1064), and is by Mr. J. Nicholls. It appears to be intended to be constructed chiefly in flint, the usual material in that district: the design is of early character, and has a well-pro-

Digitized by Google

portioned tower and broach spire at the west end of the aisle, but is otherwise poor. No. 1063, "Design for the new Government Offices," by Mr. Granville, is essentially of French type, like some portions of the Louvre or our old British Museum; but not treated with anything like the same skill:—no plan is appended. A more comprehensive design for the same object is exhibited (1071) by Mr. H. R. Newton, in a large bird's-eye view, which shows the proposed buildings entirely occupying the area, both east and west of Parliament-street, between Whitehall and Westminster Bridge. The style is Classic, and a prominent feature in the plan is the large circular open court, surrounded by a handsome colonnade.

There are four telling drawings by Mr. Billings, boldly tinted, and representing different works now being carried out under his designs and superintendence. The most important of these is the first mentioned in the catalogue (1068), and consists of an extensive range of street architecture,—a "warehouse at Glasgow." In this design the author evinces his thorough acquaintance with the peculiarities of Scotch architecture, and he has contrived to infuse not a little of its true spirit into the design under notice. (1121) and (1148) illustrate respectively the Vicarage at Kemble, Gloucestershire, and the entrance Gateway to the mansion of Robert Gordon, Esq., at the same place. In these, as well as the remaining picture, (1156) "Crosby Church, Cumberland," a like versatility of idea is perceptible, and all partake more or less of the same school in which Mr. Billings has so laboriously studied.

Mr. Street is an exhibitor of only one picture (1069), but it embraces two designs for churches he is about to erect in Yorkshire and Hampshire. They are drawn in the author's excellent pen-and-ink style, and are completely illustrated by ground plans as well as external and internal perspectives. While both designs are noticeable for their unpretending simplicity, each possesses an individual character which is well preserved in the subordinate details. A clever adaptation of the plan in one case provides for a picturesque grouping of the shelter over the west entrance with the square dwarf tower at its northern end. The way, too, in which the latter is converted to an octagon in the upper stages is very well managed. We notice in the second design that the chancel roof is made higher than that of the nave.

A very well drawn and elaborate elevation next claims attention (1070), being "A design for the south front of a National Institute of Arts and Science, adapted for the site of Burlington House, Piccadilly," by Mr. J. B. Waring. It presents a curious admixture of the details of all styles of architecture, for it is amusing to observe how Gothic buttresses are interchanged with rusticated Italian piers, and how Classic, Saracenic, and Byzantine features are amalgamated. The elevation forms however a thoroughly symmetrical mass, each extremity being terminated by a cupola surmounted by a glass dome, on the ridge-and-furrow principle. Carving and sculpture are freely introduced in various places with success, but though novelty and ingenuity are manifested throughout, we cannot imagine that in execution such a building would have a satisfactory appearance. It is an effort to produce a new style by combining the details of existing ones; but, to whatever extent this may be allowable, it must be evident that incongruities, such as could be readily pointed out in Mr. Waring's scheme, are by no means admissable.

In Mr. Macquoid's view of the "Cathedral at Autun" (1073) we have a picturesque drawing of a not very satisfactory piece of architecture; but his view of Hampton Court (1145) is an eminently truthful and characteristic picture,—one of the best, certainly, in the room, and which deserved a better place in the hanging. (1074) is a capital sketch of the Tomb of Queen Philippa, in Westminster Abbey, slightly tinted, and by Mr. H. W. Brewer. In (1079) the subject of the Islington Vestry Hall is brought into notice by Mr. Barnett's design, in praise of which there is not much to be said. It is very ordinary Italian, principally marked by its portico of four rusticated columns. By its side (1084) is Messrs. Legg's design for the *Chelsea* Vestry Hall, designed in the same style, but equally poor. It shows an artificial mode of contriving a central feature, by raising the middle of the façade an additional story, as a mere screen, the would-be window openings being absolutely perforated.

(1085) is a mansion, by Mr. Penson, very consistently treated in every way. It is here shown complete, with a plan and several sketches of bits of the interior, also small elevations of the different sides. It has the merit of not being overdone in ornament.

The new Westminster Palace Hotel, the scene of the late melancholy accident, is represented in (1088) by an interior view of the centre hall, which is a large handsome area, four stories in height, and having a flat ceiling trabiated and coffered. The windows partake of the Byzantine type, and, with the other parts, have a good deal of enrichment. The galleries for communication across the ends of the hall are an excellent idea well worked out.

The Royal Albert Asylum, Cambridge (1089), by Mr. Peck, is an unpretending building of good outline; the bands of colour in the material are well introduced. The Choir of Sherborne Abbey, by Mr. Slater (who has recently completed the costly restoration there, commenced by the late Mr. Carpenter), is shown in a large and highly-finished outline drawing of the interior (1091). The magnificent reredos forms a prominent object, and so do the oak fittings; the design of the stall and seat ends is particularly good. The style throughout is Perpendicular, and local peculiarities have not been lost sight of.

Mr. W. Webbe's "Normal College Training Schools, Upper Bangor" (1092), form an excellent group, but have the fault of too much "prettiness," as is frequently observable in his designs. (1097) is decidedly the reverse, as indeed it should be. It shows the "New entrance to Gosford Castle, Armagh," by Mr. G. A. Burn, who has duly preserved the associations connected with the look of impenetrable walls and round towers, portentous machicolations, battlements, and the like. The material is native granite.

Mr. Talbot Bury sends but one drawing (1098), a view of "New Lodge, Windsor Forest," now in course of erection by him for the Belgian Minister. This is really a sensible-looking building, and shows, in its tasteful and unexaggerated details, the author's thorough acquaintance with our mediæval domestic architecture. From Gothic to Classic, from ancient to modern! Such is the destiny of those who follow the leading of the Exhibition catalogue. We next come to the "Arch of Titus" (1099), a very masterly delineation, by Mr. Binyon, and then to (1102), Mr. Dobbin's highly-wrought view of the "Court of the Lions" in the Alhambra, a subject, with all its gorgeousness, not worth practically the pains here bestowed. It is a miracle of work. (1101), "The Hendon Union Schools," just completed from the designs of Mr. C. H. Cooke, is apparently an unusually large red brick building, plain in character, but well balanced; the style Elizabethan. We should like to have seen a block plan.

We cannot pass the "Drawing from Mr. Foley's equestrian statue of the late Lord Hardinge," at Calcutta (1103), without a word of admiration at so noble a memorial; and we may mention, while on the subject of sculpture, the skilful "Monumental effigy of Queen Catherine Parr" (1259), about to be placed in Sudeley Castle, Gloucestershire, where she lies buried. The figure is executed in marble, with every attention to the costume, &c. of the period, and is highly creditable to the sculptor, Mr. J. B. Philip.

(1108), "The drawing-room, library, and other additions to Barton Manor, Oxon," by Mr. S. S. Teulon, form a good group. The style is Tudor, the walls are of stone, with red brick ornamental chimney shafts. The entrance porch is absurdly overwrought; and (1110), by Mr. Joseph James, shows his design, submitted in private competition, for a mansion and farm buildings near Halifax. The style selected—the castellated Tudor—was possibly suggested by the bold nature of the site, and its characteristic features certainly harmonise. The upper portion of the large tower is, however, weak in outline, but the oriel in the building below, corbelled out from the buttress, is very well managed.

The principal merit of Mr. Brakspeare's design for restoring Bowdon Church, Cheshire (1111), is that it preserves as much as possible of the present structure, which, though of the latest period of Perpendicular, has that peculiarity of breadth of parts, produced by repetition, which is not uncommon in works of that age, and which, as a principle, we in the present day are too apt to ignore. (1112) "Long Hall, Guisborough," is a not very prepossessing looking dwelling. The plan shows it to be spacious, but does not appear to be well arranged. (1114 and 1125) exhibit the exterior and interior of a "Design for a Jardin d'Hiver, for H.I.M. the Sultan of Turkey." The Crystal Palace type has been naturally followed, but not servilely, indeed Mr. Lane may be complimented on many variations which give his design an air of individuality, besides contributing to the special requirements of its continental destiny. (1118) is a distant hazy view of the would-be Gothic palace of the Archbishop of York, at Bishopsthorpe. On Mr. Spurgeon's new tabernacle we have already

Digitized by Google

sufficiently descanted, otherwise we might comment on (1119), in which Mr. Pocock shows a well-finished perspective of his design "now in course of erection." (1120) is the garden front of a handsome mansion,—Cromwell House, Mortlake,—exhibited by the architect, Mr. R. P. Pope. It is a clever intermixture of northern and southern Gothic, but, if any thing, is too frittered and pretty. The material is red brick, with black bands.

In (1122) Mr. I'Anson has another adaptation of southern Gothic, applied to "Merchants' offices, Mark-lane." It bears a marked resemblance to the handsome chambers which the same gentleman has erected in Fenchurch-street. (1123) "Competition design for a church at Berne," by Mr. Pedley, is not sufficiently foreign in its aspect. There is also a prevalent tone of fussiness, which detracts from the dignity which such a building should assume. In the design of the low central tower the author appears to have had in view our fine English specimen at Melton Mowbray. The whole is well illustrated by a plan and two interior perspective sketches.

Mr. Goldie's "St. Peter's Church, Scarborough" (1130) partakes quite as much of Italian as of English Gothic, both in form and details. A well-proportioned octagonal apse is an important feature in the plan. Externally, the best portion is undoubtedly the tower, placed at the south-west angle. The domestic buildings shown in connection with the church are very well designed. We are glad to observe also the small plan.—(1131) "The Telegraph Station, Threadneedle-street," by Mr. Horace Jones, now nearly finished, is one of the most showy of our modern city buildings. It is in the French style, and the flatness of the front, which is still too apparent, is relieved by an abundance of excellent carving. The turret surmounting the whole has great play of outline, and has evidently been carefully studied.

(1132) "Design for Mortuary Chapels at Sudbury," by Mr. Moye, is in the ornate Gothic style, and the two-and-two uniform arrangement. (1133) is a gloomy and not very successful view (internally) of the Temple Church. The spectator is supposed to be in the circular vestibule, looking eastward.

(1137) Is a somewhat original idea for the Ellesmere Memorial, by Mr. H. S. Ridley. It may be briefly described as a square pillar or obelisk, shafted at the angles, and resting on a substantial base enriched with festoon and other carving. It was classed as one of the six selected designs, and seems to have deserved the honourable mention which it obtained.

(1138 and 1139) Are views of two mediæval and classic ruins—Kenilworth Castle, and the arch of Septimius Severus, at Rome; —both well given. On (1140), "A memorial cross now in course of erection to the memory of the late Dean of Llandaff," we are rather at a loss to speak. It appears to be an almost exact reproduction of one of our ancient *churchyard* crosses, and their usual situation. Its base is well composed, but the upper part is too spiky.

Mr. Edmeston sends a beautiful drawing (1135) of the Great Gallery of the Architectural Exhibition, Suffolk-street. It has, however, this fault, that it conveys an exaggerated impression of the actual length of the room, and thereby injures its proportions, which in reality are very good. Mr. Gray's "Villa about to be erected at Highgate Rise" (1144) is, like most of his works, clever and picturesque. It is *really* in the villa style. We cannot bestow approval on Mr. S. S. Teulon's "additions to Shadwell Court," as here delineated. The style is Gothic, but badly and coarsely handled; less successful than most of the author's works. (1147) "Interior of Heywood Church, Lancashire," is one of Mr. J. Clarke's best designs. The proportions are especially good, and so is the open roof. There is some novelty in the management of the clerestory windows, which are coupled in each bay, and separated by detached marble shafts

A fine interior of "Durham Cathedral" is exhibited by Mr. Brewer, in (1150). It is taken at the junction of nave and transept, and shows to advantage the stupendous Norman pillars, covered with zigzag work. Of (1151), "Design for a building in place of the present National Gallery," suffice it to say, that it here presents no shadow of a recommendation. Unworthy as may be the present building of occupying "the finest site in Europe," the one before us would be no improvement. The "new schools in Theobald's-road" (1152), are highly creditable to Messrs. Wigg and Oliver, from whose designs they were erected. They are of red brick, deep in colour, and the plan is ingeniously contrived, so as agreeably to break the monotonous line of the street frontage. A circular staircase in the angle aids the general effect.

"Wallasey Water Tower" (1153), by Mr. Rawlinson, is a heavy-looking square mass, dotted on the surface with a host of little windows. The design is not equal to many we have seen from the same hand. (1155) the "Entrance lodge erected at Whittlebury," by Mr. G. Morgan, is a pretty specimen of the simple Palladian style;—(1165) an interesting india-ink sketch of the "ancient wooden porch at Merton Church, Surrey," by Mr. J. D. Wyatt; and (1169) a distant view of Baron Rothschild's magnificent seat at Mentmore—not very flattering. An interior view of the "Britannia Theatre, Hoxton" (1167), lately completed from the designs of Messrs. Finch, Hill, and Paraire, makes an excellent picture. Apart from this the whole conception is unusually good and well carried out.

Into the subject of the Exhibition generally we are not in the habit of venturing; but here and there one out of the thirteen hundred objects chances to be an architectural one. This year they are fewer and less interesting than usual. David Roberts has a masterly interior of St. Mark's, Venice (420), and a fine exterior (160) of Baldassare's noble church of Santa Maria della Salute, in the same city, though it has been objected that, as here painted, it does not look to be of its real material—white marble. Mr. Brandard has (590) a small but pretty view of the "North transept of Tintern Abbey;"—(608) is a grand picture of "Hieropolis, Asia Minor," by Mr. H. Johnson;—(611) a pretty bit of old English domestic work — the "Fishing house, near Marlow;"—(643) by Mr. Stanfield, jun., is a view of the "Grey Friars' Tower, Richmond, Yorkshire,"—careful, but rather hard; —(709) an elaborate picture of the "Grand staircase, Burgos Cathedral," by Mr. Dobbin;—(718) that picturesque ivy-clad ruin "Chingford Church," hung too high up to be properly seen;—(840) "Hayes Church, Kent,"—very poor;—(923) "St. Wulfran, Abbeville, Picardy," by Mr. A. J. Wood, nicely shown;—and (924) "Pæstum," will be viewed with interest. There are some few others of minor importance.

ON THE RELATIVE VALUES OF COKE AND COAL IN LOCOMOTIVE ENGINES.*

By Benjamin Fothergill.

Having attended a meeting of the Society of Arts, on December 2nd 1857, and taken part in the discussion relating to the use of coke and coal in the furnaces of steam-engine boilers, I then undertook to lay before its members the results of a series of experiments which I had made with coke and coal in locomotive engines in corroboration of the truth of my assertions.

First, that coal was decidedly superior to coke in respect to heating power, and consequently more economical;

Second, that a plentiful supply of steam could be generated by the use of coal for working engines at high velocities and for drawing heavy trains;

Third, the capabilities of coal-burning engines for consuming their own smoke; and,

Fourth, the increased durability of fire boxes and tubes when coal was used.

On that occasion I stated that my experiments had been conducted upon the London and South Western Railway, and were made, at the request of the directors, to ascertain the value of an invention which had been patented by their locomotive superintendent, Mr. Joseph Beattie. In this contrivance the fire-box is divided transversely into two compartments by an inclined water space mid-feather or diaphragm, and a dependent water space hanging from the roof. Both compartments are arched over with fire tiles at narrow intervals apart. The boiler is constructed with a combustion chamber extending to about one-half its length, and it has a vertical mid-feather or diaphragm in the centre running parallel with its sides. The other half is supplied with tubes in the ordinary manner. The object of this contrivance is to increase the amount of direct heating surface and to diminish the indirect or tube surface, whilst the combustion chamber affords sufficient space for the introduction of a series of fire tiles for the purpose of retaining a portion of the heat given off from the combustion of the gases in the fire-box, and for diffusing the unconsumed carbon, as well as effecting a complete mixture of the air with the gases, and thereby producing a mass of flame which is brought in contact with the direct heating surface of the combustion chamber

*Paper read before the Society of Arts

before it enters the tubes, and at the same time prevents practically such an escape of smoke from the chimney as could be deemed a nuisance.*

The back or first furnace is the most actively worked, the second being intended to carry incandescent fuel. The ash pans are furnished with dampers for the admission of air when necessary; and also through the small apertures in the fire doors and through hollow stays in the fire-box.

In addition to the mechanical contrivances referred to, Mr. Beattie has another of considerable importance for using a portion of the exhaust steam for heating the feed water before it enters the boiler, and, as I have tried both his contrivances for this desirable object, I need only refer to the one having pipes for conveying the water and steam to a tank under the foot-plate of the engine, from which the feed-pumps receive their supply. The water is received on to a perforated plate in this tank, and in its descent comes in contact with and condenses the steam, and thereby becomes heated; the supply of water is regulated by a ball-tap or valve, and the steam is admitted or shut off whenever the engine driver has occasion to supply or shut off the feed-water to the boiler.

In the course of my first series of experiments, I have used the feed-water supplied by Mr. Beattie's apparatus, at a temperature of 196°.

I may here observe that I was anxious to obtain an analysis of the fuel used by the London and South Western Railway Company, and the more so as I found that they manufactured their own coke from "Ramsay's Coking Coal" (Newcastle), which is of a superior quality; and as it was desirable to ascertain, as far as possible, whether the coke or the coals which were supplied to me contained the greatest amount of sulphur, I sent samples of each to Mr. Dugald Campbell, Analytical Chemist to the Brompton Hospital, London, and he, after a careful examination, furnished me with the following statement, viz.—

"The samples I received were four in number, and marked as follows:

No. 1.—Ramsay's coking coal.
No. 2.—Coke, made from ditto.
No. 3.—Llanguathog Merthyr, shipped Swansea, Neath, and Cardiff.
No. 4.—Griff coal.

"*No.* 1.—*Ramsay's Coking Coal*

"Is of a jet sparkling appearance, and is broken up without much difficulty by the fingers into rather thick layers, between most of which are thin plates of iron pyrites, which, I may state, is a compound of iron and sulphur, in the proportion of one of the former to two of the latter. When the coal is reduced to a very fine powder—and in which state it is required for analysis—its jet black appearance gives place to a considerable brown tint, which indicates it to be of a bituminous character.

"The calorific value of a substance is generally estimated in two ways; firstly, by calculating from its ultimate analysis what quantity of water a known weight of the fuel would evaporate from 212° Fah.; and, secondly, by ascertaining how much oxide of lead is capable of being reduced to the metallic state by a known quantity of the fuel.

"These experiments when conducted upon the different specimens of fuel under precisely similar circumstances, and which has been the case in this instance, give results extremely useful for comparing the economic value of the fuel. By such means, 1 lb. of No. 1, Ramsay's coking coal, was found to be capable of evaporating 15·18 lb. of water from a temperature of 212° Fah.; and 1 lb. of reducing 34·99 lb. of metallic lead from the oxide."

"*No.* 2.—*Coke made from Ramsay's Coking Coal.*

"The specimen I received of this substance was a thin column, which, from its appearance, must have occupied a space from the top to the bottom of the coke in the coking furnace. An average sample was selected from this for examination.

"One pound of this coke is capable of evaporating from 212° Fah. 12·78 lb. of water; and 1 lb. of reducing from the oxide of lead, 31·35 lb. of metallic lead."

"*No.* 3.—*Llanguathog Merthyr.*

"This coal has a bright sparkling appearance, resembling to some extent (No. 1) Ramsay's coal; but it is rather more dense, and not so easily broken; when broken however, the layers are not so thick, and between them no iron pyrites are visible, but thin plates of silicate of lime are occasionally noticed.

"One pound of this coal is capable of evaporating from 212° Fah. 14·74 lb. of water; and 1 lb. of reducing from the oxide of lead 34·74 lb. of metallic lead."

"*No.* 4.—*Griff Coal.*

"This is a coal of a dull appearance, dense and hard, with a concoidal fracture, different from either of the other two coals.

"One pound of this coal is capable of evaporating from 212° Fah. 9·8 lb. of water, and 1 lb. of reducing from the oxide 25·14 lb. of metallic lead."

"*Table of Results.*

	No. 1, Coal.	No 2, Coke.	No. 3, Coal.	No. 4, Coal.
Density, water being 1000 ...	1·279	1·055	1·333	1·341
Carbon	85·57	86·91	89·16	66·21
Hydrogen	5·68	1·32	4·06	4·09
Oxygen	3·07	0·10	1·65	11·07
Nitrogen	1 48	0·80	1·21	1·13
Sulphur	1·46	1·94	1·39	1·01
Moisture	0·74	1·28	0·67	9·23
Ash	2·00	7·65	1·86	7·26
	100·00	100·00	100·00	100·00
Pounds of water which 1 lb. of fuel would evaporate from 212° Fah.	15·18	12·78	14·74	9·8
Pounds of lead reduced by 1 lb. of fuel	34·99	31·35	34·74	25·14

"In glancing at the above table, the first thing that arrests the attention is the per-centage amount of sulphur being greater in the coke than in the coal from which it was made, and by nearly a half per cent.

"It appears from my analysis that although in coking coal there may be a notable loss in the per-centage of carbon, hydrogen, oxygen, and nitrogen, in the coke, yet the sulphur has not only not decreased, but has actually increased in the per-centage. I find in the coking oven that not more than one-twelfth of the sulphur goes off from the coal, whilst the loss of the other gases is upwards of one third of the whole.

"But portions of the coke may be found to contain a very much larger quantity of sulphur than I found in the above specimen, and if I had selected a piece from near the top of the column, instead of taking an average of the whole, I should have found very much more than I did.

"The pieces of coke delivered to me by your assistant, which he told me he had taken from a quantity from the tender of an engine in going down to Southampton, on the 2nd ultimo, gave on an average 5·62 per cent. of sulphur, and some which I selected myself from the coke-heap at the Nine Elms station gave about 5 per cent.

"The next peculiarity to be noticed between the coke and the coal from which it is made is, in the amount of ash being very much higher in the former than in the latter; this is caused by an excess of iron and silica principally, and were it not for the increase of ash there would not be so very much difference in their heating power, &c. I can only account for this increase in these two substances from their being volatilised in the coking-ovens, and entering into the crevices of the fuel from which the gases escape.

"It is common to find large quantities of a hairy-like substance adhering to the coke, varying in colour from a light-grey to black; this is silica, with a trace of carbon and iron, and which has been in a state of volatilisation till arrested by coming to a cooler part of the coking-oven, where it has condensed, and is found as I have described it.

"No. 3, Llanguathog Merthyr coal, you will observe, is a coal of a very superior quality, and is nearly equal to Ramsay's coking coal in heating power, and has a very little less per-centage of sulphur; but No. 4, Griff coal, though containing less sulphur than either, does not possess such heating power, which is partly owing to its containing a large per-centage of water; this water is expelled when the coal is reduced to a fine powder, and submitted for some time to a temperature of 212° Fah. The

* For illustrations and description of Beattie's Engine, see *ante*, vol. xxi. p. 270.

Digitized by Google

moisture in the other specimens was determined in a similar manner.

"I may state that my experiments were repeated, and great care was bestowed to verify any results which appeared contrary to what should have been expected, such as the larger amount of ash in coke in comparison to the coal from which it was made, and the larger amount of sulphur in coke than in coal, the general belief being that in the coking of coal most of the sulphur is driven off."

I will now proceed to give a detailed statement as to my mode of procedure to ascertain the quantity of fuel consumed per trip from the Waterloo Station, London, to Southampton and back again, inclusive of the quantity used in getting up steam in the morning and whilst waiting at Southampton. I personally inspected the weighing of the fuel in the morning, and again at Southampton; and on the return of the engine to Nine Elms I took an account of the coal which remained on the tender, and I had the fire-box cleared out, the hot material cooled and riddled, and the worthless portion separated, and I allowed the value in good coal for the remainder.

I commenced my experimental trips with the coal engine Ironsides, which had been constructed on Mr. Beattie's patented plans, for burning coal only, and heating the feed-water, and took the 10.15 A.M. mail train from Waterloo to Southampton, and arrived there at 1.5 P.M. We commenced the return journey at 3.0 P.M., and arrived at the Waterloo Station at 5.58, the engine having performed the trip in a most satisfactory manner, and without any appearance of smoke, save and except when the steam had to be got up in the morning, or the fires prepared for the return journey.

The result of that day's trip will be seen by referring to the tabulated summary opposite November 15th, where the average consumption of fuel is shown as 16·71 lb. of coal per mile, or when reduced to its coke value equal to 11·14 lb. per mile, with an average load of 12·2 carriages per mile, travelling at an average speed of 31·25 miles per hour.

I have said that the consumption of coal, when reduced to its coke value, was equal to 11·14 lb. per mile; in explanation of my meaning, I beg to state experience has proved that, in order to make one ton of good coke suitable for locomotive engines, 1½ ton of the best coking coal is required, and with some kinds of coking coal, 1½ to 1¾ ton are necessary to produce one ton of coke. It will be evident then, that if the same load can be taken at the same velocity and under the same circumstances in respect to weather, with equal weights of fuel, say with coal in engines fitted up with Mr. Beattie's patented contrivance, and with coke in the ordinary class of engines, a net saving is effected of one-third, or 33 per cent., in fuel alone, without taking into consideration the incidental saving consequent on the construction of coke ovens, the interest on capital, the cost of maintenance, and the wages of workmen employed in the manufacture of coke.

From the tabulated summary it will be seen that I worked the coal engine Ironsides for three days with little variation in respect to the quantity of fuel consumed, that little variation arising from the change in the weather. I then selected the coke-burning engine Vesuvius, one of the ordinary class, and being nearest in dimensions and weight to the Ironsides, and in good working order, and with it I took a similar train (10.15) to and from Southampton, burning coke only, and I adopted the same course of proceeding as on the former trips, but with a very different result as regards the consumption of fuel; for, on referring to the general summary, it will be seen that the average load was 12·1 carriages, the average speed 30·27 miles per hour, while the average consumption of fuel was 20·62 lb. of coke per mile. On the following day I took the express train with the same engine, but the results were substantially the same as on the previous day with the mail train.

Having tried the Vesuvius, I decided upon taking another coke-burning engine (the Frome), which was a similar class engine to the Vesuvius, in order to ascertain if there was any difference in the results of their working. On referring to the summary of the trip opposite November 22nd, it will be seen that the consumption of fuel was remarkably near that of the Vesuvius.

I then determined to test the capabilities of another coal-burning engine, the Canute, and compare the results of its working the express train with that of the Vesuvius. The load was lighter, averaging 9·3 carriages, but the average speed attained was higher, being 36·76 miles per hour. The consumption of fuel was 16·71 lb. of coal per mile, the coke value of which is 11·14 lb. per mile against 20·62 lb. per mile consumed by the Vesuvius. —See trip in summary, November 23rd.

The experiments up to this period showed a decided advantage in the coal-burning engines, so far as regarded economy of fuel, &c., but the results were not conclusive to my mind, inasmuch as the engines had not worked under precisely the same circumstances with respect to weather and uniformity of load and speed. I therefore obtained a sufficient number of carriages to form two trains of equal size and weight, and I had a quantity of material weighed and placed in each of them equivalent to a load of passengers. The coal-burning engine Canute was attached to one of the trains, and the coke-burning engine Vesuvius to the other. The weight of the train, including engine and tender, drawn by the Canute, was 170 tons 8 cwt., and that drawn by the Vesuvius 167 tons 12 cwt.

The trains left London and Southampton within a few minutes of each other, so that there could be no difference between them in respect to weather, but lest either train should run heavier than the other from extra friction in the axle bearings, I took a second trip on the following day with the engines changed from one train to the other. I registered the particulars of each day's trip separately (see November 30th and December 1st); but taking the average of the two days' working, the difference in respect to consumption of fuel will be more readily seen.

	Average speed.	Average consumption of fuel in lbs. per mile	Load.
Canute	28·40	Coal 20·36	19 carriages
Vesuvius	27·23	Coke 24·37	19 ,,

Coal reduced to its coke value 13·57, which shows a clear saving of 10·80 lb. per mile.

I subsequently tested the capabilities of the coal-burning engine Canute for making sufficient steam when drawing heavy loads, and as this engine was rather heavier than the coke-burning engine Vesuvius, I obtained an additional number of carriages, and after they had been weighted I had twenty-eight of them attached to the Canute, and twenty-two to the Vesuvius, making the total weight of the Canute train 235 tons 13 cwt., and that of the Vesuvius train 189 tons 6 cwt. I was very desirous of testing the capabilities of the coal-engine Canute for drawing a heavy load up the incline from Southampton to Andover (a distance of 22 miles) without the aid of a pilot engine, and for that purpose I added about 20 tons extra weight to this train beyond its proportionate load.

Early in the morning of December 19th, 1855, we proceeded to Southampton with the two trains, but unfortunately the water pipe attached to the lower part of the boiler in the Canute engine gave way, and the leakage therefrom became so great soon after we left Southampton that we were obliged to pump into the boiler an extra supply of water to compensate for the loss sustained. A reference to the registered account of the trip on that day will show that while the Vesuvius (coke) engine evaporated 7·13 lb. of water by 1 lb. of fuel, the Canute (coal) engine evaporated 9·05 lb. of water by 1 lb. of fuel. The amount of water, therefore, which passed from the tender of the Canute engine was greater by 1·92 or nearly 2 lb. of water per 1 lb. of fuel than that from the tender of the Vesuvius, but notwithstanding that mishap, the Canute generated sufficient steam to draw the 28 loaded carriages up the bank without any aid whatever.

The firing from the same cause was increased, but the result on the day's work of the two engines was still in favour of the coal-burning engine, as will be seen from the summary; and it is worthy of remark, that when the coal is reduced to its coke value the result is 10·30 lb. per mile in favour of the coal-burning engine Canute.

I have shown that the saving effected by the coal-burning engines with the ordinary trains was equal on the average to 8·56 lb. of coke per mile, or 10·80 lb. of coke per mile when each engine worked under the same circumstances as to weather, &c. with equal loads. Now if the former quantity, viz., 8·56 lb. per mile, be taken, the saving is equal to 1·348 lb. on each trip, or at the rate of 187¾ tons per engine per annum, at six days' work in each week; but if the latter quantity (viz. 10·80 lb. per mile) be taken, the saving is equal to 1·721 lb. at each trip, or 239½ tons per engine per annum.

The consumption of coke by the coke-burning engine Vesuvius during one of the trips referred to was 29½ cwt., which at 31*s.* 6*d.* per ton was equal to £2. 6*s.* 6*d.*; whereas the consumption of the coal-burning engine Ironsides, during another of the trips, was 24¾ cwt., which at 19*s.* per ton was equal to £1. 3*s.* 6*d.*, giving a

Digitized by Google

clear saving on the latter per trip of 23*s*. In my report to the directors of the London and South Western Railway Company I stated that if they had seventy engines in steam per day, and each of them was fitted up for burning coal, and all worked under similar circumstances to the Ironsides, there would be a daily saving to the company of £80. 10*s*., or £25,116 per annum.

From the result of these important and interesting experiments I trust I have succeeded in demonstrating the truth of the assertions I made at the meeting to which I have referred,—viz., that coal can be used more economically in locomotive engines than coke; that by the use of coal sufficient steam can be generated to supply locomotive engines when working at high velocities and when drawing heavy loads; and in support of my assertion relating to the capability of coal-burning engines built in accordance with Mr. Beattie's patent, consuming their own smoke, I have to observe that a goodly number of them are at work on different lines of railway, and testimonials of thier efficiency have very frequently been given.

Summary of Experimental Trips made on the London and South Western Railway.

Date.	Name of Engine.	Description.	Average time in hours and minutes.	Average speed in miles per hour.	Average feet consumed in lbs. per mile.	Coal reduced to its coke value.	Quantity of water evaporated per mile per lb of fuel.	Highest temperature of water in tender during each trip.	Load in number of carriages.	Weight of train, including engine and tender.	Remarks.
1855.							lb			Ton. cwt.	
Nov. 15	Ironsides	Coal	2·31	31·25	16·71	11·14	8·29	124°	12·2	...	Beautiful, clear frosty day, and calm.
,, 16	Ditto	,,	2·31	30·68	17·24	11·49	6·72	158°	10·6	...	Damp foggy day; rails greasy for 50 miles.
,, 17	Ditto	,,	2·39	29·71	19·02	12·68	7·07	164°	12·1	...	Clear day, with strong side wind in favour of down and against up journey.
,, 19	Vesuvius	Coke	2·36	30·27	20·62	...	7·15	76°	12·1	...	Wet drizzling rain, with light wind on our back.
,, 20	Ditto	,,	2·26	35·23	20·62	...	7·78	74°	12·2	...	Rails rather greasy; wind against down journey.
,, 22	Frome	,,	2·27	32·14	20·97	...	7·62	94°	13·3	...	Ditto.
,, 23	Canute	Coal	2·11	36·76	16·71	11·14	7·35	166°	9·3	...	Fine clear day, with light wind in favour of down journey.
,, 30	Ditto	,,	2·49	27·65	20·51	13·67	8·26	142°	19·0	170 8	Fine frosty day; rails greasy for first 50 miles.
,, 30	Vesuvius	Coke	2·56	26·54	23·82	...	8·21	54°	19·0	167 12	This was the first trip with equal loads.
Dec. 1	Canute	Coal	2·39	29·16	20·22	13·48	8·07	150°	19·0	170 8	Great difficulty in starting; rails slippery in consequence of frost and damp fog; wind rather stiff against us.
,, 1	Vesuvius	Coke	2·47	27·92	24·92	...	7·78	54°	19·0	167 12	
,, 19	Canute	Coal	2·55	26·92	29·80	19·86	9·05	...	28·0	235 13	Frosty, with strong head wind against us.
,, 19	Vesuvius	Coke	3·09	24·71	30·16	..	7·13	36°	22·0	189 6	Water pipe in Canute gave way: shut off heating apparatus.

There yet remains the question of the durability of the fire-boxes and tubes when coal is used instead of coke; and I do not think that I could offer a better proof of the superiority of coal over coke in this respect also, than by quoting a portion of a report which I made on this important subject, on May 26, 1858, to the locomotive superintendent of the Manchester, Sheffield, and Lincolnshire Railway. The engines there referred to were built in accordance with Mr. Beattie's patent for burning coal and coke:

"With respect to the durability of the tubes and fire-boxes when coal is used instead of coke, I consider that question to be settled beyond dispute in favour of the former, inasmuch as it no longer remains a matter of opinion merely, but the result of continuous working with coal and coke demonstrates beyond all doubt that not only is coal superior to coke in respect to heating power, and consequently decidedly more economical, but it is less injurious to both the tubes and fire-boxes of locomotive engines; as a proof of this I beg to append a copy of a tabular statement which I had the honour of laying before the directors of the London and South Western Railway in the month of March 1856, showing the average duration of a set of tubes in their locomotive engines when coke alone was used. At that time as well as in the latter part of 1855, after I had made a series of experiments with coke and coal, I came to the conclusion that the tubes and fire-boxes would sustain less injury by the use of coal than coke, and although one of their coal engines had then run but 51,300 miles, and no really appreciable depreciation had taken place in either fire-box or tubes, I saw sufficient to warrant me in concluding that the life of a set of tubes as well as that of the fire-box would be considerably prolonged by the use of coal instead of coke. Time has proven that the opinion I then formed was a correct one, inasmuch as I have up to the present moment carefully watched the effects produced on the fire-boxes and tubes of the locomotive engines on the London and South Western Railway; and taking two of their engines which I have examined, where even part coke and part coal have been used up to the commencement of the present month, you will perceive the amazing difference in favour of coal when you compare the results with the tabulated statement in my printed report dated March 25, 1856. The average duration of a set of (coke engine) tubes was 94,518 miles; whilst in the two engines I have referred to where coal and coke have been used, one of them has run 154,955 miles, and is now carrying 120 lb. pressure of steam,—none of which tubes have failed, and they are still in good working condition, and I am unable to say how much longer they will last. The other engine has run 137,676 miles; and I have had two of her tubes sent to my office in Queen's-chambers, Manchester, which you can see at any time.

"I personally paid a visit to the works at Nine Elms and examined these engines; and bear in mind, that although a portion of the fuel used in these engines is coke, yet the tubes I now refer to have only worn to the extent of three wire guages in thickness; they were ordered and made to No. 13 wire guage, and are now No. 16 wire guage.

"No doubt exists in my mind that the principal portion of this amount of reduction in thickness is attributable to the cutting action of the coke, and not to the effect of any deterioration produced by the action of the coal. With regard to the effect on the fire-box of the latter engine, the back, sides, and crown are $\frac{1}{33}$ of an inch less than their original thickness, namely, $\frac{1}{2}$ an inch; the tube-plate has been reduced $\frac{1}{16}$ of an inch, the original thickness being $\frac{3}{4}$ of an inch. From these facts you will be able to draw your own conclusions—they speak for themselves—for in one case where coke alone was used, you have an average (taken from the company's books) of 94,518 miles as the life of a set of tubes, whilst in the other, where coke and coal are used on the same railway, and working similar trains, you have 154,955 miles run in the one case, and of 137,676 miles in the other, and the tubes still in good working condition.

"I have given you these facts as a sample of the results when coke and coal are used, because the fuel you are using in your engines is of a similar character; but I am prepared to prove that were your engines constructed to burn coal alone, the fire-boxes and tubes would be protected from the cutting action of the coke, and greater durability, much beyond the mileage I have reported for coke and coal, would be the result. I am not ignorant respecting the argument that some parties have advanced as to coal containing a greater amount of sulphur than coke; this is a fallacy which I had proved beyond doubt, and therefore I hesitate not to give you a strong opinion in favour of coal, for instead of its proving destructive to fire-boxes, tubes, or smoke-boxes, the result of my observations and experiments proves the contrary."

In further confirmation of the increased durability of the tubes,

Digitized by Google

I beg to state that the mileage of another engine of the same class as the two referred to, and burning a mixture of coke and coal, amounts to 181,589 miles, and the tubes are still in good condition, and working at a pressure of 120 pounds to the square inch.

In conclusion I beg to remark, that previous to the year 1853, several attempts had been made by different individuals to introduce coal as a substitute for coke in locomotive engines, but from various causes they did not persevere in developing its true commercial value, and I would take this opportunity of stating that the credit of this important saving in railway expenditure is due to the skill and persevering industry of Mr. Joseph Beattie.

Discussion.

The Secretary read the following communication, received from

Mr. D. K. CLARK.—I perfectly agree with Mr. Fothergill in assigning to Mr. Beattie the honourable position of pioneer in the successful practical introduction of coal as a substitute for coke in locomotive engines. I believe that from this source of economy alone an addition of nearly 1 per cent. may be made to the dividends on the original share capital of railways, taking one with the other, with the reduced wear and tear of locomotives. I think, however, that the mode adopted in the paper of illustrating the saving in cost effected by the substitution of coal for coke is open to criticism, and does not place the question on its proper basis. It is true that the quantity of coke manufactured from a given weight of coal weighs only two-thirds of the original coal so consumed, and that 1½ ton of coking coal make only one ton of coke. But in seeking to establish this ratio of 3 to 2 as the measure of saving, that is, that the cost of fuel is reduced one-third in dispensing with the coking process, it is overlooked that coking coal, as coal, is not the proper fuel for locomotives, and that therefore the calculation of saving should be based, not upon the relative quantities of coking coal and of coke made from it, but upon the relative prices and efficiency of proper locomotive coal and coke. This ratio is necessarily very variable, as it is affected by cost of transport and other elements. For instance, on one metropolitan line, whilst coking coal costs 12*s.* 6*d.* per ton, and the coke made from it costs 18*s.* 6*d.*, other coal suitable for locomotive uses costs as much as 15*s.* per ton. On another line, whilst the cost of coke is 23*s.* per ton, the coal suited for locomotives costs 20*s.* per ton, or only 13 per cent. less. Again, take the North Eastern Railway, at Newcastle, the difference of the cost of coke at from 8*s.* to 11*s.*, and locomotive coal at 7*s.* per ton, is so inconsiderable as to scarcely make it worth while to use coal on that line. Notwithstanding such local approximations in cost, there can be no doubt of the economical importance of the question before the meeting. Again, in the comparison of the coal-burning engines with the coke-burning engines of the South Western Railway, no allowance has been made for the benefit of heating the feed-water of the former, as against the use of cold water in the latter; whereas my own experience with Mr. Beattie's engine, the Canute, showed a most material increase in the consumption of coal when the feed-water was not heated. The following were the results I obtained from the engine with hot and cold water respectively:—

	Average train.		Coal consumed per mile.		Temperature of feed-water.
With heated water...	11 carriages	...	17·4 lb.	...	191 degrees
With cold water.....	11 ditto	...	24·0 lb.	...	56 ditto

Showing an increase of 6·6 lb. of coal per mile by using the feed-water cold, as was done in the coke-burning trials recorded by Mr. Fothergill. The coke value would therefore be 16 lb. per mile, and not 11 or 12 lb. as assumed in the paper, for comparison with the coke-burning engines. The large extra consumption of coal, by shutting off the heating apparatus, is no doubt greater in proportion than would be deducible from the known constituent heat of steam and water; but it is caused also by the less favourable working conditions of the engine involved in the use of cold water.

SIR JOHN RENNIE said that Mr. Fothergill proposed to establish that which appeared to be a very simple proposition, namely, that the whole was greater than its part; in other words, that coal, which contained all the elements of combustion and locomotive power, was more effectual than the same coal when deprived of some of its elements and converted into coke.

Mr. GRANTHAM said that the paper had disappointed him upon one or two points; Mr. Fothergill had not stated whether he employed the hot water apparatus in the coke-burning engines, as well as in those burning coal. He would also ask him whether he had considered the question of the blast in the coke and coal-burning engines, as he was of opinion that a much greater heat would be found in the smoke boxes of the latter than of the former, and less blast would therefore be required. That was an important point. Mr. Fothergill had stated that the wear and tear of the tubes of the boiler was very much less in the coal than in the coke-burning engines. That fully corresponded with his own experience; but there was another element to be considered, viz, the first cost of this particular description of engine. There might be a question whether the first cost of the engine, which appeared to be an expensive one, did more than make up for the difference in the wear and tear under the two systems. He did not say this with a view to depreciate the statements made in the paper, for he was an ardent admirer of the use of coal in locomotives. There was also another very important question, viz., the heat of the gases in the smoke box. He was afraid that railway engineers had overlooked this too much, and that those who had made experiments upon the subject had made some mistakes. He had lately taken pains to make inquiries of some of the leading engineers as to the heat in the smoke boxes of locomotives, and the answer he got generally was, that experiments had been tried, and that the temperature had been reduced as low as 300 deg. of heat; others had informed him that it was about 400 deg. of heat in the smoke box. A curious experiment had been tried in his own neighbourhood, where a thermometer had been let down into the smoke box, the bulb of the mercury going into the box for some distance, and the scale being in sight of the engineer. When the engine was standing at the station the thermometer recorded 300 degrees, but it had no sooner started than the thermometer fell to 150 degrees. This gave rise to some speculation as to the cause of this wonderful phenomenon, and many theories would, perhaps, have been founded upon it, but the whole was easily explained by the fact that round the thermometer there was a space, so that when the engine was put in motion, and the blast came into operation, the cold air struck upon the bulb of the thermometer, and lowered the temperature of the mercury. He believed the temperature of the fire-box would be much affected by the use of coal, and he was sorry that Mr. Fothergill had not brought that subject forward as an element in his experiments. Referring to specimens of spiral heat-diffusers before the meeting, Mr. Grantham explained that the glass tubes shown represented the tubes of a boiler, and contained a spiral bar of metal. This was the invention in the first instance of Mr. Duncan, who took out a patent for it. Mr. Charles Wye Williams, without being aware of these experiments, was making others in the most accurate manner of his own upon the same subject. Mr. Williams's apparatus was also patented, and as these patents clashed, and there were points in each desirable to be retained, they amalgamated, and the invention was now known as Duncan, Gwynne, and C. Wye Williams's Heat-diffusers. Mr. Grantham detailed the results of experiments made with the heat-diffusers as recorded by Gauntlett's pyrometer. The diffusers were placed in the tubes of the boiler, and he knew from experiment that they reduced the heat in the smoke box prodigiously, probably 200 or 400 degrees. The indication of the pyrometer with the heat-diffusers in was 800° in the smoke box, and he believed it would have risen to 1000 or 1200 degrees if the heat-diffusers had not been in use. He had every reason to suppose that if coke had been used in the engine instead of coal, the heat in the smoke box would have been less. If, therefore, Mr. Beattie's or any other coal-burning engine had this enormous temperature in the smoke box, it was evident that there was room for improvement in that respect, and it was another item in favour of coal if these deductions were correct. The heat-diffusers above alluded to promised very good results, the first trials showing nearly 20 per cent. of gain; and one of the practical difficulties in using them, viz., the supposed tendency in the tubes to become closed with ashes, had not arisen. For a great many years he had attended the experiments of Mr. Wye Williams, and had been a party to most of the investigations made by that gentleman upon the combustion of coal, and from the experience thus derived, he was of opinion that the operations so necessary in this matter would be carried on by a simpler engine than that of Mr. Beattie—combining, it might be, many of his contrivances, but doing away with a great deal that was complex.

Mr. JOHN BRAITHWAITE thought that ere long the boilers of engines would be constructed of a different form, so as to produce

Digitized by Google

more efficiently the draught in the furnace, not precisely after the plan which he (Mr. Braithwaite) brought forward in 1829, but such an improvement upon it that the combustion would be steadily carried on, and the gases essential to the generation of steam would be given out without the use of the diffuser to which allusion had been made. This principle had been carried out in the caloric engine, and had been found so far successful.

Mr. JOHN BETHELL said some years ago it was stated at the scientific institutions that the coke made from a certain quantity of coal would give the same amount of heat, and evaporate just as much water, as the coal from which it was made. He believed that was a theory advocated by Mr. George Lowe. He (Mr. Bethell) was astonished at that theory, for when they observed the great heat that was generated in converting coal into coke, it seemed very remarkable that the coke should, after being subjected to that process, give as much heat as the coal itself. The difference arose entirely in the mode of burning the fuel. It was possible, no doubt, to construct a furnace which would give coal no advantage over coke. The real point was the proper construction of the furnace. It was excessively simple to burn coke when operated upon by a strong draught, so as to get all the heat out of the carbon which it contained; but it was not so simple to burn coal, because this involved two operations; they had to burn the gases, which required one mode of treatment, and the carbon or coke, which required another mode of treatment. He had not yet seen any plan which, in his opinion, was perfect for burning all the gas and all the carbon. The plan laid before them that evening appeared to him very complicated. In France and Belgium, where they burnt a great deal of coal, as well as a patented fuel which contained more gas than coal, they had a simple apparatus for doing it, and they carried out the process in the locomotive engines without producing so much smoke as he had met with on railways in this country. It was a simple arrangement of the fire-box, which allowed air to pass in over the fire. With regard to the analyses before them, he could hardly believe them to be correct. It was easy to take an analysis of the composition of coal, but the ascertaining how much water a certain fuel would evaporate was a different matter, as apparatus specially adapted to the different kinds of fuel was necessary in order to obtain reliable results. If they were using an apparatus to burn coal which contained the gases as well as the carbon, they must have an apparatus in which the air came over the fire, and if the same apparatus was used for burning coke it would not answer. Hence they found it stated in the table before them that 1 lb. of Ramsay's coal evaporated 15 lb. of water, whereas 1 lb. of coke evaporated only 12 lb. of water. He believed if the coke were used with a proper apparatus it would evaporate more. Again, they found it stated that the Merthyr coal, which contained 89 per cent. of carbon and 4 per cent. of hydrogen, or 93 per cent. of heat-giving properties, evaporated only 14 lb. of water per lb. of coal; whilst Ramsay's coal, which contained only 90 per cent. of heat-giving properties, evaporated 15 lb. of water. That, to a theoretical man, seemed an absurdity, and showed that in all experiments as to using fuel for the evaporation of water, everything depended upon the manner in which the fuel was used. The Welsh coalowners had, for a long time, contended that their coal would evaporate a larger quantity of water than the Newcastle coal; latterly, however, the Newcastle gentlemen had asserted that their coal would evaporate more water than the Welsh coal: but, to his mind, such statements ought to have no weight, unless each description of coal was used with an apparatus especially suited for it. Then came the question whether the apparatus which was suitable for any particular description of coal could be practically adapted for general use with steam boilers. That was a matter of considerable difficulty. They could easily construct a small experimental apparatus, but they might not be able to apply it, when coal was burnt in masses for heating large boilers. He did not think the meeting was in a condition to argue this question upon the data given in the paper before them, or to enter into it in a way that its great importance deserved.

Mr. GEORGE LOWE, F.R.S., said, with reference to a statement which Mr. Bethell had noticed as having been made by him (Mr. Lowe) on the occasion of the reading of a paper upon this subject by Mr. Apsley Pellatt, that on that occasion he gave the general opinions of the books—of the schools—rather than his own. Mr. Pellatt's experiments upon the relative value of the coal and coke for the purposes of his immense manufactory had been of the most beautiful and satisfactory kind. Mr. Pellatt would work one week or a fortnight with coal, and the next with coke made from the same amount of coal, and he had shown that in every instance the work in his manufactory was done as well with the coke produced from a ton of coal as with the coal itself. There were eminent French chemists who confirmed Mr. Pellatt's views, which were further confirmed by some experiments made at Philadelphia; and it was to be remarked that whilst Mr. Pellatt was working upon a large scale, the French chemists on a small scale in a laboratory, and the Americans on another scale, and he (Mr. Lowe) was also making his own experiments, the results of all these trials seemed entirely to coincide. Some of the experiments recorded by Mr. Fothergill were made as far back as 1855; but the French engineers, during the last two years, had made immense progress in the successful introduction of coal into the locomotive engine. The great thing was how to conduct the combustion so as to make use of all the heat-giving properties contained in 1 lb of coal. Mr. Bethell had, no doubt, hit the point in stating, that it was absolutely necessary that a certain amount of air should go over the fire as well as through the furnace to produce the proper combustion of coal. The great object was to prevent smoke and produce heat. Many years ago his (Mr. Lowe's) father conducted one of the largest malting establishments in the country, and the whole of the heat in the kilns was produced by the bituminous coal of Derbyshire. All the products of combustion went through the kiln, and if any smoke had been produced, five minutes would have sufficed to destroy a very large quantity of malt. For the last thirty-five years there had not been a furnace erected by him in any part of the world in which the principle of letting a certain amount of atmospheric air pass over the surface had not been adopted.

Professor JOHN WILSON, F.R.S.E., referred to a point mentioned in Mr. Clarke's letter, in which that gentleman spoke of the difference between coal which was suitable for locomotive engines and that from which coke was made. He stated that the bituminous coals were not those best suited for these engines. If his (Professor Wilson's) idea was right, as to the value of fuel depending upon the amount of hydro-carbons it contained, then the more highly bituminous the coal was the greater would be its evaporative power. He could reconcile the difference in the relative quantities of sulphur in coal and coke in Mr. Fothergill's analyses, for when, as had been stated, it took $1\frac{1}{2}$ ton of coal to make a ton of coke, it was possible that an extra amount of sulphur might exist in the coke; but he could not understand how coal containing 2 per cent. of ash could be converted into coke containing 7 per cent. of ash, when only $1\frac{1}{2}$ parts of coal went to make one part of coke.

Mr. BETHELL thought he might have been misunderstood in his remarks in reference to the experiments on the relative heating powers of coal and coke. The point he desired to lay stress upon was, that he could not understand, and he could not believe, that if proper apparatus had been used for burning the coke, the evaporative power would have been so small in comparison with that produced by coal.

Mr. FOTHERGILL, in reply upon the discussion, said he had been entirely misapprehended by one or two gentlemen in reference to the analyses he had given. These analyses had been made in the laboratory of Mr. Dugald Campbell, and were not the result of actual experiment from the use of the fuel in a locomotive engine. With regard to the question of heating the feed-water referred to by Mr. Clarke in his letter, he would state that when experiments were first made with Mr. Beattie's engine that contrivance was not appended to it. The apparatus then used did not enable them to feed the boiler with hot water at starting, but as they proceeded on the journey the temperature of the water became higher; but in the modern contrivance they could commence the journey with the feed water at a high temperature. With regard to the relative quantities of the fuel, he had stated that $1\frac{1}{2}$ ton of coal had been used to produce 1 ton of coke; in some instances the quantity had been $1\frac{3}{4}$ ton of coal to produce 1 ton of coke; but in order that there might be no misunderstanding upon that point, he had put the calculation into the money shape, and he had stated what the result was without taking into consideration how much coal it required to produce a ton of coke, but had at once given the cost of working the train, which he thought was the legitimate question to which they should turn their attention. He took the coal furnished at a given price, and also the coke, and then instituted a comparison between the two, not

Digitized by Google

troubling himself about the different classes of coal and coke. He had conducted experiments for the Lancashire and Yorkshire, and the East Lancashire Railway Companies, but there was not time to apply the contrivance for heating the feed-water. With regard to the blast-pipe in Mr. Beattie's engines, they had had to increase the amount of air to soften the blast, for if they had a powerful blast, they then got an over-heated smoke-box. He never knew an instance of that upon the South Western line but once, which was during a heavy wind, where they had a powerful blast, and the whole of the steam was used in passing up the chimney.

THE NEW TOWN HALL, HALIFAX.

THE drawings for the new town hall at Halifax, prepared by Mr. Stevenson, the borough surveyor, have been exhibited in the present town hall during the past month. They are fourteen in number, and include two views of the principal elevation, together with the interiors of the Borough Court and Council Chamber. There are also three designs for the front towards Crossley-street, one with a dome attached, one without, and one without dome, but with a clock placed in a receptacle in the surmounting cornice. The style adopted is the Græco-Italian, the basement story being rusticated. In the lower story are four windows, circular-headed, and enriched with carved key-stones, marble shafts, &c. Each window is placed between two columns of the Doric order, slightly differing from the ancient examples. The principal entrance is in the centre of the front, and is boldly treated. A richly detailed string-course, with dentil moulding, divides this story from the one above. In this latter are five circular-headed windows, treated differently from those mentioned before. Their enrichments consist of marble shafts, carved capitals, and richly moulded architraves. Between each pillar are a couple of columns of the Corinthian order. The principle cornice is proportionately deep to harmonise with the scale of the elevation, and has ornamental carving occasionally introduced, while above, the line is broken by six pedestals, on which are placed a corresponding number of vases. The dome, as proposed, would consist of a tambour of plain masonry, upon which stands twelve Corinthian columns, placed in couples, having in each space a plain circular-headed window. From the cornice springs the semicircular dome itself, which is intended to be in stone, and to be terminated by an ornament in keeping with the rest of the design. The two other exposed fronts are comparatively simple, but that towards Broad-street has a four-column portico.

The accommodation provided for is as follows:—Upon the basement is a workshop for the plumbing department 75 feet long by 35 feet broad, and which faces Crossley-street. At the Broad-street end are the offices for the police, including a police parade, measuring 49 feet by 20. There are also cells (twelve in number), two day rooms, an inquiry water office, &c.

Upon the principal floor is a merchants' exchange, 52 feet by 28; a borough court, 51 feet by 28; rate offices, accountant's offices, residence for superintendent of police, magistrates' retiring room, warrant office, &c. The entrance corridor, with the grand staircase (placed beneath the dome), is also on this floor.

The other story is devoted to the council chamber (facing Crossley-street), and whose dimensions are 41 feet by 27 feet; also town clerk's offices, engineer's offices, mayor's parlour, committee rooms, &c. Both the interior of the council chamber and the borough court are designed in a style to harmonise with the exterior of the building. The estimated cost of the building is about £20,000.

THE ARCHITECTURAL EXHIBITION.

(CONCLUDING NOTICE.)

OUR concluding notice of the architectural works in the Conduit-street Galleries commences with

(203) Mr. T. Goodchild's "Front of Aldershott Market" ought to be mentioned, inasmuch as it is in course of erection, otherwise so insipid a design might well escape attention. Whether it can be classed under any particular style is a question; but we suppose it is intended for Palladian. The area of the market is stated at 11,000 super feet, and is L shaped on plan.

Several designs for the Chelsea Vestry Hall (about which there was so much discussion) find a place here, and thus invite comparison, more especially since that which obtained the first premium is among the number. This figures in our catalogue as (214), and is by Mr. W. W. Pocock, the finally successful competitor in the late competition for Mr. Spurgeon's tabernacle. The design before us shows a Classic façade, not servilely following any particular examples, but it is a specimen of the use that may be made of such by competent hands; being a really excellent composition. Another design, one of the three selected, is (210) by Messrs. Green and De Ville, and is also Italian, but appears to have too much of a chapel look for its purpose. There are no plans to explain the arrangements of either of these designs. But with the remaining one we are more fortunate, for Messrs. Godwin, besides their perspective view (212), send the sheet of three plans (213) to explain it. The ability shown in these plans is, it must be confessed, far greater than in the elevation, which is of that peculiar sort of nondescript Gothic that is novel without being at all successful, and in which it would be easy to point out flagrant breaches of even the principles of design and construction. The merit of the plans consists in their being so simple and straightforward. (209) is an Elizabethan design (very poor) for the same building, by Mr. Eyton.

More numerous than the designs around us submitted in the last-mentioned competition, are those for the Ellesmere Memorial, which here number no less than twelve sheets, and, as may be supposed, present a goodly array. Unfortunately, however, the quality is not equal to the quantity. Even the successful design (229), by Messrs. Driver and Webber, now in course of erection, though unquestionably the best we have seen, is not equal to some that have been called forth in connection with Crimean monuments. The place fittingly selected for this memorial is close to the stately family mansion, at Worsley, near Manchester, and its materials are Hollington stone and Derbyshire marble. It will not be necessary to particularise the design itself, as it has been recently made familiar to the public in more than one illustration. The other drawings are, it must be confessed, in the main undeserving of sober criticism; (215) for instance, is a specimen of that kind of bastard Gothic which is now all but exploded. It appears, however, to find especial favour in the eyes of Mr. P. Brannon, for we have seen the like from him before; and in this exhibition there are some ambitious flights of fancy in the same vein, in which the author pictured to himself an appropriate Trinity College Church, Edinburgh. (216), another design for the Ellesmere Monument, is equally absurd. We might well be spared such anomalies. (219) which is obeliskal, is also devoid of specific character; (220) is a strange combination of masses; (221) pseudo-Gothic with Scotch features engrafted; (224) an unwieldy tasteless affair, with which the little elegant design next to it (225) oddly contrasts, though the latter is too dwarfish, and does not altogether realise our conceptions. (226) A square campanile, is, in some respects good looking, but is inappropriate to the site; while (227) appears to us still less deserving, although it was "one of the eight selected designs which obtained honourable mention." (230), like some others, is based upon the Venetian Gothic; and, though heavily treated, looks more reasonable than many.

(232) A Crimean Memorial to the fallen of the 23rd Royal Welsh Fusileers, erected at Carmarthen, by Mr. E. Richardson, is a Gothic design, poor in its details. The inclosing railing has, however, more significance, military weapons being introduced in an effective manner by way of ornament.

For the "Trinity College Church, Edinburgh," we have several designs, some few accompanied by plans and brief explanations. These adjuncts (as we have repeatedly urged) are absolutely essential to the proper understanding of a design; it is therefore as much to the interest of the author as the examiner, that, to some extent at any rate, such clues should be given. In this, a professedly "architectural" exhibition, such omissions are inexcusable;—we are of course presuming that the fault of their non-appearance does not rest with the committee. (233) is by Messrs. Oliver and Lamb, and is one of the six which received special commendation. (234) is another elevation of the same, Gothic in style, and freely treated.

Mr. J. Nicholls, in (240, 241), has the exterior and interior views of his design, which was also one of the six selected, and it appears to be, on the whole, very well studied and carried out. The two succeeding drawings (242, 243) are by Mr. Dunn and Mr. Goldie. Both have founded their designs upon continental models, but the latter is by far the more successful. A plan and some sketches serve to elucidate it pretty clearly.

Digitized by Google

In both of Mr. Ellis's designs for the Cambridge Asylum (235, 236), the attempt at originality is more commendable than its realisation. The whole lacks spirit and character. Nor can more be said in reference to Messrs. Oliver and Lamb's "Attempt to improve the Ecclesiastical Architecture of Congregational Nonconformists," as exhibited in (245, 246). The plan consists of nave and aisles, under one span: the interior columns to be of iron, 10 inches in diameter, and the roofs constructed *double*, to meet the objection of extremes of heat and cold urged against Gothic open roofs. Another drawing (244) shows the authors' mode of introducing iron columns in tiers, to keep down the cost of roof timbers in buildings of large span.

Considering the number of designs sent in for "Heigham Church," it is a wonder that more have not found a place here. (248) appears to have nothing in its favour, unless there be merit in the plan, which does not accompany the view. Judging by the exterior, it is based on the *auditorium* principle, and the junction of the roof tells unfortunately on the general outline. Mr. J. H. Browne's design is shown in four drawings (249, 250, 272, 273); and looks better outside than in. The material indicated—red brick with stone dressings—would not be so suitable to the locality as the flint-work which is in that district almost universal.

The several designs for Mr. Spurgeon's New Tabernacle which are here re-exhibited, have been already commented upon when noticing the collection as a whole. The design for the Town Hall, &c. at Wokingham (259), submitted in a select competition by Mr. Fowler, jun., is cleverly planned to suit the site. The several frontages are also good;—their type, the ordinary Gothic of Northern Italy. "Upton-on-Severn National Schools" (262), erected from the designs of Mr. G. R. Clarke, have the merit of good taste combined with simplicity. The same gentleman has in (364) the New Toll-house erected at the Mythe, near Tewkesbury," a plain red brick building, with a convenient open timbered porch.

Mr. Mileham's "Competition design for the new Town-hall at Sutton Coldfield (264) is, as a composition, good, but is wanting in appropriateness of character. The author has made free use of continental details.

In (265 and 266) Messrs. Oliver and Lamb exhibit two poor designs for the Scarborough Sea-bathing Infirmary. In the plan however some good arrangements are noticeable, viz., the principal wards face the sea, and are open on all sides, the beds being only between the windows: the ventilation is natural and the warming by open fireplaces. Provision is made for 100 beds, and 1500 cubic feet are allowed to each patient in the wards. The estimated cost is between £5000 and £6000. Two other designs for the same building are in close proximity with these, but they do not claim especial mention.

The idea of a combination of materials with a view to produce ornamental effect has been tried in various ways, but it is, we believe, something novel to see metal crockets applied to stone, and the specimen in (270) does not quite reconcile us to its use. It shows a Caen stone chimney-piece with fittings complete. The crockets, &c. of polished brass, are fixed by means of screws and points in elastic cement filled into holes cut into the stone; —there are also dwarf columns of Serpentine, and recesses lined with tiles.

The Tottenham Church competition has produced drawings by Messrs. Knightley (274), Mumford (275), J. James (276), and F. G. Lee (277). Of these, the second mentioned is stated to be in course of erection; but a comparison of this with its neighbours only suggests a question as to the propriety of the decision. There is a peculiar barrenness of expression which alone would, one would have thought, been sufficient to condemn it. This cannot be said of either Mr. Knightley's design, (one of the six selected), or of Mr. James', both of which err to some extent in the opposite direction.

Competition designs for the proposed Schools and Residences at Forest Hill, are numbered (280, 283, 284, and 285), the latter by Mr. Messenger, is "about to be erected." Of the others, that by Mr. Eyton has an excellent outside arrangement, and that by Mr. Stapleton a good plan.

The "Parsonage house, Caversham," recently erected by Mr. A. Billing (286), is a very tame production, built of flint, with red brick dressings. A shade better is his "New Church about to be erected in Islington" (288), but it has a very common-place look. "Rosslyn Chapel" finds two delineators of its wild picturesque beauties,—(281) by Mr. A. G. Clayton, and (299) by Mr. P. Justyne. The latter is by far the best. In (298) Mr. Dobson exhibits a capital view of the "Interior of the Lady Chapel, Tynemouth Priory," as restored; and in (359, 360), two views, which are perfect gems in their way, of portions of the interior of the old Norman Castle at Newcastle-upon-Tyne.

The "Church lately erected at Dundee" (301), by Mr. H. E. Coe, is essentially English Gothic in its character, but there is sufficient evidence that its author is not over fettered by precedent. The bold staircase turret, which terminates pyramidally, and appears to balance the composition of the west end, may be cited as a happy idea. Of another department of our art—the domestic—we should be at a loss to point out a more consistent specimen than Mr. R. H. Shout's "Strangways Railway Arms Inn, Evershot, Dorset" (303). It is partially of half-timbered construction, and in execution looks better, we think, than in the drawing; which is a rare occurrence.

Mr. W. White's contributions are all of the same class,—plain, simple, and good, especially in their grouping. Italian Gothic appears to be still the source of most of his ideas; however, he contrives to clothe it with sufficient originality to entitle him to honourable mention on that account. He sends several drawings: —(118), "Milton Vicarage";—(297), "Winscott, North Devon," which has some relieving arches particularly well designed; and (316), a "Bank at St. Columb, Cornwall."

Mr. E. B. Lamb's style is too well known to need any description. An examination of his drawings this year induces us to repeat the opinion that, while everything he produces is distinguished by originality and talent, he is ordinarily more happy when following out a Palladian than a Gothic model. We need only compare (308), "The Working Men's Institute at Lower Norwood," with (323), "The new Market-house, &c. now erecting at Berkhampstead." (314), "Knotley House, Penshurst," is clever, but too much broken up by slight projections, corbellings, and dodgy excrescences, which, however ingenious, tend to disturb that dignity which buildings of magnitude should invariably possess.

Of Mr. Joseph James' "Spring-hill Cottage, Birmingham," we gave a bird's-eye view in a former number of this *Journal;* in (325)—a S.W. view—its well-studied detail is seen to advantage. Mr. W. P. Griffith pursues his application of natural types to ornamental architectural purposes, and in (321) shows the fruit of the evergreen oak converted into the purposes of the ordinary ball-flower. Mr. Heskett's two views of his "Design for the Schools and Soldiers' Institute at Chatham" (335,336), may be referred to as examples of simplicity combined with good taste, as we have had occasion to point out in others.

Mr. D. Brandon, sends some good Elizabethan designs. (332) is one of these, and shows "Taverham Hall, Norfolk," which is built of red brick relieved by white dressings. (354) is another such building—a "Manor House erected at Aylesbury." Mr. F. P. Cockerell, in (339 and 344), gives two of his beautiful gleanings from Venice; Mr. J. Drayton Wyatt sends an india-ink view of Pippbrook House, near Dorking, an old mansion enlarged and Gothicised by Mr. G. G. Scott; and Mr. Goldie (349) has a sheet of "Studies" in pen-and-ink, suggested by G. G. Scott's *Secular and Domestic Architecture.* These latter consist of a porch, greenhouse, window (with a balcony carried by corbelling shafts placed out of the upright!), interior of a room, shop front, and staircase; and they evince considerable ability. The next frame (350) consists of "Studies for Works in Progress," by the same gentleman, and is wholly devoted to ornamental details for various Roman Catholic works.

Mr. Edmeston sends two drawings—(173), a "Tomb now erecting in Highgate Cemetery," which is a great improvement upon the majority of such works. It is triangular on plan, each angle being masked by a full-length sculptured figure under a well-contrived niche, and the intermediate faces being filled in with panels in basso relievo. The covering to the whole is also of stone, pyramidal, and terminating in a handsome cross. The other drawing (351), is of two "Stone Porches, Canonbury-place, Islington," which are a kind of Italian, boldly handled.

The "Tower of Newport Church, Essex" (356), was rebuilt in 1858, from the remains of the former tower, by Mr. G. E. Pritchett. Its fine outline and commanding position render it an attractive object from the Eastern Counties Railway; the present drawing fails to do it justice.

Messrs. Finch, Hill, and Paraire send (357) an external view of the "Britannia Theatre, Hoxton," recently erected by them. Being to a great extent inclosed by dwellings, one would not

Digitized by Google

readily divine its purpose from this drawing: the architecture is of very questionable taste and the ornament trashy. The interior (of which a view is to be seen in the Royal Academy) is a much more favourable specimen.

The two most important drawings of their kind in the exhibition are (328 and 329), in which Mr. Goodchild has most ably given interior views of "Sir Christopher Wren's first design for St. Paul's Cathedral," from the model now in the Kensington Museum. One of the views is taken directly under the dome, and the other is taken in the nave. These drawings are to a large scale, carefully outlined, and tinted in sepia in a very masterly manner.

Other important drawings—one of them the largest in the room—are by Mr. Pennethorne, who, in (291 and 292) shows the two principal façades of his "Design for the new Government Offices,"—one being towards St. James'-park, and the other towards Parliament-street. This latter would be 600 feet long, and occupy the whole area between Downing-street and Great George-street. It is of Italian character. The lines of frontage are but little broken, perhaps not sufficiently so, the author having aimed apparently rather at a grandeur in the whole mass than completeness in detached portions. These drawings are very carefully executed, but would bear more making out in the expression of many of the features.

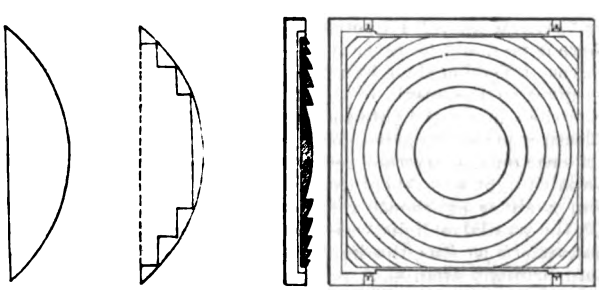
Mr. S. S. Teulon exhibits but one drawing (293),—"The almshouse and chapel erected by him at South Weald, Essex," a good specimen of brick design, and in which a great inequality in the levels of the ground has been turned to due advantage in a picturesque point of view. The buildings are actually close to the road-side, but here are shown as if in a spacious plantation. In the same frame is a view of some schools built in similar style in the same village; also a design for restoring the church, which it may be remembered is in a most lovely situation, and whose south door is one of the most curious and perfect examples of Norman work existing. (It was published, we believe, by Britton.)

Mr. Owen Jones contributes a highly coloured drawing (358) of the "Ceiling decorations of St. James' Hall," developed so as to show the exact outline of its pattern, which is painted in white on a blue ground, with excellent effect. — "Christ's Hospital, Sherburn," near Durham, by Mr. Austen, provides for thirty-five inmates, the comfort of whom appears to have been praiseworthily consulted. The fall of the ground gives room for a covered promenade open to the south, and fitted with benches against the walls, between the centre wing and the kitchens. The warming is effected by open fire-places, assisted in the corridors by the hot-water apparatus. All the flues are formed of combined smoke and air flues, the latter communicating with each room near the ceiling. The walls of the new building are constructed of "Snecked rubble," with Ashlar dressings to windows, &c. The roofs are covered with blue Welsh slates.

Messrs. Vulliamy and Johnson, in (337), have a very effective exterior of the proposed church at Rochester. It is thoroughly Gothic in its conception, and very well proportioned. A lofty tower and spire are prominent objects; the latter has spire lights immediately above the parapet, but above is totally devoid of any kind of enrichment whatever, and compared with the rest of the building it has a very bare look. (334) Mr. Goldie's "Design for Memorial Altar and Reredos at St. Vincent's Roman Catholic Church, Cork," is highly elaborated. Ornament of every kind is lavished by means of sculpture, marbles, and inlay work. There is a very well designed metal cresting running above the principal cornice.

A few photographs which we have not mentioned are deserving of notice. Two of the "Additions to Hampton Lucy Church, Warwickshire," are given in (385 and 390), the former showing the very rich and beautiful apse externally, and the latter an equally handsome reredos and arcade which surrounds its wall internally. The original church was erected from the design of the celebrated Rickman. It cost a large sum, and was considered among his best works, though very different from such as we are now accustomed to rear. The carving to the new additions, which is of the most ornate description, has been executed by Mr. Philip, who in (391) has a very perfect photograph of "The upper part of the column erected at Melbourne, in memory of the late Sir C. Hotham, Governor of Australia," of which a full account has already appeared in our pages. Other photographs exhibited are—(381, 382) two views, by Mr. Brakspeare, of "Great Lever Church, Lancashire;" and (384) is a tasteful monument erected in the Mauritius, the workmanship being by Mr. Cundy of South Lambeth.

A rather extensive collection of designs for stained glass (principally the full size cartoons) is dispersed in various parts of the galleries, and includes specimens from most of our best artists. (5) is Messrs. Ward and Hughes' design for the large "West Window of Glenalmond College, Perth;" and (395) is the West Window of All Souls' Church, Halifax." There are also several of a series of "Crimean Memorial Windows" designed for Harrow School chapel by Mr. Powell, of Messrs. Hardman's establishment, and exhibiting considerable talent. Messrs. Hardman and Co. have also a design for part of a "Crimean monument at Eton," and part of a "Window executed for Carlisle." Messrs. Clayton and Bell send some beautiful cartoons for the stained glass they are now preparing for "St. Michael's, Cornhill;" also "One of a series of Lancet Windows, now executing for the North Transept of Westminster Abbey." Messrs. Lavers and Barraud show the "East Window of Upper Tooting Church," which illustrates the "Te Deum;" also some full size cartoons for churches in Cornwall and Sussex. Several interesting studies of the same class, from the celebrated Cathedral of Chartres, are exhibited by Mr. J. J. Laing, who also sends one or two "designs for stained glass medallions." There are not this year any frames of the actual material, glazed up, such as we have seen in some former exhibitions, and it is difficult to pronounce opinions as to real results from an inspection of the mere preliminary cartoons; we therefore reserve any decided expression on these subjects till we have had other opportunities of forming our judgment on them.



It remains to add, that the attendance on the occasion of the several architectural lectures this year was, as heretofore, highly encouraging;—that the exhibition is now opened on Tuesday *evenings* also;—and that it will finally close on the 30th inst.

REVIEW.

Lighthouse Illumination; being a Description of the Holophotal System. By THOMAS STEVENSON, F.R.S.E.—London: J. Weale. 1859. 8vo. pp. 122.

The most characteristic modern improvement of the optical apparatus of lighthouses, consists in refracting the light by means of annular zones of glass built up together to form a composite lens. It may very easily be seen that the effects of a common lens to concentrate or disperse light will in many cases be unaffected by cutting away a large part of the material of the lens. For instance, if parallel rays are incident perpendicularly on the plane surface of the plano-convex lens (Fig. 1), they will suffer no refraction at that surface, and their refraction depends solely on the curvature of the convex surface: it is clear that they will be similarly refracted by the lens Fig. 2, of which the anterior surface has the same curvature as that of Fig. 1, and the posterior surface presents a number of annular planes, so that the light enters the lens perpendicularly as in the former case. It is clear

FIG. 1. FIG. 2. FIG. 3.

also that the optical effects of the lens Fig. 2 will not be altered by arranging its several parts so that the planes last mentioned lie all in the plane represented by the dotted line. In this case the lens assumes the form Fig. 3. This annular lens is a most important part of the modern system of lighthouses. The idea of such a lens originated before Fresnel's time, and was suggested in various forms by Buffon, Condorcet, and Sir David Brewster; but the first actual construction of such lenses for the purposes of lighthouses is due to Fresnel. The great merits of these lenses are that they are capable of being made up of several pieces;

Digitized by Google

that not being so thick as ordinary lenses they absorb less light; and that as the several component zones may be ground to different curvatures, the aberration due to a common spherical lens is in a great measure corrected.

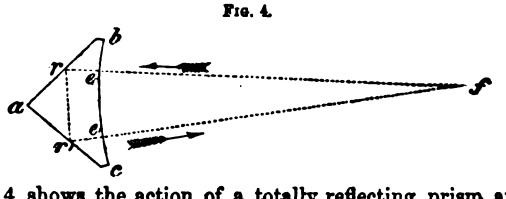
Mr. Thomas Stevenson, who has been the engineer of many important lighthouses, has carried the improvements of the optical apparatus of lighthouses beyond the point where Fresnel left them, and in the work before us records various practical applications of optical principles to the economy of light. It is no mean merit to have advanced beyond so illustrious a predecessor as Fresnel, but we conclude the perusal of the clear and interesting account before us with the conviction that modern engineers of lighthouses—and Mr. Stevenson pre-eminently among them—have succeeded in several important particulars in improving and extending Fresnel's method.

The improvements here referred to relate solely to the optical apparatus; the improvements of the light and of the construction of the building are not within the scope of the present treatise. What it designates the "Holophotal System" is a number of contrivances having for their object the economy of light. As these contrivances are various, the word "system" does not appear applicable to them; and the word "holophotal" seems rather to describe that which is the plain *duty* of the engineer—the economical distribution of the light—than to any one optical principal or method of illumination

The principal improvements here described are of two kinds,—improvement of the material of the apparatus, and improvement in the disposition of its parts. The former head comprehends the substitution of totally reflecting prisms for metal reflectors; the latter, various improvements of the forms of Fresnel's lenses, and combinations of them with reflectors for the purpose of advantageously directing light in the directions which the exigencies of the mariner require. The principles on which these improvements depend do not require for their comprehension a profound knowledge of the laws of optics. On the contrary, all the material parts of the work before us would be perfectly intelligible to a person barely acquainted with the elements of the science, and who brought to the reading no more knowledge than a rough notion of the laws of refraction and reflection, and the aid of a fair stock of what for want of a better phrase we must call the *common sense* of the subject.

The principle of "total internal" reflection, which is one of those made use of in the improvements here described, consists simply in this—that light incident very obliquely on the surface of a transparent medium will be reflected from it instead of entering it; much in the same way as a stone striking the surface of water very obliquely glances from it instead of entering it. By reflection from metallic reflectors a large proportion of the light (amounting to a quantity between one third and one half) is lost; whereas the loss of light by internal reflection is inconsiderable. Indeed, this species of reflection is termed *total* reflection on the supposition that no light is lost by it; but we apprehend that in practice this is not strictly the case, as the surfaces from which the light is reflected are not mathematical planes, but have unavoidable irregularities; so that the whole of the light is not incident at the same angle, and where the angle is greater than the "critical angle," refraction instead of reflection takes place. There is no doubt however that the loss of light is much less by internal reflection than by reflection from specula. Mr. Stevenson gives as the result of 31 trials, by four different observers, upon the amount of light available after passing through a totally reflecting prism prepared for lighthouse purposes (the angle of incidence on the external refracting surface being 39°), that the available light was ·805 of the incident light. But after reflection from a silver lighthouse reflector, the angle of incidence being 45°, the available light was only ·556 of the incident light; so that, *cæteris paribus*, the light reflected on the former system is more brilliant than that reflected on the latter system in the ratio of 16 to 11.

Fig. 4.



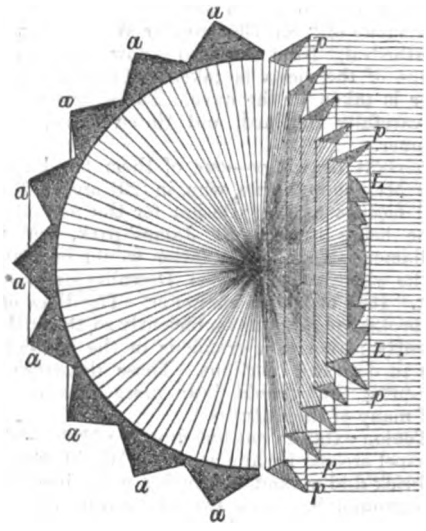


Fig. 4 shows the action of a totally reflecting prism applied to the back of the lighthouse, to reflect the light forward through the flame from which it emanates: *f* being the flame, *bc* a spherical surface of which *f* is the centre, and *r*, *r'*, points at which total reflection takes place. An application of these prisms is shown in Fig. 5, which is one of the holophotal arrangements proposed

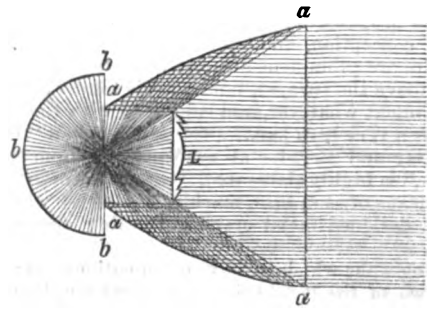
Fig. 5.

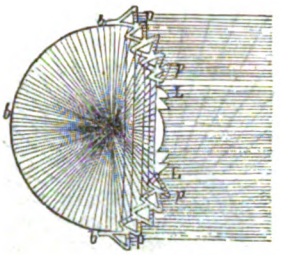


by Mr. Stevenson. In this arrangement the light incident on the reflecting prisms *a*, *a*, *a*, at the back of the lighthouse, is thrown forward through the flame, and then with the rest of the light diverging from it passes partly through the annular lens L, L, and partly through the prisms *p*, *p*, *p*, *p*, in a state of parallelism. With respect to the last-mentioned prisms it will be observed that they produce only one internal reflection, whereas those at the back of the apparatus produce two.

It does not appear however that this instrument has ever been used in practice. We imagine that the cost of its construction would be very great, and Mr. Stevenson states that the instrument would have been completed "but for the difficulty in the present state of the manufacture of flint glass of procuring castings of sufficient size and purity, it being essential to the action of the instrument to employ flint glass, or some other glass of high refractive power."

Another of the holophotal arrangements, less costly, but subject to the loss of light due to metallic reflection, is shown in Fig. 6. The object, as in the last-mentioned arrangement, is to throw the whole of the light forward in a state of parallelism. This is effected by the combination of an annular lens L, a trun-

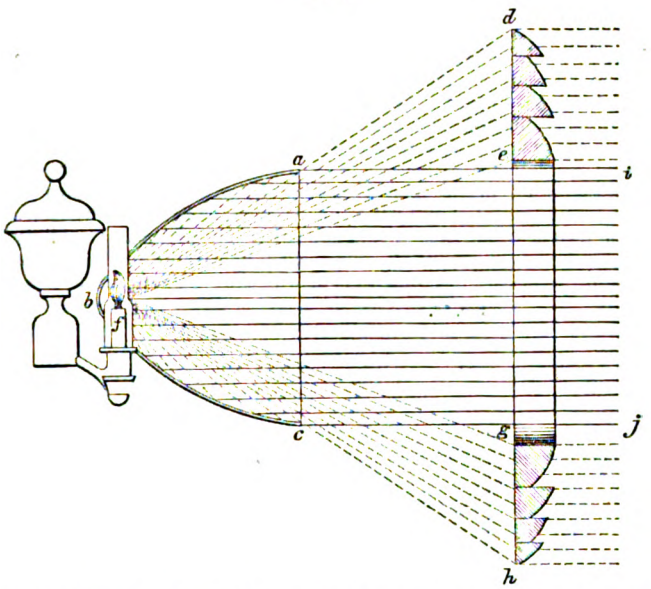
Fig. 6.



cated parabolic reflector *a*, and a spherical mirror *b*. The latter reflects the light incident on it back through the flame, whence it diverges with the rest of the light,—and part of the diverging rays are transmitted in a state of parallelism by the refractor L, and part are reflected in a state of parallelism by the reflector *a*.

In this arrangement there is the loss due to metallic reflection, but a sort of compromise between the two methods just described has been invented by Mr. Stevenson, and applied by him to the Horsburgh light, near Singapore. This light (Fig. 7) has the spherical mirror for reflecting the posterior rays of the Fresnel lens, parallelising a portion of the diverging beam, but for the parabolic mirror last mentioned are substituted the prisms *p*, *p*, *p*, *p*. These prisms act in the same way as the prisms *p*, *p*, *p*, *p*, of Fig. 5;

Digitized by Google



that is, they are partly refracting and partly reflecting. These prisms Mr. Stevenson, apparently on good grounds, claims to be his own invention; but he states (in a note, p. 31) that there are other claimants of it.

Fig. 7.

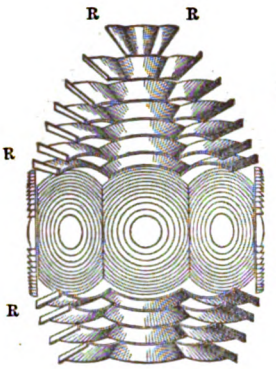
The contrivances for the purpose of throwing forward in one beam of parallel rays the whole body of light emanating from a flame are very numerous. The work before us describes an invention for the purpose by Fresnel, and which consists of a combination of lenses and plane reflectors; also a reflector invented by M. Bordier Marcet in 1819; another, invented by Mr. Barlow in 1837; and lastly, the invention of Mr. A. Gordon, C.E., described by him in this Journal for 1847 (vol. x., p. 385). This invention is shown in Fig. 8: it consists of a parabolic mirror *abc*, with the flame *f*

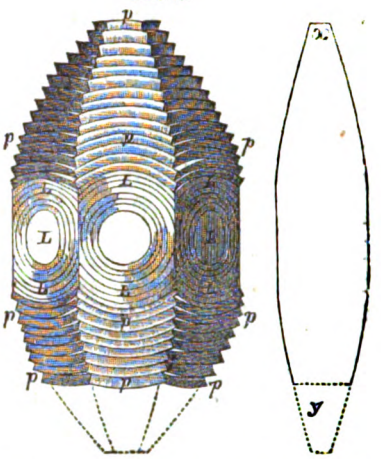
Fig. 8.

in the focus, having in front some of the outer refracting rings of Fresnel's lens *degh*. It will be observed however that the diverging rays of the cone having the vertical angle *efg* are not parallelised. Now apparently this is a larger portion of the light of the lamp than the portion incident on the parabolic reflector in front of the flame; but it is in order to parallelise the latter portion that the aperture *eg* is left. It seems therefore clear that there would be gain of light by filling up the aperture with a lens in order to parallelise the former portion, and by suffering the latter or smaller portion to diverge. But if we remove the parabolic reflector in front of the flame, there remains nothing of the invention except the reflector behind the flame, which from its small size is probably very ineffective.

The work before us describes two methods of applying the holophotal system to revolving lights, and compares them with Fresnel's method for the same purpose. The three methods are shown in Figs. 9, 10, and 11. In the first of these parabolic reflectors, R, R, are used, similar in principle to those of Fig. 6, and combined as in that case with an annular lens. In the second method for revolving lights (Fig. 10) the metallic reflectors are dispensed with, and in their place are the partly reflecting partly refracting prisms which we have already described. This apparatus was constructed for the lighthouse of North Ronaldshay, and completed in 1854. Lastly, Fig. 11 represents Fresnel's revolving light, constructed with the latest improvements, for the great light of Skerryvore, and lighted in 1844. In this light, L, L are the lenses which parallelise the central portion of the light, and *a* and *b* are the compound arrangement of lenses and plane reflectors already adverted to for intercepting the rays above the lenses L, L.

Fig. 9.





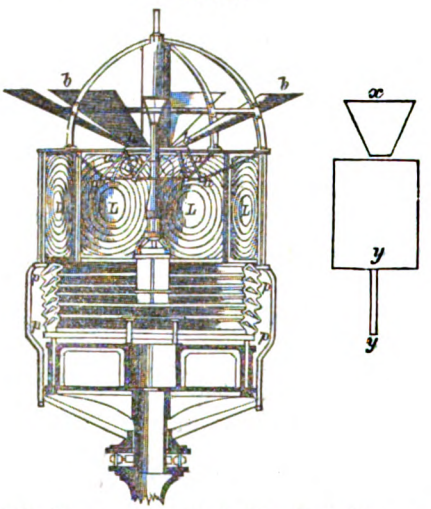


Fig. 10.

In comparing the holophotal method, Fig. 10, with the method of Fresnel, Fig. 11, Mr. Stevenson remarks that in the former the light is parallelised by a single agent where in the latter two are required; moreover the latter is subject to the loss of light due to metallic reflection; and M. A. Fresnel himself, with respect to the latter, estimates that the incident light is reduced to one-half in its passage through the apparatus.

Fig. 11.

In each of the three systems the light collected in as many beams of parallel rays as the polygonal apparatus has sides; so that if the polygon revolves once in a minute, there will be the same number of flashes of light in a minute succeeded by intervals of darkness.

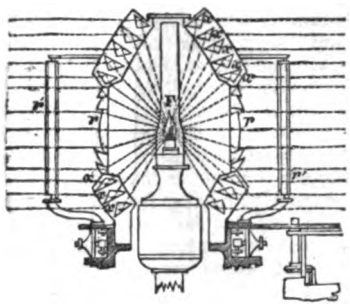
Among the numerous variations of lighthouse lights described in the work under review, one of the most interesting is that consisting of a *fixed light varied by flashes*. This kind of light is the invention of M. Augustin Fresnel, but the mode in which he produces it is entirely different from Mr. Stevenson's. M. Fresnel surrounds the light by a fixed light apparatus as shown in Fig. 12, so that all the rays are brought into a horizontal direction, but *radiate in every such direction equally*. In order to produce the flashes he places outside the apparatus straight prisms *p'p'*, which revolve round it. Now it is a well-known principle of optics that the effect upon light passing through two prisms, one of which is horizontal and the other vertical, is similar to that of a lens; for the one prism collects the light horizontally, and the other collects it vertically, so that the two together produce actual *condensation*. (We are here speaking in rather loose

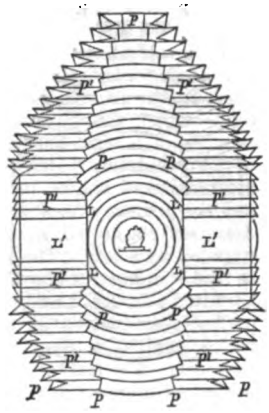
Digitized by Google

language, as our object is merely to give a popular explanation of the subject.) Thus, in the apparatus Fig. 12, the fixed annuli effect the purpose of horizontal prisms, by bringing all the light into a horizontal direction, and the revolving vertical prisms complete the condensation wherever they act, by deflecting the light in the horizontal or azimuthal planes.

Mr. Stevenson effects the same object by a very different and very elegant method, which is shown in Fig. 13. He surrounds

Fig. 12.





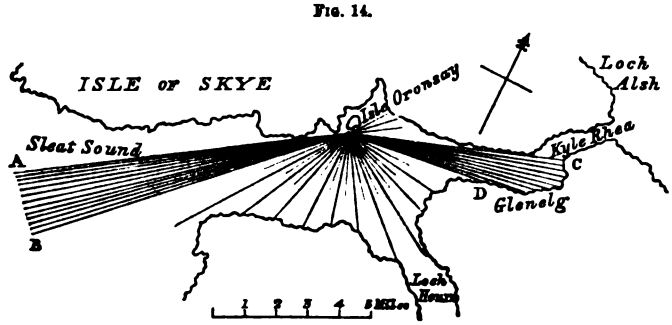


Fig. 13.

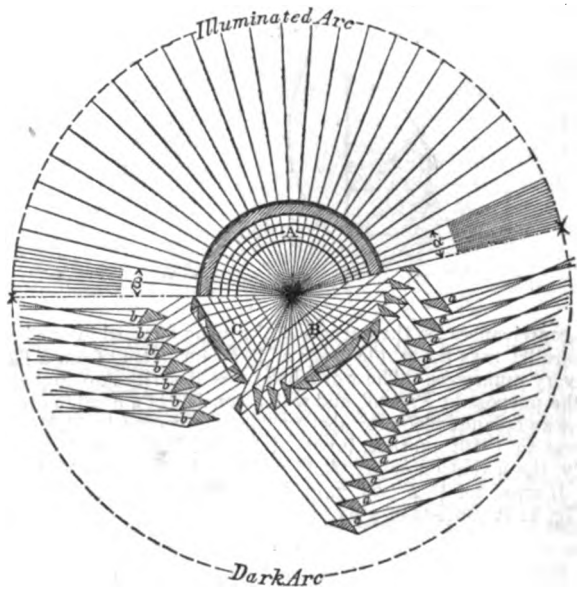
the light by a polygon, of which the sides alternately consist of cylindrical annuli $p'L'p'$, and spherical lenses and parts of lenses pLp. The former merely bring the light into the horizontal direction: the latter collect the light into beams. In both kinds of apparatus the characteristics of a fixed and a revolving light are given, the light being at regular recurring intervals bright and feeble.



There are many ingenious contrivances in the work before us for varying the direction of light, which we are unable to notice for want of space. The following however may be adverted to, on account of its intrinsic interest, and because it has been practically applied to a work of great importance. The Oronsay Lighthouse, which was publicly lighted in 1857, was required to fulfil certain conditions depending on local circumstances. The lighthouse is situated in the narrow Sound of Skye (Fig. 14), and

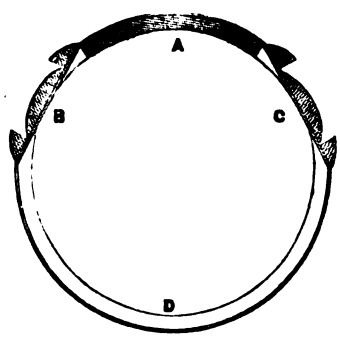
Fig. 14.

was required to cast a bright beam of light AB, down the Sound, and another bright beam DC, up the Sound; and likewise to illuminate, but less brilliantly, the intermediate arc BD. The arc next the Isle of Skye was not required to be illuminated. In order to satisfy these exigencies, the method represented in Fig. 15 was resorted to by Messrs. Stevenson, and carried out by Mr. James Balfour, who also made the necessary drawings and calculations. The one bright beam was obtained from the posterior rays parallelised by the lens B, and subsequently deflected by the prisms *a*. The other beam was similarly obtained from posterior rays parallelised by the lens C, and subsequently deflected by the prisms *b*. The illumination of the remainder of the illuminated arc was obtained by suffering the remainder of the rays to fall on the Fresnel's lens A, from which they radiated horizontally. The apparatus seems to have been entirely successful, but we should imagine must have been costly from the number and complication of its parts. As there must be many situations in which it is requisite to direct beams in fixed directions, we venture to suggest that the principle of Mr. Stevenson's own invention, Fig. 10, may be applicable in such cases. That invention was designed for revolving lights, but the apparatus when not revolving collects portions of the light into beams

Fig. 15.

having fixed directions. If as in Fig. 16 the lenses B and C were employed to direct the beams in the required directions, and the arc A were occupied by a Fresnel's apparatus for radiating the light horizontally, the posterior rays being reflected by the spherical reflector D, it seems to us that all the conditions of the problem would be satisfied. It is true that by the employment of a metallic reflector there is a loss of light, but there must be also a considerable loss by the rays passing, as in Mr. Stevenson's plan, first through lenses and then through prisms. Certainly the method here proposed is simple, though we admit that there may be practical objections to it of which we are ignorant.

Fig. 16.



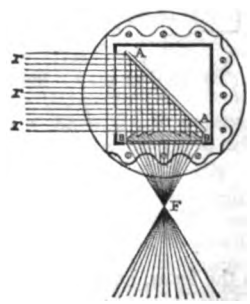


Fig. 17.

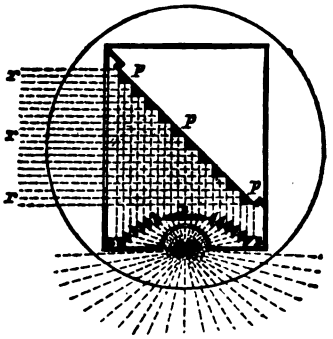
Another remarkable contrivance of Mr. Stevenson is the *apparent* light or beacon erected by him in the bay of Stornaway. The beacon was required to be situated at a point (Arnish Rock) on which, on account of its inaccessibility, a light could not be kept burning. The manner of overcoming this difficulty was the erection on the rock of a beacon which *reflects* a beam of light, of which the source is a lighthouse on the adjacent coast, 530 feet distant. Fig. 17 shows the plan of the beacon. The rays of light are directed from the lighthouse in a beam of parallel rays *r*, *r*, upon a plane mirror A, A, and after reflection are refracted by the prisms B, B, and diverge at the required angle from F. Mr. Stevenson remarks that in the case of this beacon it would have been difficult to have substituted totally reflecting prisms for the plane reflector, as the rays were required to be deflected through so large an angle that such prisms could not have been employed unless made of glass having a high refractive index. A plan is suggested by Mr. Stevenson, Fig. 18, for an apparent light capable of illuminating half a circle. In this plan the rays are incident on a plane mirror *p*, *p*, thence pass through the totally reflecting prisms B, and thence emerge through the outer pane of glass of the beacon. This pane is

Digitized by Google

semicircular in plan to avoid loss of light, which would be occasioned by the oblique incidence of the emergent rays upon it.

FIG. 18.



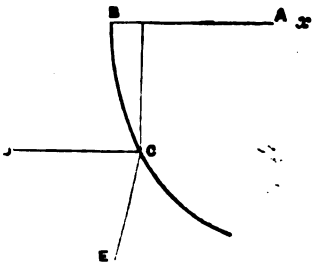


FIG. 19.

It seems to us that illumination of half a circle by the apparent light might be obtained by a single agent, namely, a cylindrical convex reflector, instead of p, p. From such a reflector the rays would be reflected so as to illuminate a semicircle without the aid of the prisms B. In ordes that the illumination might be equally bright in every part of that semicircle, the horizontal section of the reflector should be a proper curve, which can be easily obtained by analysis.

Let BC be a horizontal section of the reflector, and the direction of the illuminating rays be parallel to BA. Let the ray DC be reflected in the direction CE. Then, since the angle of incidence is equal to the angle of reflection, if the normal through C be inclined to AB at the angle θ, the angle DCE$=2\theta$. Since the dimensions of the beacon are inconsiderable compared with the distance of the horizon, all the reflected rays incident on BC may be considered to illuminate an arc of the horizon which subtends an angle 2θ, and has its centre anywhere in the beacon.

Let B be the origin of co-ordinates, BA the axis of x, and the perpendicular on this axis from C$=y$. In order that equal portions of the illuminating beam may illuminate equal arcs of the horizon, y which is the breadth of the portion of the beam incident on BC, must be proportional to the arc illuminated by it, and therefore to θ. Consequently $ay=\theta$, where a is a constant determined as follows: Let h be the total breadth of the illuminating beam, and α the greatest value of θ. Then the total arc illuminated subtends an angle 2α, and therefore by the last equation $ah=2\alpha$, which gives the value of a.

By the geometry $\tan\theta=\frac{dx}{dy}$. Therefore $\tan ay=\frac{dx}{dy}$. Integrating, and making x zero when y is zero, we get $\cos ay=e^{-ax}$ for the equation to the required curve.

We regret that we have not space to describe more of the ingenious contrivances which are mentioned in the book before us. We believe that many of its subjects have been already discussed in previous treatises by Messrs. Stevenson, but the present work, besides being a summary account of established modern improvements of lighthouses, is valuable as a lucid and clear exposition of the more recent modifications of the author's valuable system of illumination.

EXHIBITION OF INVENTIONS AT THE SOCIETY OF ARTS.

THE Eleventh Annual Exhibition of Inventions collected in the rooms of the Society of Arts is not equal to several of its predecessors, in the novelty, utility, and importance of the objects exhibited. Several of them, instead of being the inventions of the past year, have seen many summers, and the introduction of even a few known old inventions throws doubt on the novelty of the remainder. Assuming however that, if not actually new, they are now for the first time exhibited publicly, we shall proceed to notice those mechanisms and contrivances that claim attention either by their ingenuity or by the usefulness and importance of the objects they are intended to effect.

A large portion of the space of the exhibition is, as usual, allotted to railway mechanism; commencing with coal-burning locomotive boilers, safety-valves, railway chairs, brakes, buffers, and new systems of railway signals. We do not, however, observe a single model of a contrivance for making communications between railway passengers and guards, and between the latter and engine-drivers, of which class of inventions there is usually a fruitful crop in mechanical exhibitions. It may be that inventors are tired out by the obstinate perseverance with which railway directors refuse to adopt such contrivances, though the want of communication is daily more and more experienced.

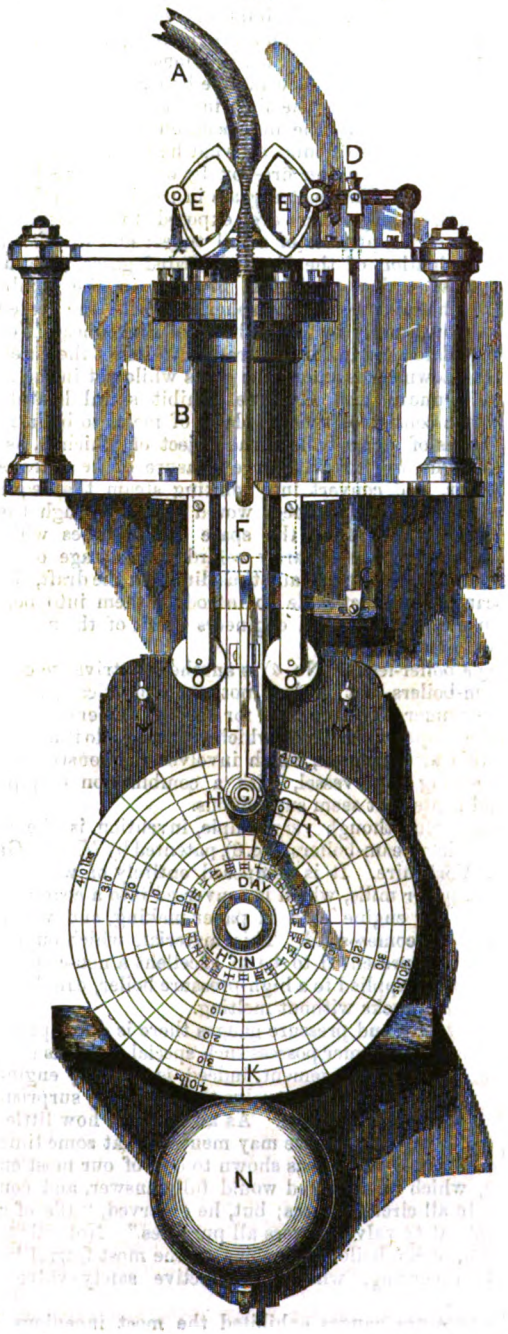
The contrivances for burning coal in locomotive boilers have all of them the same object as the smoke-consuming furnaces; but, however effectually they may succeed in preventing the intolerable nuisance of the emission of volumes of black smoke from the chimneys of locomotives as they are propelled along the green valleys and past rural habitations, yet they do not prevent the sulphurous exhalations and the pouring forth of carbonic oxide, which, though invisible, are a serious annoyance to the passengers. The coal-burning locomotive boiler of Mr. Brotherhood, of Chippenham, which is the first in the catalogue, effects the combustion of smoke by the interposition between the fire-box and the ordinary flues or tubes of what he terms a "combustion-chamber" connected to the fire-box by one or more tubes surrounded by water. The heated gases in passing from the furnace to the combustion-chamber are exposed to atmospheric air, admitted through a number of small tubes; and to effect a more perfect combination of the air and heated gases, they are impelled against a disc of heated fire-clay in the combustion-chamber. The mixture of atmospheric air with the heated gases is effected more simply by Mr. Ashton, of Birkenhead (No. 2), by a deflecting plate fixed inside the fire-box to deflect the air entering by the door downwards among the gases while yet in the furnace.

Messrs. Duncan and Gwynne exhibit spiral heat-diffusers (No 5), which consist of twisted plates of metal to be introduced into the tubes of steam-boilers, the object of which is, as stated in the catalogue, to "arrest a large measure of heat, transmit it to the water, and convert into working steam that equivalent which without these appliances would escape through the flues and be lost." The filling the space of the tubee with these twisted plates must necessarily retard the passage of the air, which seems to be its object, and thus diminish the draft, therefore it can scarcely be practicable to introduce them into boilers at present in use, but practical engineers speak of them as a valuable improvement.

Picking's boiler-feeder (No. 4) is another contrivance connected with steam-boilers, but it does not seem practically applicable. There are numerous inventions for feeding boilers and keeping them at the proper water level, which propose to do it more simply than by this arrangement, which involves the construction of a separate strong iron vessel, with a combination of pipes and valves and floats that seem superfluous.

A more useful, though very simple, invention is the woollen felt for covering steam-boilers (No. 6), patented by Messrs. Garnett, of Otley, Yorkshire. It is composed entirely of waste woollen refuse from paper mills, which is converted into a coarse pulp by the ordinary rag engine used in paper making, and when felted by heating it becomes solid. This material, which ought to be very cheap, is represented to be so excellent a non-conductor of heat, that, when applied to a high-pressure boiler, candles may be laid upon it for weeks without melting.

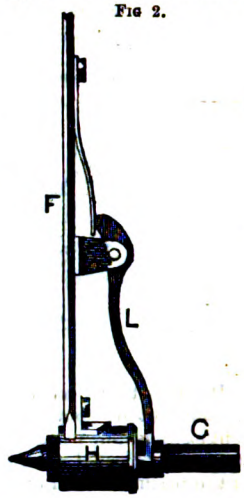
Of safety-valves and pressure gauges there is a fair proportion, though none of the former possess such special merit as to deserve notice. So little encouragement, indeed, is given by engineers to the improvement of the safety-valve that it is only surprising any such attempts should be made. As an example how little attention is paid to this subject, we may mention that some time ago a new kind of safety-valve was shown to one of our most eminent engineers, which he admitted would fully answer, and could not fail to act in all circumstances; but, he observed, "It's of no use; the present safety-valve answers all purposes." Notwithstanding this dictum, steam-boiler explosions of the most fearful kind are frequently occurring, which an effective safety-valve would prevent.



Of the pressure gauges exhibited the most ingenious, but at the same time the most complicated, is that of Mr. Mann (No. 15). The steam is admitted to a spring piston working on a small cylinder, and to the piston-rod is attached a pencil that is maintained in a vertical position by guides. The piston of course rises or falls according to the pressure, and it communicates the same movements to the pencil, which is pressed against a vertical paper disc. The disc is caused to rotate once in twenty-four

Digitized by Google

hours by clock-work, and as it turns round the marks of the pencil indicate the degree of pressure at each hour of the day and night.



The accompanying woodcuts, Figs. 1 and 2, will illustrate the action of the apparatus. The pencil-bar F is attached to the piston-rod, and it raises or depresses the pencil G, in accordance with the pressure of the steam. The quadrant heads E E serve to guide the pencil-bar and keep it in a vertical position. The disc K is divided into radial lines indicating hours, and into concentric circles corresponding with pounds of pressure on the square inch. The pendulum bob of the clock is shown at N.

Fig. 1.

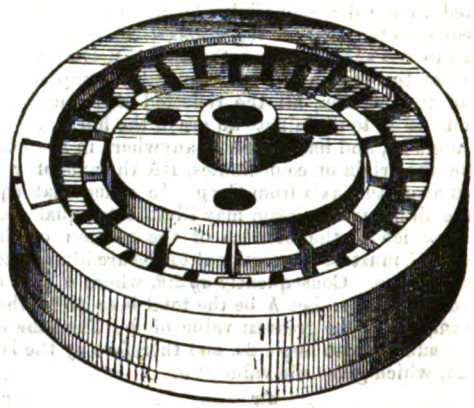
The metallic spring pistons and plungers exhibited by Messrs. Parkin and Co. of Sheffield, No. 22, if they possess the advantages attributed to them by the patentees, will prove a valuable invention. It consists of an elastic pressure ring, which is made elastic by indents or slots in opposite directions and of more than opposite depth, which make the ring spring in circumference when a wedge is forced into the ordinary opening for it, and thus enlarges the ring to the requisite degree. This elastic ring is so formed as to yield up and down, and by this means it enables the piston to work with greater facility. It is stated that these pistons will resist a pressure of 500 lbs. to the square inch.

Fig 2.

The annexed woodcuts, Figs. 3 and 4, exhibit the completed piston and the structure of the elastic ring. The indents are shown at B B; the wedge is seen at C, and the opening into which it is forced is marked at D.

Among the domestic wants of the present day which mechanical science has failed to supply is a cheap and effectual water meter, which shall enable those who are supplied with water to measure the quantity they use as easily as the consumers of gas now tell the number of cubic feet of gas that they burn by the gas meter. Water companies and individuals would be equally benefited if water could be sold by measure; for those who employ it carefully are, at present, compelled to pay for the reckless waste that frequently takes place, to compensate the companies for the loss. No water meter has yet been constructed that is generally applicable, and the only one exhibited (No. 33) is adapted to high pressures, and is much too costly and complicated for general use. It is constructed like many others on the principle of the double-action steam cylinder, each stroke of the piston being marked by an index, and measuring the quantity of water contained in the cylinder. There has been some objection raised on sanitary grounds to the measurement of water, which it is said should be used without stint; but the cost of the quantity really needful would be so insignificant as not to prevent its sufficient use, and the paying only for what is used, and not for the extravagant waste of others, would no more stint the requisite quantity than the measurement of gas diminishes the requisite amount of light, though it restricts the wasteful and injurious consumption of gas. The difficulty of measuring an aeriform fluid is much greater than

Fig. 3.



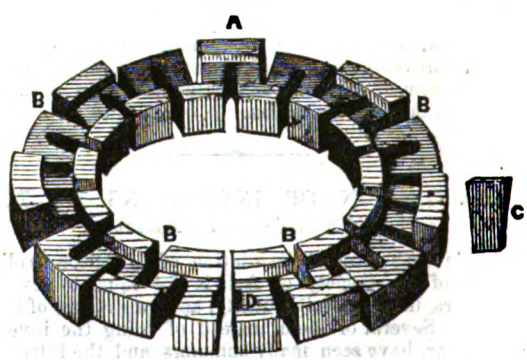


Fig. 4.

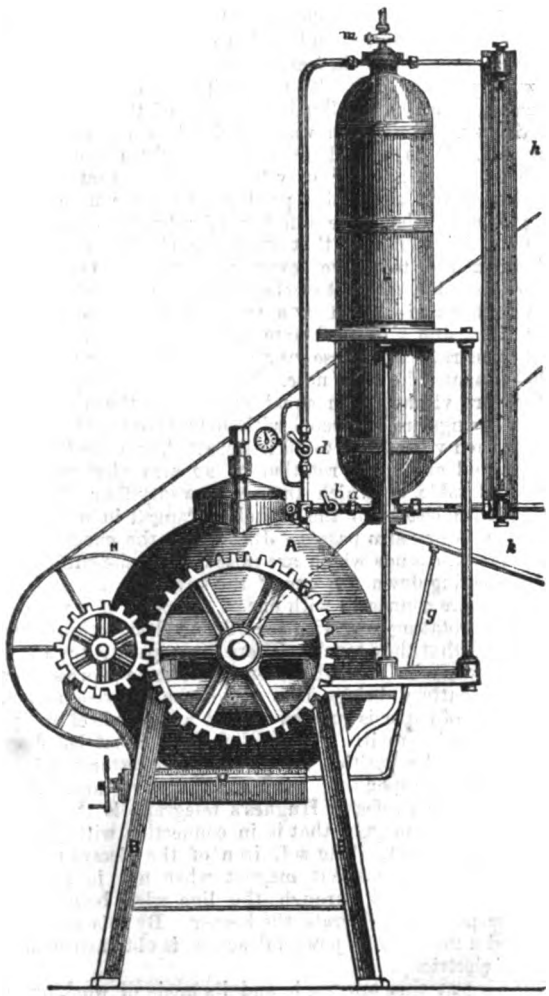
Digitized by Google

that of measuring a liquid, and if one half the amount of ingenuity that has been bestowed on the perfection of gas meters were exercised in the production of a generally applicable measurer of fluid, instead of a single machine that is only suited for special occasions, we should have numbers of water meters exhibited.

The models of railway chairs, of sleepers, buffers, and brakes that are exhibited we shall at present pass unnoticed, as the vast varieties of contrivances for improving the permanent way, and for stopping trains when in motion, render it impossible, without a very careful examination and comparison, to ascertain whether those now exhibited differ in any material respect from those that have preceded them. There is however one large model (No. 60) representing several contrivances for the prevention of accidents on railways that deserves notice, from the completeness of the arrangements for making signals and for rousing the attention of the engine-driver to danger. Messrs. Whitworth and Gibson's inventions are rather improvements on those previously known and partially adopted than original contrivances. On approaching a semaphore with the danger signal displayed a raised projection near the rail strikes a trigger on the engine that sounds the steam whistle, so that whether the signal be seen or not, warning is given to the driver. The engine itself works the semaphore in passing, and elevates the danger signal; and as it nears a station pulls a wire that sounds a bell to give notice of the coming train; one of the chief points claimed by the patentees being an improved compensator which operates as a self-acting regulator, and keeps the connecting wire always at the same tension, so as to insure its ringing the bell. In all the other arrangements the patentees claim improvements by which the making of the signals we have mentioned are facilitated and rendered more certain in their action.



The Manchester Cotton Supply Association have directed the attention of the machinists of this country to the production of an improved machine for the dressing of cotton, and have sent for exhibition an Indian churka or cotton gin (No. 74), for the purpose of showing the implement at present used. The committee of the association intend, at the suggestion of the Bombay Chamber of Commerce, to have a trial of the merits of the gins that may be constructed in response to this invitation, and offer premiums for the best. There are eight objects to be accomplished by a perfect cotton gin, which will task the utmost efforts of inventors to combine in a machine of low cost, such as the natives may purchase; one of which conditions is, "That the machine be able to do its work faithfully in spite of carelessness or neglect." Notwithstanding this invitation and encouragement only two cotton gins are exhibited, neither of which seems to comply with the required conditions, and one of them (No. 75, exhibited by Messrs. Garnett, of Cleckheaton), is intended for operations on a large scale, though it may be worked by two persons, and produce by their labour, as stated, 200 lb. of cleared cotton per day.

A hand-planing machine (No. 83), intended for the use of philosophical instrument makers, is exhibited by Messrs. Muir and Co., of Manchester. It is worked by a continuous rotary motion of a small fly-wheel turned by hand. The tool is moved by elliptical gearing, which produces a nearly uniform forward motion, with triple speed in turning. The compactness of this arrangement will make it a convenient accessory to the workshop.

A brick, tile, and pipe moulding machine (No. 86), invented by Mr. W. A. Smith of Belper, deserves attention. It is intended for stiff plastic clay, which is pressed by two cylinders through a perpendicular channel into two sets of moulds open at top and bottom, and fixed on a frame that moves to and fro, so as to bring the moulds alternately under the feeding channel, and under pistons which force the bricks out of the moulds. This machine, it is stated, will produce 25,000 bricks in ten hours.

Machinery has for some time been advantageously employed for making bread, and the cleanliness of the operation, compared with the method of kneading the dough with the hands or feet, is calculated to bring it into general use. There are four models of such machines exhibited, the first of which shows the new mode of making bread by mechanically aerating the flour and water. Unfermented bread has, indeed, been made for some years past, but the plan adopted is to employ carbonate of soda and muriatic acid, by which the carbonic acid is liberated from the soda and aerates the dough, whilst the combination of the acid with the soda forms salt, and thus becomes innocuous. There are however several practical objections to this chemically-prepared bread, which have prevented it from coming into general use. It is to be hoped that none such will prevent the aerated from supplanting the fermented bread. The process as adopted is this:—A strong globular iron vessel A, capable of bearing considerable pressure, serves for the kneading-trough. Connected with it by pipes is an elongated copper cylinder, tinned, L, which must also be capable of bearing strong pressure. Into this vessel, which is nearly filled with water, carbonic acid gas is pumped in the same manner as in making soda-water, but there is no agitator to mix the gas and water together, for the gas that does not combine with the water in passing through it is conducted by a pipe into the kneading-trough, into which the requisite quantity of flour and salt have been introduced. When a sufficient quantity of gas has been forced into the water the latter is admitted into the flour, and they are mixed together into dough by the revolution of an iron axis, on to which strong mixing arms are fixed. A water-gauge serves

Fig. 5.

to indicate when the proper quantity of water has been admitted to the flour, and the dough is stated to be perfectly mixed in about five minutes. The dough is then *drawn off* into moulds or baking tins, when the carbonic acid compressed within it expands and produces the lightness of well-fermented dough. It is stated in the description of the apparatus that the vessel must be strong enough to bear a pressure of 300 lb. on the square inch; but this must be a mistake; it is most probably a misprint for 30 lb. We have tasted very good soda-water that had a pressure in the machine of only 15 lb. on the square inch, and three or four atmospheres of pressure are the utmost that the strongest bottled soda-water contains. If one-half the pressure mentioned in the printed description were needed it would be an effectual bar to the practical application of the plan.

In two of the other bread-making machines, No. 100 and 101, the same plans are adopted as in the Government biscuit-making factories, with this exception, that yeast and salt and more water are added to the flour. Mixing arms fixed on to an axis work the

Digitized by Google

flour and water and yeast into a consistent dough, which is then passed through rollers several times and cut into sizes fitted for loaves. The object of the fourth machine, No. 100, exhibited by E. Stevens, is merely to assist the usual operations of making bread.

One of the greatest attractions of the exhibition is the printing telegraph of Professor Hughes, the performances of which have for some time past excited much attention. Printing telegraphs which transmit messages printed in Roman type, are no novelty in telegraphy, for even before the needle telegraph was in practical use we remember to have seen experimental printed messages transmitted from a distance of seven miles. Mr. House's and Mr. Brett's telegraphs have more recently brought this form of transmitting telegraphic messages to a great state of perfection. They were, however, slow in their operation, and could not correctly print above forty letters a minute; but Professor Hughes with his instrument is represented to be able to transmit upwards of seven hundred. This telegraph does, indeed, seem to work with marvellous rapidity, and we have seen a sentence of forty-four words printed by it in less time than it would take to write them with pen and ink. The principal novelty of the apparatus consists in the application of one of the laws of sound to obtain synchronous movements in two or more distant instruments. It is well known that a given sound is produced by a given number of vibrations, and that when two steel wires of the same size produce the same note they are making exactly the same number of vibrations in a second. It is upon this principle that Professor Hughes regulates the two instruments to move exactly together. On each instrument there is a thin flat steel spring of the same size, to which rapid vibrations are given by a train of wheels impelled by a heavy weight; and a musical note is produced. A small sliding piece of brass regulates these vibrations, so that the two may be adjusted to sound the same note. When that is done, it is known that they are vibrating an equal number of times per second. The steel springs are connected with detents on toothed wheels, so that at each vibration a tooth is liberated, and the wheel turns rapidly round and gives rotation to an arm that passes over an insulated table, on which there are twenty-four slots, corresponding with letters of the alphabet, ranged in a circle, over which the rotatory arm passes. Just below the surface of these slots are metallic studs which are raised above the surface of the table by pressing down any one of the keys of a key-board; and as the studs are connected with one of the poles of a voltaic battery and the rotating arm with the other, voltaic action is excited every instant that they touch. There is a separate key for every letter of the alphabet, and whenever one of them is pressed down, the voltaic battery brings into action an electro-magnet, by which a strip of paper is pressed against a type-wheel and prints the letter opposite to it. The type-wheel, it must be observed, is brought into the position for printing the letter required by touching the corresponding letter on the key-board. Another leading feature in Professor Hughes's telegraph is the construction of the electro-magnet that is in connection with the corresponding instrument. The soft iron of the electro-magnet is magnetised by a permanent magnet when not in action, the electricity transmitted through the line wire being used to reverse the poles and liberate the keeper. By this arrangement it is stated a much more powerful action is obtained by a feeble current of electricity.

On looking at this telegraph and its mode of working, there seem so many elements of uncertainty in its action that we should be at once inclined to say it was impossible the two instruments would work correctly when separated; but we understand that it has been proved to work satisfactorily between London and Liverpool, and transmitted the Queen's speech in a marvellously short time. As exhibited at the Society of Arts, with only one instrument in action, it is no test of its ability to transmit messages from one to the other.

Building and Sanitary Appliances.

Under this head several things are exhibited worthy of notice, among which are the dry and the wet gas meters of Mr. N. Defries (236, 237), and Geyelin's gas burner regulator. Hart and Son, of Wych-street, exhibit (243) a mediæval gas standard, the artistic character of which is what might be expected from their well-known reputation. No. 244, a patent chandelier, by John B. Smith, is an arrangement intended to supersede the ordinary method of raising and lowering by means of the hydraulic tube and balance weights; instead of which is used a quick-travelling internal screw, by which the chandelier can be raised or lowered as required. The advantages claimed for this invention are that it prevents accidents arising from the breaking of the chains to which the weights are attached; and dispenses with the necessity for using water to prevent the escape of gas, as, when once fixed, it requires no further attention.

Among the gas stoves exhibited there are several worthy of consideration. The first we notice is No. 437, a sanitary gas stove and standard for gas light; R. W. Giblett, architect, and F. W. Campin, 156, Strand. This is an arrangement intended to secure the removal of smoke or foul air without the aid of the unsightly pipes which for this purpose are usually carried through the side of the apartment. Two tasteful designs for such a gas-warming apparatus are exhibited, one mediæval, the other of modern character, both proving that such an apparatus need not be offensive to the eye, as is generally the case. A hollow pillar or standard open at top and bottom is substituted for the ordinary smoke and foul air funnel, and at the top of this hollow pillar is a gas light, which is not only useful for illumination, but ensures also, by its heat in the upper part of the interior of the pillar (as well as by the effect of the pillar considered as an upcast air shaft), the ascent of the smoke and products of combustion to the top of the room, which can be ventilated at top by an Arnott's valve or otherwise. The hollow pillar and gas light must be carried up sufficiently high to be above the heads of persons in the room. We think this stove is an effort in the right direction.

Another invention, "A Stove with apparatus for purifying the air" (247), consists in a stove with or without a flue, inclosed in a case with which it is not in contact, the air of the room being admitted by apertures in the lower part of this case, as likewise the external air by a pipe connecting it therewith. From the top of this case the heated air passes to a hollow shelf or projecting case, the edges or sides of which are perforated. The top surface of this shelf or case having a fountain pipe issuing therefrom whereby a small fountain is kept playing beneath a glass shade, the streams from which are continually dropping into the shelf or case, and thus the heated air which has to pass through this shelf or case is purified before it issues from its perforated sides into the room. This invention will of course be unavailable where a water pipe with sufficient pressure cannot be obtained.

A third invention, though not particularly novel, appears to be the right thing to combine with that first alluded to, whenever it can be readily done; this is "The ventilating gas lamp for drawing-rooms," T. C. Hine, Regent-street, Nottingham (No. 438), in which the products of combustion are to be collected in a glass dome, the top having a tube carrying these products into the smoke flue of the apartment. There being also an arrangement by which fresh air heated or not can be admitted, so as to raise or lower the temperature as required.

Mr. White exhibits a modification of the same idea in his gas stove for the purification of the air in large buildings, which, he states, has been applied in Holy Trinity Church, Finchley.

No. 252, Mr. John Roberts of Upnor, near Rochester, exhibits a stove in which a smokeless fuel is to be burnt, which fuel, however, he does not exhibit or describe except by stating that its cost is 1*s.* 6*d.* per bushel, and the residue of the combustion is valued at 6*d.* per bushel. What this fuel is that burns without any resulting deliterious product we have to conjecture. There are some plans for smokeless fire-places for coal-burning which appear to be very ingenious, though probably too complex for ordinary domestic service.

No. 275, Specimens of veneers adapted for fixing in plaster walls (the London Parquetry, Victory Works, Camberwell). These specimens are veneered on cement, may be applied at much less cost than the ordinary panelling, and are said to offer no inflammable body in case of fire.

No. 276 is a specimen of wood carving by machinery (Cox and Sons, Belvedere-road, Lambeth), consisting of a bench-end with poppy-head, showing three styles of carving to which the machine is applicable, viz,—cutting the tracery, which can be done from an outline pattern; working the crooked moulding round the outside edge of the bench, and carving the natural foliage in the poppy-head. The specimen shows the amount of work that can be done by the machine, no hand-labour having been employed. This is undoubtedly a very efficient system of mechanical carving.

MARINE ENGINES.*

The Purchase and Cost of Steam Machinery.

In the directions given to the committee by the Lords Commissioners of the Admiralty particular attention was directed to this subject, and the committee, as well from their anxiety to do justice to the directions they have received, as from their strong conviction of the great importance to the country that the large sums devoted to the purchase of steam machinery should be properly laid out, have given special attention to the manner in which purchases should be entered into, and also into the cost, marking at the same time where there has been in these transactions any want of economy that ought in future to be avoided.

As a preliminary remark the committee would beg leave to observe that the improvements lately made in steam engines and boilers have a tendency to increase their cost. The tubular boiler with brass tubes costs more than the flue boiler, and the direct-action engines for propelling the screw are not only more expensive to purchase than those used for the paddle-wheel, but require a greater expenditure of tallow and oil for facilitating the motion. It would be easy to state many more changes connected with the structure of engines which have at all events required for the present extra expense.

In drawing attention to examples where the committee believe that money has been extravagantly laid out, they refer only to cases where either the vessel or engines were indifferent, omitting the cases of superior engines; for it is always some satisfaction when a good article is obtained, although the price may be large.

The hull of the Sans Pareil, of 70 guns, without masts, cost £89,032. The present engines and boilers of 400 horse power have cost the government £50,126; the reason of this large expenditure was owing to the first engines and copper boilers having been found useless: they were returned to the makers (Messrs. James Watt and Co.) with £7500 for another pair of engines and iron boilers. It is quite evident that the mistake here was purchasing the first engines with their copper boilers. With the experience that even then had been obtained of copper boilers their purchase was at all events inconsiderate. The Janus, a small steam vessel, was built in 1846, at a very considerable expense; her hull alone costing until sold £34,355, and her engines and boilers of 200 H.P., £29,392. In 1854 the sum of £5060 was laid out upon her machinery at Woolwich, where she remained till April 1856, when this vessel with her engines, boilers, &c. was sold for £3300. The machinery of the Sidon, of 560 H.P., cost £41,148 from Nov. 1846 to Nov. 1849.

The machinery of the Retribution from Sept. 1845 to July 1850 cost £67,246. In order to obtain great speed from the Retribution, double cylinder engines were placed on board, at a cost of £41,170, made by Maudslay and Field, of 800 nominal H.P. The authorities in 1850 determined to remove the engines, but before they were taken out they were put in order, at an expense of £2055. In 1856 an order was sent down that the engines in question should not be sold but broken up. The above was carried out, and the committee was informed that the value of the wrought-iron saved was about £2000, and when the labour employed is deducted, it may be considered that the government received about £1500.

Surveyor's Reply.

With regard to the fitting of these engines with copper boilers, it may be remarked, that in 1845 a strong feeling prevailed in favour of copper boilers, inasmuch as their use obviated the necessity of occasionally removing portions of the decks for repairs or renewal of boilers. It was therefore decided to give them a trial in the Sans Pareil.

The only instance adduced by the committee to prove the inexpediency of using copper boilers was the Volcano; but on the whole, the experience which had been obtained of the working of copper boilers in the royal navy, as well as that in respect of economy, was certainly not calculated at that time to discourage the further use of copper. The high price of copper, however, and the gradual increase in the pressure of steam, render it altogether unadvisable to use copper boilers in the present day. The total cost of the engines and boilers for this ship is somewhat incorrectly stated.

The Janus and Sidon were designed respectively by Lord Dundonald and Sir Charles Napier, and, as far as is known, ordered to be built without any reference to the surveyor's department. Lord Dundonald's ship and engine are admitted by all to have been failures. The Sidon was not a failure, she having been built nearly on the lines of the Odin, but with greater depth, for the purpose of obtaining more coal-stowage and an entire main deck—an important improvement subsequently carried out in vessels of the same class.

With respect to the Retribution, there can be no doubt that her displacement was not sufficient to enable her to carry her engines well. The only way to use them was to convert them into screw engines. This, however, their construction did not admit of, and the remaining means of disposing of them were either to sell them, or to convert their parts to such uses as they were fit for.

Every effort was used to effect the former object without success, and the Board in 1855, after full inquiry, on one of their visitations at Woolwich ordered the latter course to be adopted. The boilers had been previously converted into one large and two shallow barges. It may however be remarked, that engines alone, without boilers, coal-boxes, copper pipes, &c., are not so valuable as may be supposed; even when new their value does not exceed one-half of the original cost of the machinery complete as fixed on board. The many alterations also which they would have required to adapt them to a new paddle vessel were probably sufficient to deter any company from wishing to effect a purchase.

With the exception of those made by Messrs. Rennie and Messrs. Watt & Co. for block frigates, and subsequently fixed in sea-going ships, the engines of Messrs. Fairbairn are the only instance of screw-engines ordered by the Admiralty being broken up. The Termagant's, by Messrs. Seaward, were converted into two other pairs, and the James Watt's considerably modified. The Transit's and Urgent's, by Messrs. Napier, were made for the Russian government, and seized at the commencement of the war.

Many competent judges thought the screw system of propulsion could never be successfully carried out, and the invention had to struggle against adverse opinion, and no small opposition.

The original destinations of most of the engines to which the committee draw special attention were altered: they were put, not into "block-ships," mere floating batteries, but into sea-going ships, subject to more severe service than that for which they were intended.

There is not one screw-engine out of upwards of 300 pairs, with an aggregate horse power of above 66,000, ordered by the Admiralty since what may be called the transition year, 1845, when 23 were contracted for, which is not at this moment likely to do good service for many years to come.

It appears that some years ago, when engines were wanted for the navy it was the practice to apply to almost all the known respectable firms, giving very often a preference to those makers who could place the greatest amount of power in the smallest space. No doubt that was, at least apparently, the most economical manner of proceeding, but it introduced many bad engines into the service; for instance, the engines by Fairbairn, put on board the Odin and the Dragon, the Vulcan's engines, and those of the Sans Pareil and the James Watt. At present the contracts are almost limited to Penn, Maudslay and Field, and Miller and Ravenhill. A good deal of trouble is thus saved, and the committee have reason to believe that the best steam machinery that this country can produce has been lately received. Further, from every inquiry that the committee have made, after visiting most of the principal manufactories of steam engines, as well as receiving important information from most of the great steam companies, they have no reason to believe that the government have generally paid a higher price for their engines and boilers than private individuals have done. The committee are of opinion that although this plan of purchasing engines has been adopted by several large steam companies, still they think that the government could advantageously throw their contracts more open.

In the course of their inquiries the committee have been led to the opinion that some improvements might be made in the mode of taking the contracts for providing steam engines for the navy. The specifications do not appear to be sufficiently comprehensive; one deficiency has been referred to by Mr. Murray, chief engineer of Portsmouth dockyard, who stated as follows: "I have always been of opinion that the indicated horse-power up to which the engines are to work with a given supply of coal of average quality should be inserted in the contracts."

Surveyor's Reply.

The general system adopted by the Admiralty for obtaining engines is to specify beforehand the minimum area of fire-grate and of absorbing surface of the boiler, on which the power mainly depends, and to approve of the size of cylinder, length of stroke, and other particulars of the engine, before the tender is accepted. That eminent marine engineers would do their very utmost, regardless of cost, to realise the best results which can be obtained, is notorious.

Such being the case, it may be asked, is it probable that if the proposed condition were inserted in future contracts, that with a certain quantity of coal of "average" quality—a vague definition—a certain amount of

* Extracts from a Report to the Admiralty by the Committee on Marine Engines, with Replies by the Surveyor of the Navy.

Digitized by Google

power must be realised, it would have the effect of eliciting greater skill or judgment on the part of the manufacturers?

But further, if this amount of power were fixed at a point difficult to attain—and without so fixing it the condition would be simply useless—might it not be an inducement to them, rather than risk a failure, to endeavour to effect the object without due regard to permanent excellence or the satisfactory working of engines and boilers under the ordinary requirements of the service?

It is well known that the actual power developed by an engine, which is seldom two days alike, depends upon many circumstances other than its own merits and those of the coal and boiler; such as the draught of water of the ship, state of the weather, direction of wind as affecting the ventilation of the stoke-hole and the draught of the boiler, skill and energy of stokers, duration of trial, quantity of water blown out of the boilers to prevent incrustation, degree of expansion used, &c.; and when it is borne in mind that with a boiler of given size and construction, every experienced person can predicate within very narrow limits what power it will realise if the steam be made proper use of, the difference between the power specified in the contract and that realised would never be very great; hence the aggregate influence of the circumstances before referred to would become the chief point in dispute, and it is more than probable differences of opinion on this and on the mode of conducting the trials would lead to a want of harmony and co-operation between contractors and government officers, than which nothing more detrimental to those public interests with which they are connected could possibly happen; while on the other hand, no benefit whatever could possibly be gained.

The committee having ascertained that, on an average, if 60 represents the cost of hot-blast iron, 120 represents the cost of cold-blast iron, which also may be taken as their relative mechanical value, would strongly urge upon their lordships the necessity (seeing the temptation is so great) of taking the most stringent steps to prevent the introduction of any portion of hot-blast iron into the castings required for the government engines. The committee would further add that they believe a large proportion of the breakdowns that take place on board steam vessels proceed from the use of this very inferior metal.

Surveyor's Reply.

With regard to the use of hot-blast iron, it is but just to those manufacturers who have been employed by the Admiralty to say that there is no reason whatever to suppose, nor indeed is such an imputation made against them, that they have used it injudiciously.

The principle of prohibiting the use of a material which when used with judgment is unquestionably productive of benefit, because it is cheap and may be improperly used by unscrupulous persons, cannot be defended.

The adoption of such a principle would be calculated to discourage improvements and check advancement in the manufacturing and mechanical arts; indeed in the present day it would be as anomalous as it certainly would be contrary to sound policy.

At present no engines are made at the government factories; repairs alone are done there, and those sometimes of a very extensive kind. When new engines are purchased at manufacturers', the boilers are furnished with them: the boilers when worn out are replaced by those made at the government factories. Considering the ample accommodation afforded at the government factories for the construction of boilers, there are strong reasons that the purchase of them ought to be at once discontinued, and all the new contracts for machinery should be confined to engines.

Surveyor's Reply.

If this recommendation were ordered to be carried out, no doubt many of the difficulties and objections which at once present themselves, and which appear of a serious character, would not be found insuperable; but it is quite obvious that a proposition to increase to such an extent the system of costly manufactures in the dockyards could not be decided in the affirmative without grave consideration, and a more close investigation and a fuller inquiry than it appears to have undergone by the committee.

But looking to the almost inevitable growth of a system so congenial to the feeling of the officers of the factories, even if its expansion were rigorously discountenanced by authority, and to the consequent increase of the permanent charge of those establishments, it seems at least doubtful whether the reasons assigned are sufficiently weighty to justify a departure from the system hitherto maintained.

The committee also believe that many of these advantages would be gained by government making a proportion of their own engines. The only serious objection that has been made to this representation is the one which is thus stated in Mr. Murray's evidence: "My reasons against making engines at the factories are, that I believe we should lose the benefit of the improvements that are taking place in the mercantile world; and also those improvements that we are entitled to expect from the employment of the best engineers of the country in making new engines and boilers for us on their own designs." The committee however believe that if proper precautions are taken the danger here referred to might be obviated. The committee have every reason to hope that many of the engines constructed at the government factories will be as serviceable as many of the government constructed boilers, which both in respect to excellence of workmanship and material are superior to any boilers that have as yet been made in this country. In their opinion the factories of Keyham and Portsmouth would of themselves supply abundant dimensions for doing a great deal more work than what is proposed.

Surveyor's Reply.

They also suggest that the remaining engines should not be obtained as heretofore from the engineers whose plans the committee have decided to be the most best and the most suitable for ships of war, but that two or more of these plans should be selected, or others invented by government officers, that complete working drawings and specifications should then be prepared and placed in the hands of such manufacturers as may be willing to undertake work under these conditions. Engines may, it is assumed, be thus obtained at a reduced price, and of the same or superior excellence.

To expect, however, to obtain in this manner engines of the same excellence as those manufactured by the inventors themselves, at all events for some time to come, is altogether unreasonable. For every kind of engine there are particular adjustments and allowances required, and for certain parts a suitable selection and treatment of materials, a knowledge of which can be acquired only by long practice, and cannot be communicated by any drawings or instructions. It relates more especially to those practical details learned by experience in constructing a succession of engines on the same plan. Moreover, it would be difficult if not impossible to ensure the same excellence of workmanship in ordinary engineering establishments.

These considerations, however, are at present beside the main and the preliminary question, namely, whether or not such a mode of proceeding, whatever its presumed advantages may be, is one which any government would feel themselves justified in adopting.

High-pressure Steam.

The important question regarding the expedience of using steam without condensation, or, as it is commonly called, high-pressure steam, has occupied much of the attention of the committee. For many years high-pressure steam was considered altogether unsuited for marine purposes, more particularly in men-of-war, but during the Russian campaign, when there was so much demand for gun-boats, recourse was necessarily had to the high-pressure steam engine, because there was not sufficient time to construct the more complicated condensing engine.

The great and paramount evil of the high-pressure engine for marine purposes, and which the committee think ought to decide the question, is the necessity of using salt water in the boilers. The salt soon accumulates about the tubes, in spite of every care that can be taken, and full power can only be used for a very short time. The boilers themselves deteriorate before their due time, and the efficiency of the vessel as a man-of-war, that ought to be ready to act at a moment's notice, is lowered. Upon this head all the witnesses examined agree that they see no means of remedying the inconveniences that accrue from being obliged to use salt water in the high-pressure boiler. Under these difficulties, as rendering the continuance of high-pressure engines most inexpedient, the committee naturally turned their attention to ascertain if the engines of high-pressure gun-boats could not be altered. The committee recommend that when any of the high-pressure engines placed on board the gun-boats or steam batteries require repairing, that a condenser and two air-pumps should be fitted. They do not, however, propose to disturb the present arrangement of exhausting up the funnel, in the event of its becoming necessary at any time to return to the use of high-pressure steam.

Surveyor's Reply.

For general marine purposes few have advocated, and few at present would advocate high-pressure steam. For special purposes, however, it may have its value. The difficulties attending its use, as was expected, are entirely confined to the boilers; but these difficulties, although aggravated by having to use salt water, will it may be hoped be gradually surmounted, or at least in part. Be this as it may, the recommendation of the committee to convert all the engines of the gun-boats into condensing engines does not appear to be based upon sufficient experience.

Digitized by Google

Boilers.

On board a steam man-of-war there are peculiar circumstances that must be attended to in the construction of boilers; for instance, the space for them is not only limited, but they are still further limited by being necessarily below the water line. Now the great desideratum has been not only to adapt the boiler to this limited space, but further, to spare weight as much as possible; and with this to put in a boiler that would have the power not only of generating steam economically, but with sufficient rapidity to supply the engines. For this purpose what is commonly called the tubular boiler has been adopted, and no doubt the reason it answers so well is this, that the greatest possible amount of heating and grate surface is obtained.

The committee are decidedly of opinion that the common tubular boiler is, of all known boilers, the best adapted for men-of-war, whether applied to high-pressure or condensing engines. The only other species of boiler that has come under their cognizance, and that has been actually tested at sea, at all likely to answer on board Her Majesty's ships, is Lamb and Summers' patent boiler; they are largely used in the mercantile marine, and are no doubt well planned; but after mature examination, the committee do not recommend them to the Admiralty for trial. At the same time, it is but justice to state that they do not see any positive objections, nor could it be thought a wasteful expense to give them a trial.

When first the tubular boiler was introduced into the navy the tubes were made of iron; that metal has now been abandoned in all cases, and brass tubes are substituted, except where high-pressure engines have been placed in steam-vessels, and in these cases iron tubes are now used. There can be no doubt that brass tubes are much better adapted for naval purposes than iron ones. One objection to iron tubes is, that they deteriorate so rapidly when the vessel is laid up in harbour as to become unserviceable after long inaction.

Engines.

All the marine engines, whatever may be the particular plan of construction adopted, which have been lately made in this country by the manufacturers of established reputation, when they come to be examined with mathematical accuracy, and when their motion has been analysed, have been found to give out so nearly the same amount of power, that the difference amongst them is hardly worthy of consideration.

It is more than probable that no form of marine engine, in a mere engineering or working point of view, either for driving paddles or the screw, is superior to the upright inverted cylinder engine; but this formation, from its exposure, is evidently unfit for vessels intended for the purposes of war. The principal requisites for steam machinery for a man-of-war, different or partly different from the machinery which is to be placed on board mercantile vessels, are as follows:—1. All the machinery must be well beneath the water-line. 2. The engines must be simple in construction, at least as simple as is consistent with efficiency. 3. All the parts of the engine must be readily and easily accessible, so as to be easily removed and replaced when they require repairs.

The committee have no hesitation in giving their opinion that with our present knowledge, if the government ever again require engines for propelling the paddle-wheel, that the "oscillating" and "double cylinder" engines are the two best, the latter especially (patented by Maudslay and Field) where great power is required.

The committee have no difficulty in coming to this conclusion: that of all the variety of engines that have been purchased by government for our screw ships of war the following are so far superior to all others, that no engines of an older make should ever again be put on board. The engines to which they now refer are—1st. The single piston-rod engine, with the connecting rod attached direct to the crank shaft, and with a single flat guide. 2nd. The engine commonly known as the Trunk Engine, and patented by Messrs. Penn and Sons. 3d. The double piston-rod engine.

The committee are of opinion, that with our present knowledge of steam machinery, that up to 300 collective nominal horse power there is no engine for men-of-war superior to the single piston-rod engine with a single flat guide, and they are not prepared to say that above that power its qualities may not be found equally good. And that the trunk engine, as constructed by Penn and Sons, has answered so extremely well, more particularly where great power is required, that the committee recommend that with such improvements in the details of these two engines as experience points out, they should be considered for the present the naval engine.

The committee have also made investigations into the relative advantages of the arrangements adopted by the different firms who have constructed the double piston-rod engine; and they are of opinion that in the general construction Messrs. Maudslay and Field's engines are more simple than those of other engineers who may have adopted this species of engine; and they think also that the particular parts of their engines are more accessible and more easily removed.

Surveyor's Reply.

The captain of the steam ordinary at Devonport, in his letter to the committee of the 9th September, expresses an opinion that boilers without being urged should be capable of supplying their engines with as much steam as they can condense, even when working at their utmost power, and consequently he considers it a bad arrangement when, in order to obtain the utmost power of the engines, the fires have to be urged.

The inspector of machinery afloat of the steam ordinary at Devonport is of an opposite opinion, as regards the quantity of steam the engines might be able to consume. He says, and very reasonably, "I should advocate carrying the steam further into the cylinder, say 8-10ths of the stroke, as by so doing, in an emergency such as getting a ship off a lee shore, or towing, the power could be increased."

Now this could be done, indeed it has been done sometimes, but not without a difficulty, and not with quite so good an adjustment of the slide valve. Moreover, the quantity of power would not be greatly increased, and not in any degree in proportion to the extra quantity of steam used.

In some cases, doubtless, such an arrangement would be attended with benefit; but on the whole, the ordinary one is generally admitted to be practically the best. That it cannot be far wrong may be inferred from the fact, that this officer is desirous to alter it in one direction, and the captain of the steam ordinary in the opposite.

If the former alteration were adopted, the boilers would be pronounced bad, because when the engines worked at the full velocity the additional supply of steam could not be obtained, and it would have to be used expansively to the same extent, exactly as it now is under the same circumstances. Still, more might be used, if it could be had; therefore it would be said the boilers are short of steam. With the latter alteration the boilers would be pronounced good, because the discretion which is now vested in the commander of a ship to fill the cylinders of the engines, say to two-thirds of their length at the utmost, would be limited to something less, which lesser limit he can, under existing arrangements, confine himself to whenever he thinks fit. The possibility of an officer exercising unsound judgment in such a simple matter, and urging boilers when they ought not to be urged, cannot be a sufficient ground for virtually reducing, at least under some circumstances, the power which engines are now capable of giving out.

Working Steam Expansive'y.

It has long been a complaint, and a just one, that owing to the quick motion of the direct-acting screw engines, the expansive gearing on board our men-of-war seldom acts for any length of time. It is found either that they have to be removed on account of breaking, or from the apprehension of their breaking, when the link motion now generally adopted in the navy is left as the only means of expanding the steam. In order if possible to obviate the above complaint, the committee at an early period of their labours directed their attention to the improvements that could be made in the direct-acting screw engines, so as to enable steam to be used expansively with the greatest advantage. They soon saw that with the direct-acting screw engines to work the steam expansively by means of cams was out of the question; and after much inquiry and examination they came to the decision of recommending that to all new engines, and to those undergoing repairs, should be fitted what is called the "expansion flat gridiron valve." This valve is worked direct from the shaft, with a separate eccentric.

Surveyor's Reply.

There is doubtless the want of a good and simple expansion valve fit for quick-working engines, although it is practically of less importance now than formerly, for in the present day all such engines are fitted with what is termed a link motion, which, within certain limits, does all that can be desired, and beyond those limits goes far to meet the remaining requirements. Still a good and simple expansion valve is a desideratum, and it has occupied the attention of marine engineers for a long time.

The fact that such a valve has not yet been designed, if we except that of Messrs. Maudslay, applied by them to some of their more recent engines, and which may, perhaps, be found practically unobjectionable, sufficiently shows that the difficulties are not easily surmounted.

Digitized by Google

The one suggested by the committee, which has not the testimony of any eminent engineer in its favour, together with many others, have been fully investigated; its action, however, is admitted to be imperfect, and this is probably the reason why it has not been preferred to others.

Superheated Steam.

Steam, as generated from the boiler, whatever be its temperature, contains such a quantity of moisture as makes it act in some measure as a lubricator to the cylinder. If, however, the steam were sufficiently superheated apart from the water, so as materially to increase its elasticity, the consequence of its drying qualities upon the working parts in the cylinder would be such as to cause either leakage or much friction. From this it may be deducible that the superheating of steam out of contact with water can only be beneficially employed for the evaporisation of any priming water carried out of the boiler by the steam pipe.

From what has been here stated, the reasons may be explained why the experiments made on superheating steam have given such different results. When the boilers were indifferent, and there was much priming water to evaporate, the gain from using this process appeared large; with good boilers, on the other hand, the gain appeared small.

If it is desired to secure to the navy the advantages of the process of drying the steam, the committee would recommend an addition to the steam space to be made round the uptake of the funnel.

Surveyor's Reply.

For many years all doubt has vanished respecting the fact that considerable economy arises from the use of superheated steam,—the degree of economy depending, as might be expected, upon the extent to which the principle is carried out, and upon the mode adopted for superheating the steam.

But the late Dr. Haycraft's experiments, and others, as well as those recently made in the Black Eagle, and now being continued in the Dee, prove incontestably the fact of economy, which generally, at a moderate estimate, may be taken at about 20 per cent.

The main points yet to be satisfactorily determined are—1st. Will no mischief be done, or greatly increased wear occasioned to the working parts of the engines in contact with this kind of steam at a high temperature; and whether, without greater care and attention than can be insured, is serious damage to the machinery likely to happen occasionally? 2nd. What is the most practical mode of carrying the principle into effective operation?

The subject cannot now be lost sight of, or fail to be prosecuted with assiduity. All persons interested in steam matters are fully alive to its importance, and well acquainted with what is being done.

On the Amount of Steam Power that can with most Advantage be placed on board Men-of-War.

Many mistakes appear to have arisen in making the calculations for ascertaining the exact amount of steam power required for any particular ship. The source of these mistakes has often been sufficiently obvious, and the greatest uncertainty will always prevail as to results, where there has not been the most accurate estimate of the differences of resistance consequent upon different formations of vessels, as well as taking into account the capability of the ship when fitted with an engine for carrying weight.

The error has been sometimes committed of putting too great power on board of our steam-ships as at present planned.

The Diadem, with 800 nominal horse power, although a noble ship, is quite a case in point. In perfectly smooth water and little wind (force 3) it required an indicated horse power of 2·390, or in other words, nearly three times the nominal horse power, together with a consumption of 60 tons per day, to obtain 9·9 knots from the Diadem.

The following is an important example, to show that the length of a ship may be increased, that 300 tons more weight may be placed on board, the immersed midship section being unaltered, and yet that the speed may remain the same, with the same engines and boilers. The Peninsular and Oriental Company's ship Candia before being lengthened was 280 feet long, and her trial at the measured mile in Stoke's Bay gave 12·5 knots. This vessel was lengthened 35 feet before the midship section, and on her second trial had 300 tons more weight on board than on her first trial. Her second trial took place on the 12th August 1857, also at Stoke's Bay, and the speed of the Candia was then 12·45 knots.

Surveyor's Reply.

It appears from the tenor of the remarks of the committee on the forms of ships, that they suppose there are some persons holding office in the government service, and who, having made this subject their especial study, and being well acquainted with the dimensions, forms, and other elements of Her Majesty's ships, and of many others, as well as with a vast number of authentic facts relating to their actual performances, are not yet aware that fineness of lines is conducive to velocity, and essential to high velocity. Such an opinion, however, it may be confidently stated, is altogether erroneous.

Our frigates have now reached the length of 300 feet. Almost the first of the large ships designed especially for the screw were the Duke of Wellington, Agamemnon, and Imperieuse, when a considerable step was taken; the Agamemnon having been made 230 feet in length; the longest sailing two-decker being only 205 feet. It being found that these ships sailed and worked quite as well as the ordinary sailing ships of the same classes, it was decided to make a further step in this direction; and, in consequence, the Renown was built of the still greater length of 245 feet, to enable her to receive larger and more powerful engines than the Agamemnon, and to give her finer lines with a view to increased speed under steam. The trial of the Renown having proved so far satisfactory, it has been decided to take a yet further step by building the Bulwark, and other ships of this class, of the still greater length of 252 feet, for the purpose solely of making them of still finer forms for greater speed. High speed under steam is, in the present day, considered of such paramount importance, that no reasonable expense should be spared, nor means left unresorted to, which are likely to accomplish it, provided the sailing and other essential properties of ships are left intact.

But in still further increasing the length of ships there is another and very important consideration, whether, looking at the fineness of their extremities, and weight of their machinery, it will be possible to make ships built of wood of sufficient strength to retain their forms for any length of time. It has always been felt that it is by means of experiments at sea chiefly that any reasonable expectations can be entertained of advancing the art of designing ships and their machinery, and with this view, experimental trials of ships have been made from time to time when their services could be spared; but the absolute necessity for such experiments has been still more felt since the introduction of the screw, for this has rendered necessary an entire change in size, proportion, and form of ships, in consequenee of the enormous bulk and weight of their machinery and coals, and of their being required to sail well, to steam well, and also to behave well under sail and steam combined.

Far more complex and difficult considerations are thus introduced, and almost incompatible conditions required; in fact, so complete a change has been made in Her Majesty's navy within the last few years, that the former accumulated experience derived from the behaviour of sailing ships becomes comparatively useless as a guide for the construction of modern steam-ships.

Data, however, founded on the actual performance of these ships at sea are now fast accumulating, and it may be expected that the conclusions drawn from them and from an elaborate comparison of the lines and calculated elements of ships of different classes, will gradually but surely point out the nature of the improvements which are still needed, and the best mode of effecting them. Immediately connected with this subject is that of the engine power which ought to be used. This is also an important question, and one involving difficult considerations, which experience and observation will alone help us to deal with satisfactorily. It by no means follows, that because a vessel carries a wave before her when urged to the utmost at the measured mile, she has more power than can generally be used advantageously. This is an exceptional case, and should not of itself be taken as a criterion of the proper amount of power required for general use. A certain speed for every particular class of vessel may be regarded as essential, at which speed the power placed in her should be capable of propelling her under ordinary circumstances without difficulty.

The rule generally has been to place in ships of war as much power as the displacement and general arrangements connected with the necessary stowage of the ships admit of being placed in them, and in no instance has the amount of power so determined been reported too great by the officers who have commanded such vessels; but, on the contrary, complaints have been sometimes made of its being insufficient.

The next case of too great power, in reference to form, is that of the Diadem. At the time when the design was made for this ship a strong feeling was entertained against increasing the length of ships, both on account of the additional cost of their construction and of the difficulty which might attend the working of them under sail, together with the greater dock and basin room they would require. These considerations have prevailed up to within a short period to prevent the lengthening of ships sufficiently to enable suitable forms to be given them for attaining high speed, except with some sacrifice of power. The Diadem, it may however be observed, was designed originally for 600 H.P. engines, and 800 H.P. engines were subsequently ordered to be placed in her, because the French were then placing engines of this power in their 50-gun frigates of about the same length. In fact, the only important question is, is the Diadem a better ship with 800 H.P. than she would be with 600, or any less amount of power? It is assumed that few practical men would hesitate in answering this question in the affirmative.

It must not however be supposed, from anything that has been said upon the subject of placing great power on board un-

Digitized by Google

suitable ships, that the committee are not desirous of guarding against the opposite extreme, namely, that of placing only very small steam power in ships, merely because they have not good lines of construction. A certain degree of speed for a man-of-war has now become essential; and in converting old sailing ships into screw steam-ships, the nominal horse power that ought to be placed on board each ship must be carefully considered in reference to the size and lines of the particular case. For instance, from the size and formation of the Queen it would probably be advantageous to place 100 nominal horse power more than should be placed on board some of the other line-of-battle ships that are being converted.

Surveyor's Reply.

The question here raised is not one of opinion, but of fact, namely, the internal capacities of the several ships referred to. This was of course ascertained in the first instance, before any suggestion was made to the board respecting their conversion into screw-ships, and if the committee had communicated their intention of expressing their opinion on the subject, the necessary information would have been freely furnished to them; and they would thus have been prevented from making loose statements, so calculated at first to convey erroneous and unjust impressions, but afterwards to lessen the confidence which the statements and opinions of a committee generally command. Instead of the Queen being capable of carrying larger engines than the other three ships, she is in fact the least capable; she has actually less available displacement than any of them, and less internal space.

The Screw as a Propeller.

Various forms of screw propellers have at different times been proposed, and various experiments made as to their respective utility; but from all these it does not appear that any form that has ever been applied to our men-of-war is superior for the purposes of propulsion to that of the common two-bladed screw, supposing, of course, that the proper pitch and diameter applicable to the vessel has been arranged. It has also the advantage of being more easily hoisted up than the three-bladed screw.

The attention of the committee was directed to the consideration of the qualities of Griffith's screw, and as its pitch is capable of being altered, they recommend its use for determining the most suitable pitch where a common screw is to be fitted for any particular ship.

There is one detail of considerable importance which the committee would recommend, more particularly as in the greater number of our screw ships the plan has been adopted, and found to answer well; it is this, that the screw shaft shall not draw in, but be fitted with a T head.

The committee cannot close these brief remarks upon this subject without strongly urging that the purchase of screw propellers should be at once abandoned, and that they should be all made at the government factories. The brass screw, on Griffith's plan, intended for the Doris, cost £637 more than it could have been furnished for at one of our own factories. And taking a general average, it will be found that upon this article of steam machinery a saving may be effected by government being their own constructors, to the amount of at least 30 per cent. upon the price at present paid, besides the certainty of having the best articles that the country can produce.

Admiralty, 24 December 1858.

In returning the Report of the Committee on Steam, their Lordships' attention is called to the observations therein made agreeably to their directions.

As regards matters of great importance, and these are comparatively few, a perusal will show in what respects the committee and the surveyor agree in opinion, and in what respects they differ.

For instance, there is a perfect agreement in opinion as to the excellence of the engines obtained for Her Majesty's ships, and as to the reasonableness of the price paid for them; but not as to the propriety of setting aside approved plans in favour of some engine to be designed by Admiralty officers, or as to the policy of setting aside the approved makers of these engines, in order to employ others to manufacture the same kind: nor do they agree in the opinion as to the policy of extending the system of manufacturing machinery in the dockyards to such a degree as would have the effect of increasing the cost of maintaining the factories by at least one-half the sum which, under the existing practice, would be voted for the purchase of new engines and boilers.

There is also no difference of opinion as to the praiseworthy manner in which the principal engine-makers acquited themselves of the trust reposed in them during the exigencies of the Russian war.

The surveyor of course agrees with the committee in their conclusion, that from what they have seen in the proceedings now adopted by the steam authorities of the navy, there is no appearance, at least for the present, of what they term "grave errors" being repeated.

With respect to the fineness of ships' forms, and the engine power which ought to be used, the committee, as might be expected, express themselves vaguely, but they seem to hint an opinion in favour of increasing the fineness of forms, and of putting engines of less power into the ordinary class of ships. Now this being a complex subject, it has been dealt with elsewhere at some length. It may be sufficient here to observe, that already frigates reach the length of 300 feet, which is necessary to give them fine extremities. Ultimately, perhaps, to keep pace with our rivals, they must be made longer still.

However this may be, it is confidently believed that no report has ever been received from an officer commanding a ship that she had too much power, unless she was unable properly to carry it, and for this clear reason, that he need not use it unless he choose to do so: and when he does not use it, which is always the case except when a great object is to be effected, he burns no more coal than if the engine were incapable of exerting a greater amount of power. Here again we must in some degree be guided by the practice which obtains on the continent.

(Signed) B. W. Walker.

THE EXHIBITION OF MR. DAVID COX'S PICTURES, SKETCHES, AND WATER-COLOUR DRAWINGS.

Few art exhibitions are more interesting—none more instructive—than those devoted to the works of one great artist exclusively. Each work is a key to the excellences and intentions of each other work; and the whole series may be considered to represent the history and progressive development of one great artistic mind. Unfortunately for the lovers of art, such exhibitions are very rare. The productions of important authors find their permanent place in the collections of connoisseurs, and are therefore, in a great measure, inaccessible to the general public. Almost necessarily then any collection of the works of an artist must be of a transitory and fragmentary character.

It has long been desired to remedy this great want, and to afford to the amateur, the artist, and the public the opportunity of seeing some of the finest specimens of some of our most renowned artists in the collected arrangement of one exhibition. To effect this, a number of gentlemen have formed themselves into a committee, and have made arrangements to present for a period in every year such an exhibition as is above suggested. From a casual circumstance the first choice has fallen upon the works of that simple and grand painter of English rural scenery and country life, David Cox; and the committee, having had placed at their disposal the German Gallery in New Bond-street, for a short period, in the first place opened the exhibition there; but that room being now required by the proprietor, it has been removed to 120, Pall-mall, and occupies the suite of rooms on the first and second floors. As may be conjectured, the removal thus necessitated is not so favourable for a good view of the pictures; the lighting of the rooms being derived wholly from the windows at the extreme ends: consequently, as many of the pictures are hung above the eye-level, and are not unfrequently small in size, they are not likely to gain all the attention which they really merit. We are aware however of the utter impossibility of securing suitable premises for such a purpose now that the picture season is so fully inaugurated, and though we cannot but draw the comparison between these pictures in their new locality and in that where they were on view till a week or two ago, we are rejoiced that so praiseworthy an object has been attempted, and so successfully accomplished. It may be mentioned, that while providing for the lovers of art so great a treat, the committee are most desirous to have it distinctly understood that the exhibition is in no sense a commercial speculation. The receipts will be devoted to defraying the necessary expenses, and whatever surplus may remain will be handed over to the Artists' General Benevolent Fund.

Altogether the collection will be found a highly interesting one, although the bent of the artist's mind and talents has led him into what might be thought a very monotonous style of subjects; but here the hand of genius triumphs, and invests even repetitions with a charm. A very favourite scene with our painter was always the Vale of Clywd, and even in this imperfect series of his works it forms the specific title of three pictures, while a similar character of landscape pervades some dozen or more besides. Welsh grandeur is Mr. Cox's especial study and delight: the proofs of this are manifold, and whether it be in the portrayal of a peaceful vale like Clywd or Dolydellan, or the

Digitized by Google

over-awing wonders of Penman Mawr, he is equally at home. Several noble views of our English castles will be regarded with pleasure, such as Windsor (2 views), Beeston, Barden, Dover (a very slight but beautiful sketch), Kenilworth, Dudley, Richmond, Bolsover, and Lancaster. The view of Rhyl gives an excellent opportunity for displaying our artist's skill in representing truthfully, without exaggeration, that most difficult object, the sea. We know not which of all the number—amounting to 174—is to be regarded as his earliest production, but we recognise that "On the moors, near Bettwys y Coed," as having graced the walls of the Old Water-colour Gallery so late as last season.

This exhibition is indebted to not fewer than thirty-four gentlemen for the loan of pictures, and it is stated that other portfolios of sketches and additional drawings have also been received, which will still further enhance the attraction.

SOME ACCOUNT OF THE LIFE AND WORKS OF BALDASSARE PERUZZI.

By Samuel Angell.*

In the notice of the life of Le Tarouilly, prefixed to 'Les Edifices de Rome Moderne' (the noble work of that indefatigable architect and author), it is remarked that although he possessed a just admiration for the works of Bramante, San Gallo and Vignola, the artist he preferred was Baldassare Peruzzi; and so great was the admiration of Le Tarouilly for this "artista valente" (as he is styled by Milizia) that he compares him to Raffaelle, from the resemblance he found in their characters and in the nature of their talents. The preference evinced by such excellent authority, and by one so eminently qualified from the direction of his labours and studies to form a correct judgment, has induced me to bring to your notice the works of Peruzzi, feeling assured that there are still among you some who have not been entirely led away from their early studies of Italian architecture, and that even from the Mediæval benches (crowded, and so honourably occupied as they are upon this evening of their triumph) I might possibly enlist some sympathy, if not admiration, for so distinguished an architect of the Renaissance period as Baldassare Peruzzi. Peruzzi was born early in the year 1481 at Accajano, near Siena, and he was sometimes called "Baldassare de Siena," but Vasari states, that both Florence and Volterra (as well as Siena) put in their respective claims for the honour of his birthplace. I believe, however, that we shall not be in error in considering him a Sanese. His early days appear to have been passed in the workships of goldsmiths and jewellers, after which he commenced the study of painting, copying and imitating the works of the best masters, as well as drawing from nature; and upon the death of his father, about this period, his exertions and progress were such, that he was enabled to support himself by his art, and to aid both his mother and sister. We may remark that it is probable his early studies as a painter (more particularly those of a decorative character) produced in him afterwards that freedom and facility in his architectural designs for interior ornamentation, of which he has given us such exquisite specimens in the Massimi Palaces, and other of his works. I regret that I have not sufficient data to place before you the works of Peruzzi in chronological order. I will adopt, therefore, the arrangement in which they are classed by Vasari, who informs us that Baldassare's first work (after some few unimportant ones at Siena) was a small chapel, near the Florentine gate at Volterra, where he painted certain figures with "infinite grace," after which he proceeded to Rome with his friend and brother artist, Pietro da Volterra. Peruzzi's early days at Rome appear to have been devoted to his studies as a painter, and he obtained great praise for the excellent manner in which he executed in fresco the Chapel of the Great Altar in the church of San Onofrio. He was next engaged in painting two small chapels in the church of San Rocco a Ripa, and having now attained some eminence, he was invited to Ostia, where he executed some beautiful historical representations in chiaroscuro, in the apartments of the tower of the fortress. Many of these represented combats, in which were introduced ancient armour and equipments of war. These decorative paintings are considered among the best of Peruzzi's works in that style, though it is but fair to state that he was assisted in them by Cesare, of Milan. Upon the completion of his labours at Ostia, our artist returned to Rome. His chief architectural work at this time was the celebrated "Farnesina Palace," for Agostino Chigi, on the Lungara. Le Tarouilly gives 1510 as the date of this admirable production, a work to which Vasari applied the happy expression of "Non murato, ma veramente nato." Situated as the building is upon the spot formerly occupied by the gardens of the Emperor Geta, Baldassare composed his plan upon the most simple arrangement, evidently considering it as devoted to pleasure and entertainment, rather than for a domestic residence. Le Tarouilly's three plates convey an admirable description of the edifice, with the sole exception that one of its most attractive features (the exquisite colouring of the ornamentation) is not rendered; this omission, however, is in a great measure supplied by the beautiful coloured plate in M. Gruner's noble volume, and in the Italian prints tinted in body colour.

The Farnesina owes much of its celebrity to the beautifnl pictorial embellishments of those eminent masters, Raffaelle, Giulio Romano, Sebastiano del Piombo, Daniele da Volterra, and Annibale Caracci; and, with all his fond preference for Peruzzi, Le Tarouilly allows that many parts of the exterior architecture are open to criticism; the design however is full of grace and elegance, and the ornamentation is deserving of all praise. Great portion of the enrichments in "terretta" are by Peruzzi's own hand, and the great Titian himself is said to have been deceived by the marvellous imitations of relievos. Peruzzi was next employed, according to Vasari, in executing a façade in "terretta" between the campo de' Fiori and the Piazza Giudea. It is described as an admirable performance, particularly the perspective views which were introduced in it. This work was a commission from one of the pope's chamberlains. In the Chiesa della Pace our artist painted a chapel for Messer Fernando Ponzetti (who was afterwards made a cardinal); he also painted in "fresco," in the same church, a picture for Messer Filippo da Siena, representing the Virgin ascending the steps of the temple; this picture contained a great variety of buildings, with many beautiful ornaments of various kinds.

The Palazzo Costa in the Borgo Novo (built for Jacobus Brixianus, surgeon to Leo X.) is not far distant from St. Peter's. Some attribute the architecture of it to Raffaelle, but Le Tarouilly (the best authority upon such points) is inclined to ascribe it to Peruzzi. The design is of an unpretending character, and the ground floor (as in many instances in the Italian palaces) is occupied by shops. Much study has been given to this design, particularly to the rustication, and it is upon the whole well deserving the attention of the student. The author of 'Les Edifices de Rome Moderne' has devoted three plates to the Palazzo Linotte, in the Vicolo dell' Aquila. This palace is situated near the Cancelleria (the great work of Bramante), but little is known of its date or history, and it is attributed to Peruzzi more from its style than from any authentic source. It has been ascribed also to Bramante, and to Michael Angelo, but there are no traces of the distinctive styles of those architects, and if not the work of Peruzzi, the claims of San Gallo I believe would be considered as most worthy.

The Palazzo Ossoli, in the Via de' Balestraji, is attributed to, rather than positively known to be the work of Baldassare. The simple and masterly arrangement of the plan, and the elegance of the façade partake of the master mind and hand of Peruzzi, and I think there can be no doubt that Le Tarouilly is correct in naming him as the architect.

The Chigi Chapel in the church of Santa Maria del Popolo, has been generally attributed (both as to its architecture and pictorial embellishments) to Raffaelle; but we owe it to the study and research of Le Tarouilly, supported by the opinion of his countryman Lalande, that the architecture is from the hand of Baldassare; the style and imprint are his, and the "Corinthian Order," as published by his pupil, Serlio, resembles in a great degree the one that has here been employed. Peruzzi's intimate friendship with Agostino Chigi may be fairly adduced as an additional reason for believing that he was employed in this chapel as architect, while Raffaelle (as in the Farnesina) was commissioned with the pictorial embellishments. This chapel is certainly a "Capo d'Opera!" and although I may be venturing upon tender ground this evening, in daring to uphold the Italian architecture of the XVIth century for ecclesiastical purposes, I am bold enough to admire this fine specimen of the taste and genius of Peruzzi, enriched by the master hand of the divine Raffaelle, and to join in the enthusiastic language of Le Tarouilly, "Honour

* Paper read at the Royal Institute of British Architects.

Digitized by Google

then to Chigi, to whom we owe this *chef d'œuvre*, and who has immortalised himself by joining his name to those of the two great artists, to whom he was the Mecænas!"

About this period (1520) Peruzzi appears to have been invited to Bologna, to enter into the famous competition for the designs for the façade of the church of San Petronio; an event which appears to have excited as much interest in those days, as the struggle for the Government Offices or the Spurgeon Tabernacle in our own times. We learn that Peruzzi sent in two designs, the one Italian and the other Gothic; they are still preserved in the sacristy of the church, and Vasari is loud in his praises of a perspective view; this, I presume, applied to the Italian design, for I suspect Baldassare was more at home with the five orders than he was with the pointed arch, and buttress, and pinnacle of the Mediævalists. While at Bologna, Peruzzi designed the portal of the church of San Michele, in Bosco, and embellished the monastery of the monks di Monte Oliveto, in the environs of Bologna. The cathedral at Carpi was also designed by Peruzzi at this period. For the Count Battista Bentivogli he made a design in chiaroscuro, "The Nativity of Christ and the Adoration of the Magi." As this drawing is now in our own national collection, we ought to be enabled to judge whether its merits deserve the encomiums Vasari has bestowed upon it, but unfortunately it is placed in so dark a position on the staircase as to be quite invisible to the eye of criticism. The catalogue, however, throws some little light upon its history, for we learn from it that the drawing was made in 1521, and was engraved on wood by Agostino Caracci in 1579. The three Magi are portraits of Titian, Raffaelle, and Michael Angelo.

While commencing the church of San Nicolo, at Carpi, our "painter architect" was called upon to enter a new sphere of action, and to bring to bear his engineering knowledge in planning and superintending the fortifications for the defence of his native city, Siena. Upon the completion of these works, Peruzzi again repaired to Rome, where, upon the death of Raffaelle in 1520, Leo X. appointed him architect to St. Peter's, when he was called upon to design a new model, upon which it is said he employed so much talent and skill, that even the fastidious Milizia considered it worthy of praise. Serlio (who was Baldassare's pupil) describes the plan to have been a Greek cross, terminated at each extremity by a semi-circular apse. There were four square sacristies, over which campanili could be erected. At each extremity of the cross was a semi-circular porch, through which, by three openings composed with four detached columns, was an entrance to the building. The great altar was in the centre, surrounded by four large piers, supporting a cupola 138 feet in diameter (within one foot of that since executed). Each of the four naves had two side aisles, with cupolas at their intersections 48 feet in diameter.

The tomb of Adrian VI. in the Chiesa dell' Anima, is the work of Peruzzi; and the Vigna of Papa Giulio, on the Flaminian way, although ascribed to Sansovino by Vasari, is considered by Le Tarouilly as the work of Baldassare. It is a most charming and elegant composition, and we are at a loss which to admire the most, the grace and simplicity of the whole, or the exquisite delicacy of the detail. Peruzzi's genius appears to have been nearly universal, for we next find him engaged painting two scenes for the representation of the "Calandra," a drama written by the Cardinal Bibiena, and performed before the pope: these scenes are said to have served as models for whatever has been since done of that kind. The preparations for the coronation of Clement VIII. were also entrusted to the care of Peruzzi in 1524. A small palace in the Via Giulia, at Rome, is also given to us by the indefatigable author of 'Les Edifices de Rome Moderne,' as the work of Peruzzi, and it presents an excellent specimen of the great extent to which external ornamentation was formerly carried. The decorations are described to have been in some instances in "fresco," and in others, painted in imitation of bronze and gilt, and portions are said to have been executed by Baldassare's own hand: they are composed in a grand style, and after the manner of the antique. The fresco figures were still tolerably preserved in 1823. The doorway under the vestibule of this palace is made to diminish in width upwards; the same method has been adopted by San Gallo, at the Palazzo Farnese: and upon this Le Tarouilly remarks, "that at this epoch (the XVIth century), when there was a general feeling for the antique, and when the cultivation of the ancient art had become as it were the true religion among all the professors; when learned commissions were instituted to make commentaries upon Vitruvius, it is not to be wondered at, that the two eminent architects, Peruzzi and San Gallo, studying together the ancient monuments, should about the same time have made the same application from what they had studied."

About this period Peruzzi executed the beautiful altar, and the chapel of St. John the Baptist, in the cathedral of Siena. The villa Belcarro, near that city, and the fine portal of the Sacrati Palace at Ferrara, were also designed by him at this date, and it was probably about this time that he painted his celebrated picture for the church of Fonte Giusta, at Siena, representing "the Sibyl announcing to Augustus the birth of Christ," which is said to be his masterpiece. So highly was this picture esteemed by Lanzi, that he says, "the painter gave it so divine an enthusiasm, that Raffaelle, treating the same subject, as well as Guido and Guercino (whose Sybils are so often met with) probably never surpassed it." Forsyth describes this picture in the following terms: "Peruzzi's Sibyl at Fonte Giusta is a sublime figure, but, perhaps, too sedate for the act of prophecy." We now arrive at the greatest as well as the last and crowning work of Peruzzi, the pyramidion of his fame—the celebrated Palazzo Massimi.

The architect to the Massimi Palaces, in the adaptation of his plan to the limited and perplexing site, and the obligation to preserve existing foundations, under injudicious notions of economy, had no common difficulties to contend with; but the genius and invention of Baldassare overcame all obstacles. The curved line of the frontage, which would have been to many a "pons asinorum," was rendered by him a "pons triumphalis."

Many of the Roman palaces are upon a larger scale than this, and are more imposing in their exterior architecture, but I doubt whether for beauty and grace of ornamentation any can compare with the Massimi. The strict injunctions to economise prevented Peruzzi from employing any expensive or rare materials, for, with the exception of two marble columns only, in the loggia of the Piano Nobile, the construction is of Travertine stone, of brickwork faced with stucco, and of wood. This example is cited as a lesson of economy; and when we consider that the exquisite enrichments derive all their beauty and elegance from the masterly design and execution, without any aid from expensive materials or costly adjuncts, we may well join in the homage that has been bestowed upon Peruzzi by French architects. I have already had occasion to remark that more than three centuries have elapsed from the period of building the Massimi palace to the time when Le Tarouilly was engaged in carefully measuring and taking note of every portion still remaining, and at the date of his labours, some thirty-five years since, when I had the gratification of being in Rome, the Massimi was generally in a fair state of preservation; but I am grieved to say that it now no longer remains so, for my excellent friend and our esteemed brother Fellow, Mr. John Davies, who last year made a pilgrimage to Italy, and revisited the scenes of his early studies after an interval of some thirty-seven years, thus describes the present state of the palace: "When I was in Rome, in October last, I went all over the Massimi, and was grieved to see the shameful state in which it was, the beautiful open vestibule and ceiling next the street falling to pieces." Le Tarouilly concludes his notice of Peruzzi in these terms: "It was about the year 1532 that Peruzzi commenced the Massimi palaces, and at that period he was in the full energy of his talents. The taste and infinite variety he has displayed in the ornamentation are a proof how well he accomplished the work studied by him in the most minute details. Poor Peruzzi died in 1536, at the age of fifty-five, in a state bordering upon misery. We cannot be altogether surprised at this melancholy termination he had to labour for a numerous family, and his income was never proportionate to his merits or his services. According to Vasari, the rich personages who profited by his talents took advantage of the gentleness of his character, his modesty and extreme reserve, and they thought less of recompensing the artist, than they did of praising his works.

Peruzzi's most distinguished pupil was Sebastiano Serlio, who was twenty years of age at the time of the lamentable death of his unfortunate master. Serlio remained in Italy three years after this event, and then proceeded to France; where he executed, together with Pierre Lescot, Jean Bullant, and Philibert Delorme (all worthy students of the same school) some of the finest works in architecture that France possesses of that period, and it is I believe principally owing to the careful study of the works of such master minds as Vignola, Peruzzi, and their disciples, that the French architects have acquired that exquisite taste in orna-

Digitized by Google

mentation so prominent in all their works. It is to the same pure sources that I would most earnestly entreat the students of our own country to have recourse, looking forward to receive the grateful tribute to talent by their brother architects, as in the distinguished instance we have had before us this evening, rather than being deterred by reflecting on the misfortunes sometimes attendant upon genius, as in the case of poor Baldassare Peruzzi.

INSTITUTION OF CIVIL ENGINEERS.

J. Locke, Esq., M.P., President, in the Chair.

April 12.—The whole of the evening was occupied by the discussion of Mr. McMaster's paper, "*On the Permanent Way of the Madras Railway.*"

It was remarked that, for India and other similar countries, the ordinary chair-and-sleeper road was not yet ascertained to be the best that could be adopted. In such cases it was desirable to aim at obtaining the smallest number of pieces, simplicity of parts, and avoiding complicated fittings. The arrangements should be made with a view to guard against peculation, as well as to the best mechanical construction; for the natives were apt to steal fishing plates and bolts. It was contended that the single-headed rail, fixed directly upon the sleepers, and with a sufficiently broad flange to prevent injury to them, was preferable. This form of rail had been extensively used in Germany and the United States of America, and the application of the "fish" rendered the joints much more secure and the surface more uniform. It was urged that the quality of the materials and the machinery to be sent to India and other distant places should be carefully attended to, as the heavy charges for freight and shipment formed a large portion of the expense. In this view it was thought that the double-headed rail first introduced by the President, provided that it was so laid as to be capable of being reversed, possessed great advantages. It was believed that rails weighing 60 lb. to the yard, to which an additional hammering had been given during the process of manufacture, would answer well for lines where very high speeds were not essential, and that their use would be attended with economy.

Allusion was made to a system of enabling the double-headed rail to be used without chairs. This was by suspending the rails between a pair of longitudinal balks, contoured to the rail channels. The rail and timbers were bolted together by flat bolts, 3 feet apart. The joints of the rails were connected by brackets of angle iron to a cross tie of timber. By this plan a thinner web could be used, and therefore a deeper rail for a given weight. When it was wished to reverse the rail, it was not necessary to disconnect the rails and the timbers, but merely to take out the joint bolts. It was believed that this system would induce economy, as no chairs were used, and less timber and ballast would be required than on an ordinary cross-sleeper road. A length of 150 yards of this way had been laid for six months on the main Cambridge line, at Stratford, where the ballast was bad and the traffic great. The timber used was only cross-sleepers cut down the middle. It made a good road, and there was a perceptible difference in passing on to it from the other portions of the line.

It had been stated that the compressed keys were liable to shrink in hot climates, and that some which had been allowed to remain on the sea coast in India had swollen so much as to be unfit for use. On the Lisbon and Santarem Railway, an oaken key 10 inches in length and slightly tapered had been substituted; and this plan was about to be tried on the Madras Railway. The employment of an iron key, with a thin cushion of wood between it and the chair, the timber being cut across the grain, was suggested as an alternative. In defence of compressed keys it was remarked, that what had been stated was scarcely so much the necessary cause of the defect of the key, as the way in which the keys were used. Twenty millions of these fastenings had been supplied for the railways in India, or sufficient to lay 2200 miles of road, and no complaint had ever been made until quite recently. The author of the paper had said, that the compressed keys lasted better than those which were unprepared; and it was also believed that the loss from premature expansion had been inappreciable during the period of three or four years during which they had been used on the Madras Railway. But being aware that the amount of dry heat to which they would be subjected, with iron on both sides of them, might have a tendency to cause even compressed keys to shrink, until they were thoroughly saturated with moisture, they had lately been made larger than usual, so as to receive a greater degree of compression. It was understood, that hundreds of casks of keys had been lying exposed to the heat of the sun for months after their delivery in India, and until the staves of the casks opened. If there had been any expansion of the tightly packed keys, the casks would have been burst open. With proper care however it was maintained that they would have remained without fault.

It was thought that one of the main points arising out of the paper was, whether it was desirable to construct permanent way in India with timber or with iron sleepers. As the cost of renewal irrespective of ordinary maintenance amounted on lines in this country to £100 per mile per annum, of which sum about 37 per cent. was for the renewal of the rails, and 63 per cent. for the substructure, attention had been directed to the use of cast-iron for sleepers, which had been proposed and tried in many different forms. In Egypt, Greave's spheroidal cast-iron sleeper with the chair cast upon it had been found best suited to the soil and climate. There was little or no ballast on the course of the line, so that it would have been difficult to have found a foundation for the ordinary sleeper. Trough sleepers of cast-iron, in which the rail was suspended between linings or cushions of timber, so that in the case of the double-headed rail the lower table was not injured, and the rail could therefore be reversed, had been in use for nine years on the Eastern Counties, and for two years on the South Eastern and the Midland Railways. In the latter case they were laid near to the Derby station, where they were subject to a traffic of 550 engines, 2400 waggons, and 120 carriages, every twenty-four hours. A modification of these two forms, which might be denominated the "cup-trough," had recently been proposed, in which the chair was entirely dispensed with, so that there were no projecting parts liable to fracture. Tie-rods passed through the neutral axis of the rail, with square washers of unequal thickness placed in the side channels, secured both the angle and the gauge. This form of sleeper was stated to be applicable to any ordinary section of rail, without alteration of pattern; was said to be inexpensive in manufacture, and to be easily maintained, as it was packed through dorner holes at the sides, which were believed to afford greater facility than holes at or near the top. For shipment they could be stowed into one another, and save space. It was assumed that the first cost of a substructure on this system would amount to £910 per mile of single way, and on the ordinary system to £551 per mile, taking the cross sleepers at 4s. each, and the chairs at £4 10s. per ton. But it was contended that the timber sleepers would require to be renewed twice in twenty-one years; for although the timber might be rendered chemically durable, the destruction would go on nevertheless, and when the time arrived for the renewal the timber would be valueless, whilst the cast-iron would be worth two-thirds of its original value. It had been estimated that the saving, by the use of iron, would amount to £1058 per mile of single line, in a period of twenty-one years, after allowing interest for the original outlay in both cases.

In regard to the durability of timber sleepers, it was asserted that when properly creosoted they lasted much longer than would be inferred from the comparison just made. Scotch fir sleepers, laid on the Eastern Counties in 1841, had remained perfect to the present time, not one having been removed on account of decay. Between the years 1840 and 1842, creosoted sleepers had been laid on the Manchester and Crewe, which were still sound; and indeed, in re-laying the line with heavier rails two years back, some sleepers that had been in wear sixteen years were employed. The sleepers for the East Indian railway were weighed previously to being placed in and when taken out of the cylinder, in which they remained twenty-four hours under a pressure of 124 lb. to the inch, in order that 10 lb. of creosote per cubit foot might be forced into them. Some triangular creosoted timbers, which had been sent to India, had shown symptoms of decay, due, it was believed, to their being of hard wood, and to the form not being the best for the purpose, as the angles were liable to be damaged, and thus expose the uncreosoted portion of the wood. Timber should be stacked and properly seasoned before being creosoted, and it had been found that heart-wood was not so easily creosoted as young sappy wood, as it was impossible to make it absorb the necessary quantity to preserve it thoroughly. In the latter case, after a few years the creosote set into a solid bituminous mass; but only the thin and volatile portions entered heart-wood, and these were liable to evaporate quickly when the sleepers were used in a hot climate. Specimens of sleepers which had been "Burnettised" in 1841, and laid at that time on the Eastern Counties Railway, were shown to be quite sound at the present time. With respect to unprepared wood, instances were given of the sleepers having been said to have lasted many years, but the evidence was not conclusive. It was stated, that good sound larch sleepers were in some cases preferable to Scotch fir that had been creosoted, and that it would last equally long. It was observed that it was impossible to subscribe to the principle which had been advocated, that wood of the lowest quality, or young timber full of sap, and which sucked up a large quantity of creosote oil, should be selected for use, because it was favourable for creosoting. It was believed that the best results would be obtained when the utmost care was taken in selecting the woods. A good result was tolerably certain under these circumstances, and in corroboration it was mentioned, that timber laid in 1835, some of which was Kyanised, although the preparation merely entered to the depth of one-tenth of an inch, and some of which was unprepared, had lasted to the present time. St. John's yellow pine had been proved to be one of the most durable woods, both for railway sleepers and marine works. At the Liverpool and Sunderland Docks there were instances of its being quite fresh after being in use twenty years.

With regard to marine works, it was said that the worm would not touch timber which was creosoted to the depth of two or three inches around the pile. When however this coat was cut through, the worm would penetrate into the heart-wood, but when it reached the creosoted portion, it was stopped by the objectionable nature of that material. This had been proved to be the case at Lowestoft, where the creosote

Digitized by Google

was found to be generally a preservative against the ravages of the worm. In all cases the timber should be cut for framing before being creosoted. It was remarked that, although in general creosoting doubled the duration of the timber, yet the creosoted piles of the pier at Leith showed symptoms of being attacked by the worm. An instance was also mentioned of the worm penetrating a balk of creosoted Memel at Scrabster, Caithness, and having eaten through the blackened portion, although the pile had been in the sea for less than six months. To this it was replied, that the discolouration of the wood afforded no correct test of the timber having been properly creosoted; and it was suggested whether the work of destruction might not have commenced before the balk was creosoted, as there was hardly a log from Memel which was not more or less penetrated by some kind of worm. Kyanising was asserted to have no effect, as the corrosive sublimate combined with the sap of the wood, and formed a substance which was not poisonous, and could be eaten by the worms with impunity.

It was thought that sufficient stress had not been laid on the importance of utilising as far as possible the resources of the country in which the works were being carried out. In Ceylon, for instance, there were forests of almost interminable extent which might be made available. Eighteen different samples of timber had been examined, at least nine of which were applicable for railway sleepers in situations where they would be exposed to extreme variations of atmosphere and weather. The drainage of railways in tropical climates was a matter of the utmost importance, as the ballast was liable to be carried away by the heavy periodical rains. In reply it was intimated that the necessity for sending out timber sleepers to India arose from the circumstance that the supply there could not be relied on. There was great difficulty in determining the precise value and quality of woods in foreign countries, especially when such practices were carried on as steeping the wood in order to deceive, as had been the case in Madras.

In closing the discussion, the great diversity of opinion that still prevailed on this subject was commented upon. Every one appeared to think his own plan the best, and naturally preferred to be guided by his own experience rather than by that of others. As to the question of the durability of timber whether prepared or not, and, if prepared, then by what process, few persons were able to obtain reliable data as far back as twenty or thirty years. The Minutes of the Institution would contain a variety of opinions on this subject, but it was doubted whether the question could be solved, or whether there could ever be universal agreement as to what was the best system of permanent way to be used under all conditions.

After the meeting, Mr. Curtis explained a system of axle boxes, in which by centrifugal action the oil was constantly thrown over the upper side of the axle, and descending slowly upon the axle was returned again to the oil chamber. As soon as it had passed the axle, a piece of thin porous flannel placed at the bottom of the oil chamber was found in practice to answer as a filter to receive the parts of the metal, or other residuum resulting from the working of the boxes. These boxes were now at work on eight railways in England and on one in France. They had been in use for upwards of eighteen months; in some cases they had run for two months without any oil being applied; but the ordinary practice was to introduce about a wine-glass full of oil to each box once a week.

April 19.—The paper read was "*Description of the Entrance, Entrance Lock, and Jetty Walls, with the Wrought-iron Gates and Caisson, &c., of the Victoria (London) Docks.*" By W. J. KINGSBURY, A. Inst. C.E.

This paper had chiefly for its object to bring forward an account of some special works, which from their magnitude and peculiarity presented novelty and interest; it was therefore rather a contribution to the history of the Victoria Docks than an attempt to convey a complete idea of that undertaking.

The Victoria (London) Docks were briefly described as being situated in that part of the Plaistow Marshes, Essex, which, projecting forward towards the south-east, was bounded on three sides by the river Thames, which there formed a loop or bend, extending from Bugsby's Reach, just below Blackwall, to Galleon's Reach, below Woolwich.

The entire area comprised within the dock was shown to be about 200 acres, of which one half, or 100 acres, was water space. This consisted of the entrance, with its lock,—the tidal chamber of 16 acres, and the main dock of 74 acres. In general terms, the basin and dock together were 4050 feet in length and 1050 feet in width at the level of high-water mark.

In addition to the quay room afforded by the sides of the basin and dock, four jetties, each 581 feet long and 140 feet wide, were projected from the north side into the dock; these jetties, with the sides of the dock and of the basin, provided a length of three miles of quay space.

The general surface of the original marsh land was about 8 ft. 6 in. below Trinity high-water mark; and the tidal water of the Thames was always excluded by an embankment, which was maintained at a height of 5 feet above T. H. W. M.; that level was therefore adopted for the top of the copings of the entrance and of the lock walls. Taking T. H. W. M. as the datum, the bottom of the docks was stated to be 24 feet below datum,—the depth on the upper gate cill 25 ft. 6 in., and on the lower gate cill 28 feet, which latter depth was maintained throughout the entrance from the river; and as the mean fall of tide was 18 feet, there was a depth on the lower gate cill of 10 feet, and on the upper gate cill of 7 ft. 6 in. at Trinity low-water mark.

The subsoil was described as consisting of beds of yellow and blue clays, of varying thickness, and of a total depth of 5 or 6 feet, then a depth of from 5 to 12 feet of peat, and then a good bed of gravel overlying the London clay, which was found throughout the length of the lock at a nearly uniform depth of 37 feet below T. H. W. M.; and on this foundation, at a depth of 37 ft. 6 in., both the upper and the lower gate platforms were laid.

The sides of the entrance of the channel leading to the tidal basin and of the lock, were composed of concrete walls, faced with cast-iron piles and plates. The main piles were driven at intervals of 7 ft. 1 in. from centre to centre, the intervening space being filled by cast-iron plates, whose lower edge rested on the upper end of four cast-iron sheeting piles, which with them occupied the entire space between each pair of the main piles. These latter were each in two lengths; the lower 25 feet, and the upper 12 ft. 8 in., and the metal was about 2 inches thick, cast in a trough form, 18 inches in width. The sheeting piles were each 20 feet long, of similar form; the three interspacing iron plates for every bay were each 5 ft. 11 in. wide, and 5 feet deep, cast with back feathers to give the necessary strength, and provided with a top flange to carry the stone coping of the wharf. In the rear of each main pile, and at a distance of 18 feet from it, a timber land-tie, 20 feet long, was driven to a proper depth, and secured to the iron piles by two eyebolts and nuts, and behind them a wall of concrete was filled in, varying in thickness from 12 feet to 6 feet at the top, where the stone coping of the wharf was laid. The main piles were driven 5 feet into the ground, and the sheeting piles about 2 ft. 6 in. into the same stratum. Clay puddle and concrete were also used to render the lock chambers perfectly sound.

As the London clay was met with at a depth of 37 feet below T. H. W. M., advantage was taken of the circumstance to dispense with an invert at the gate platforms, by substituting ordinary brickwork. This was accomplished by laying open, down to the clay, the necessary areas for the upper and lower platforms—surrounding them by single rows of elm sheet piling 16 feet long and 9 inches thick, driven close, to a depth of about 7 feet into the solid clay; these were secured by walings, and within the spaces so secured the brickwork of the platform was laid. In this mode of construction it was essential to take out all the gravel; to lay the bricks directly upon the clay, and to use close piling, in order to prevent the possibility of any water getting beneath and blowing up the brickwork. Upon these platforms the side walls, which were 20 feet in thickness where they joined the concrete walls, were carried up in brickwork.

The hollow quoins for the gates, the external arris of the gate recess, the caisson quoins and cill, and the copings and bedstones for the anchors, which constituted the bulk of the stone work employed, were of a compact sandstone, called Duke's Quarry stone. The bricks used were almost all made from clay excavated from the site of the docks, laid in mortar composed of Halling lime and clean sharp sand; the latter also from the excavation, whence the gravel and sand used in the concrete also proceeded; so that these essential ingredients for the structure were found on the spot.

The paper then described the sluices and the pipes for filling and emptying the lock, with the precautions for examination and repair, and in general it appeared that every facility was provided for access to every part liable to wear and tear or injury, and for remedying all defects.

The cost of the piled and concrete wall of the lock chamber was stated to be £17. 0*s.* 7*d.* per foot run, and that of the entrance to be £19. 5*s.* 10*d.* per foot run, or £51 and £58 per yard run respectively. The price of the cast-iron at the time of the construction of the docks was £6 per ton; and the weight of iron averaged about 1¼ ton per foot lineal of the wall.

A description was then given of the three pair of lock gates—viz., the lower and upper gates of the entrance lock, and the inner gates separating the tidal basin from the main dock. All these were constructed of wrought-iron, nearly alike in dimensions and general arrangements. The objections to the use of timber were enumerated,—the introduction of cast-iron ribs, with timber planking, was noticed; and the gradual employment of wrought-iron for the frame, the plating, the diaphragms, and all the parts except the heel and mitre posts, was described. It was shown, that on account of the large dimensions of these gates, and more particularly their amount of curvature, timber would have been inapplicable; the lower gates being 80 feet in the span by 31 feet in height, with a versed sine of 20 feet, or one-fourth of the span. The form of the outer curve of the gates was an arc of a circle, having a radius of 50 feet; the distance between the skins, at the heel and mitre posts, was 2 feet, and at a point midway between them 3 feet, the inner boundary being two arcs of circles struck from centres 9 ft. 5½ in. apart, with a radius of 59 ft. 9½ in. There were fourteen horizontal diaphragms in each lower gate, the distances between them varying from 1 ft. 11 in. at the bottom, to 3 feet at the top. Beneath the bottom plate, which was ¾ inch thick, a piece of timber to meet the shutting cill was fixed by bracket pieces. The horizontal diaphragms generally were ½ inch thick, and were attached to the skins by T and angle irons. There were also two vertical dia-

Digitized by Google

phragms passing continuously from top to bottom, and dividing each gate into three equal parts. These tended to prevent twisting, and added strength to the structure. The outside plating varied in thickness, according to the strain to which it was subjected, from ⅜ inch at the bottom to ⅝ inch at the top. The plates were disposed with their lengths vertically, and all the joints were provided with strips on the outside and on the inside, to render the structure watertight.

The heel and mitre posts were of green-heart timber, and were firmly attached by angle irons and bolts to the gates. The chain attachments were made to draw upon both skins and upon the entire frame of each gate, and to be accessible at low water. The gates were opened and closed by Armstrong's hydraulic machinery.

The peculiar arrangements for the moveable handrails of such curved gates were then described; and it was shown, that by the use of swivel sockets the curved rail could be made to shut down quite close, to permit the passage of the towing ropes.

The pivots and foundations were then described, as were the shutting cills, with the means of securing them, the roller paths, and the rollers, the latter demanding peculiar arrangements, on account of the curved form of the gates and their great weight. They were so arranged as to be easily accessible outside the gate, and by releasing a nut the column which fitted into a recess in the upper part of the roller-frame could be removed, and the roller could be drawn up by chains in the guides, be examined and repaired if necessary, and be restored to its place, without disturbing the gates.

The large anchors were also fully described, as were the modes of securing them.

The upper and inner gates were stated to be somewhat lighter than the lower and outer gates, the material was thinner, and there were fewer horizontal diaphragms; in other respects all the gates were nearly identical. The inner gates were not worked by hydraulic power, and the sluicing was done directly through four apertures in each of the gates themselves, instead of through the side walls.

The weight of metal in the gates was—

The ancient river bank, which was about 5 feet above T. H. W. M., and protected the marsh from the overflowing of the river into the low district, formed a natural dam, behind which the inner works of the lock chamber, the brickwork of the gate openings, and the other operations were carried on, and outside of which a considerable portion of the piling and the concrete walling was executed. But in order to effect the junction of the two portions, and to complete the entrance works, it was necessary to remove a large quantity of material by barrow, and then to resort to dredging below low-water mark. To admit of this being done simultaneously with the other works of the dock, it was essential to provide the means of keeping the water out of the dock whilst the river bank was broken through and carried away. A coffer-dam would have been expensive and tedious; recourse was therefore had to a caisson, which was constructed of wrought-iron plates, and from its great size and the peculiar mode of using it the description became very interesting. The ordinary form of a caisson was well known to be something like that of a ship, with a raking stem and stern, and fitting into grooves in the side-walls, whilst the keel applied itself close down against a shutting cill.

The new caisson was built of a rectangular form in its side elevation, the heel-posts being vertical and shaped like those of the gates, so as to fit into a hollow quoin, as into a kind of rebate. In plan it was similar to one leaf of the gates, being 3 feet wide in the middle and 2 feet at each end, and it was large enough to extend across the span of 80 feet between the lock walls; its curvature was not great, the rise or versed sine being 8 feet, the outer and inner curves being struck with radii of 94 ft. 8 in. and 104 feet respectively. The height of the caisson was 31 feet, and there were five horizontal close diaphragms in that height, including the bottom and top plates. It was thus divided into four spaces, the lowest of which was 4 ft. 1 in. high, the second was 9 ft. 2 in. the third 10 feet, and the fourth or upper space, 7 ft. 9 in. There were also two vertical diaphragms from the bottom to the top. The position of the lower horizontal diaphragm was designedly fixed, so that the internal capacity of the bottom space should be equal to 25 tons of water. There was a bottom lining piece of Memel timber to meet the shutting cill. There were also two rectangular sluices, one opening through the bottom lower compartment, by which the water could be admitted to fill the dock; and another of small area on the concave side, opening into the lower compartment, by which it could be filled when required. A three-throw pump, with gearing for emptying the caisson, was fixed on the top.

The hollow quoins for the caisson were built of Duke's Quarry stone, and were placed in the walls where they began to rake back from the perpendicular to meet the batter of the piling.

In using the caisson, its total weight being about 90 tons, if the water-space was pumped out it would float with the convex side downwards, nearly in a horizontal position. On the small sluice being opened, the water entered the bottom compartment, and caused the caisson to tilt gradually into a vertical position, during which time it was drawn towards its position between the quoins and the heel-posts fitted into them. Thus, with a caisson of this form and construction, no greater depth of water than just enough to float it was required to get it out of its place; and as soon as it was free from the quoins it could be turned on its back, so as to present very little surface to the wind, and in that position it was perfectly manageable.

The construction of the jetties, which had been already incidently noticed with regard to their position and general dimensions, was then described. The general form was that of a parallelogram, 497 feet long and 140 feet wide, terminated by a pointed end, the sides of which were 109 ft. 6 in. long, and met at an angle of 80°, making the extreme length 581 feet. The height of the quay was 6 feet to 9 feet above T. H. W. M., according to the situation of the jetty in the dock.

On the jetty a warehouse was built, 500 feet long and 80 feet wide, consisting of vaults and two floors, of nearly an acre in extent each. The outside space of 30 feet on each side to the edge of the quay was appropriated to railways and the temporary storeage of goods. Facilities for discharging and arranging goods were provided by hydraulic cranes; one capable of lifting 5 tons with a range of 31 feet being placed at the pointed end, and eight others, arranged in pairs, sweeping outwards from 21 feet to 23 feet, and capable of lifting 2 tons each, were placed at intervals on the sides of the warehouse. There were also turntables and sidings, for the purpose of collecting and distributing the waggons on the main line of railway leading from the docks.

The side walls were described as a combination of cast-iron piles, vertical brick inverts, and concrete, with a backing of clay.

The piles, which were T shaped in section, and 35 feet long, weighed about 1¾ ton each. They were driven to a depth of 28 feet below T. H. W. M., at intervals of 7 feet. Between them the brick inverts, which were 14 inches thick, were filled in; and behind this the concrete was carried for an average thickness of 3 ft. 6 in. The piles were connected to each other across the jetty by two tiers of tie-bars, 2 inches in diameter, and 12 feet apart; the upper one being placed 5 feet below the heads of the piles, and by means of them the piles were secured from being forced outwards, and could be adjusted in line. The bottom of the wall was commenced 1 foot below the bottom of the dock, and the wall itself was considerably strengthened at the pointed end, to enable it to bear the blows to which it was exposed, and as a foundation for the 5-ton crane. The top was finished off with a cast-iron capping and wood cill secured to the heads of the piles; and the upper surface of the jetty was ballasted, and some portions planked. As a precaution, the angle formed by the upright face with the floor of the dock was filled to some height with clay puddle, to prevent the passage of water under the wall.

The total cost of each jetty, exclusive of the warehouse and cranes, was £12,000, or £10 per foot run of the quay.

It was noticed that an incident which at first threw some doubt on the capability of the walls to resist the passage of water, was afterwards satisfactorily accounted for. It was explained that the floor of the vaults under the warehouses was about 2 feet 6 in. above the marsh level, and 6 feet below that of the water in the dock at T. H. W. M. When the water was first admitted it appeared in the vaults, and it was found necessary to remove it by means of drains. This, which was supposed at first to result from leakage either through or under the walls, was soon found from its containing iron to be water from the gravel, which in this district rose to within a short distance of the surface, and in this case gained access to the vaults by means of the concrete walls of the warehouse. The discharge from the drains was now very slight; the diminution being attributable to the consolidation of the ground against the walls, and to the silting up of the porous materials, by the rusty deposit found in the water. It was remarked in corroboration of this explanation, that quite recently the discharge from one jetty entirely ceased during the time that the level of the water in the gravel was kept down by pumping to get in the foundations of a new warehouse in the immediate vicinity, but was re-established shortly after the pumping was discontinued.

The casualties which occurred during the construction of the dock were fully described; these were comparatively few for a work of such importance.

The first, which was a fracture of the cast-iron shutting cill, arose from the subsidence of the ground under the heavy side walls being greater than that of the brick platform to which the shutting cill was bolted down. The side walls subsided about 1¼ inch, and in consequence the cill was cracked near the centre. The defect was soon discovered and as speedily remedied, by bolting a plate of wrought-iron on the back of the cill. This accident pointed out the importance of allowing the side walls to settle before the holding-down bolts of the cill were finally tightened.

The next casualty occurred in the lock-chamber, where, without any premonitory symptoms of weakness, and almost simultaneously, both sides of the chamber between the upper and lower gates moved bodily forward,

Digitized by Google

pushing up the thick puddle towards the centre, bending and breaking the tie-bars behind, and dragging the tie-piles forward, fracturing several of them, whilst however the brick side walls of the gate platforms remained entirely uninjured. Very energetic measures were adopted for reinstating the walls. The old concrete was cleared away, the iron piling was driven 10 feet lower than previously, the sheet piles entering 5 feet into the clay; in which a solid concrete wall was commenced at a depth of about 5 feet, and was carried up for a height of 18 feet, with a thickness also of 18 feet, above which it was reduced to 10 feet in thickness, with counterforts projecting 6 feet, with a breadth of 6 feet, and at intervals of 10 feet, nearly to the top of the piles. On this mass of concrete a brick wall was built, 10 feet high, averaging 4 ft. 6 in. in thickness, with counterforts 3 feet square and at intervals corresponding with those below. The piles were secured to the concrete walls by means of iron rods passing through them to cast-iron plates, to which they were screwed up tight at the back. The clay puddle was removed from the bottom, and was replaced by a mass of concrete, with a top layer of Portland cement concrete 6 inches in thickness. The damage was completely repaired in three months, and no signs of weakness were subsequently perceived. This casualty was accounted for by the previous draining of the ground all around, due to the constant pumping during the progress of the works; and on the cessation of this process the water rising behind the walls occasioned additional pressure, which forced the sides inwards. That the failure resulted from this cause was demonstrated by the fact of the movement of the two sides being nearly simultaneous.

The next casualty which occurred was the fracture of two of the pivot castings of the lock gates. This was shown to have arisen from the binding of the brass socket upon the iron pivot, so that the pressure, instead of being distributed over the whole area of the step, was restricted to a comparatively small annular portion; thus the brass "seized" or adhered to the pivot to such an extent, that the gate, instead of working upon the pivot, turned upon the brass, and burst the sides of the box in the effort to free itself. At this period also the gates were leaky, in consequence of some of the joints not being tight, and the weight upon the pivot being much increased. The mischief was aggravated by hydraulic power being employed to open and shut the gates, and thus the undue resistance was not so soon perceived as if capstans worked by manual labour had been employed for a short time after the completion of the gates. This course was recommended as a prudent precaution in similar cases. The cause of the casualty being ascertained, the remedy was easy, and was speedily applied.

The last casualty was the splitting of the roller path, which was a direct and intelligible result of the previously mentioned leakage having rendered the gates so much heavier than the casting had been intended to bear. This was remedied by rendering the gates water-tight; and in putting down a new path the surface for the roller was made 7 inches wide instead of 4 inches, and no difficulty has since been experienced. These casualties were very fully detailed, as being perhaps more useful than any other part of the paper.

The latter portion of the paper was on some advantages of the form adopted for the Victoria (London) Dock Gates, with respect to economy of material and general arrangement.

The term cylindrical, or gates of continuous curvature, was adopted to distinguish them from those formed like a gothic arch, and was employed to denote that the outer or convex curves constituting both leaves were struck from one centre, or formed portions of one and the same circle. The inner boundary was formed in the same way, or not differing materially from it.

Before proceeding to compare this form of gate with that of straight gates meeting at an angle, it was stated that no advantage was claimed for the former in respect to the amount or direction of the strain brought on the lock walls, but in regard to the section of the gate itself, even in ordinary cases, there was believed to be considerable superiority.

A few preliminary remarks were then made on the strains to which these structures were exposed; that in the cylindrical gate a compressive strain was induced by the pressure of the water, which was uniform on every radial section in the same horizontal plane (though of course varying with the depth); while in the straight gates meeting at an angle there were two strains, first, a transverse strain caused by the pressure of the water, and similar to that on a girder uniformly loaded, and, secondly, a compressive strain, arising from the pressure of the other leaf on its extremity. The compressive strain on any horizontal section of the cylindrical gate was stated to be equal to the pressure on the unit of surface multiplied by the radius of curvature, as shown by Prof. Barlow (*vide* Trans. Inst. C. E. vol. i. p. 133). The important distinction between the two kinds of strain to which straight gates were exposed was pointed out by Mr. P. W. Barlow, M. Inst. C. E., in his paper on Lock Gates, at page 67 in the volume already cited.

Some examples were then given, showing that this compressive strain in the straight gate varied very considerably, according to the ratio of the height or versed sine to the span; and consequently the importance of providing sectional area to meet this, as well as the strain induced by the direct action of the water on the leaf itself. With regard to the distribution of this strain in the two skins, the problem was not capable of accurate solution, in consequence of several practical modifying circumstances, but it was thought sufficient for the purpose of comparison to assume the equal distribution, especially as that view was in favour of the straight gate.

Some examples were then given in detail, for the purpose of instituting a comparison between the weights of gates required for spanning the same opening with the same rise or versed sine when made in the cylindrical form, and also with straight leaves meeting at an angle. The results were shown in the following table:—

Ratio rise to span.	Vertical angle.	Transv. strain in centre.	Compres. strain due to op. leaf.	Straight Gate.		Cylindrical Gate.	
				Mean section.	Quantity of material.	Mean section.	Quantity of material.
1 to 10	157° 22′	69·32	102·0	29·6	1207	26·0	1066
9	154° 58′	69·94	92·3	28·4	1164	23·6	975
8	151° 26′	70·82	82·5	27·25	1123	21·25	885
7	148° 10′	72·08	72·9	26·25	1092	19·0	801
6	143° 8′	74·06	63·3	25·3	1069	16·66	715
5	136° 24′	77·32	53·8	24·8	1011	14·5	640
4	126° 52′	83·33	44·7	24·9	1117	12·5	580
3	112° 38′	96·27	36·0	26·0	1250	10·8	552
2·66	106° 16′	104·15	33·3	28·0	1400	10·4	558

Some remarks were then made on several other practical advantages arising from the cylindrical form, in utilising sectional area, avoiding to a great extent unequal thicknesses of plates, and rendering the operation of caulking more easy and efficient. At the same time certain objections were mentioned, and it was stated that additional cost would be incurred in the manufacture of the cylindrical gates; but it was thought notwithstanding that the following propositions were fairly established:—

1. That a lock gate of the cylindrical form could be made with about half the quantity of material required for a straight gate.
2. That with the same ratio of rise to span, a saving of from 11½ to 55 per cent. might be effected in the skins alone, and that a further saving might be made in the horizontal diaphragm.
3. That by this mode of construction great facilities were afforded for rendering the gates watertight, and greater certainty be attained in accomplishing this very desirable object.

GEORGE P. BIDDER, Esq., V.P., in the chair.

May 3.—The paper read was "*On the Tyne Docks at South Shields, and on the Mode adopted for Shipping Coals.*" By T. E. HARRISON, M. Inst. C.E.

These docks had been constructed on the banks of the river Tyne, at the upper end of South Shields, on a large area called Jarrow Slake, which was covered with water at spring tides to a depth of from 5 feet to 8 feet. The area so covered amounted to about 350 acres, and of this quantity 179 acres were now inclosed. The area of water in the dock as executed was 50 acres, the depth of water being 24 ft. 6 in. at an average spring tide. The entrance basin was 9¼ acres in extent, with a depth of water of 25 feet for a width of 200 feet in the centre of the channel, gradually shoaling to the sides. One entrance had a width of 80 feet, and there was a lock 300 feet in length and 100 feet in width, with gates 60 feet in width; the cills in each case were laid 24 ft. 6 in. below high water of average spring tides—such spring tides having a lift of 14 ft. 6 in.

The total quantity of excavation in the docks was 1,783,452 cubic yards, and in forming the standage ground 281,305 cubic yards. The total quantity of masonry of all descriptions was 2,900,000 cubic feet. The cost up to the date of the opening for public traffic was £440,476. This sum included all the standage and railway approaches, the shipping jetties, the purchase of land, and all the dock-works, but it excluded parliamentary and other charges not engineering. The works were under the immediate superintendence of Mr. Robert Hodgson, as resident engineer; and the contract for their execution was let to Mr. James Gow.

The first point of engineering interest was the nature of the foundations. A series of careful borings showed, that though there was in places a strong stony clay resting on the coal measures, yet this clay was very partial, dipping suddenly away. Within a few yards of the clay-bed, borings were made to a depth in some places of 70 feet and upwards, through the mud or slake deposit, without getting a bottom; showing that not only the clay, but the coal measures, were gone. The original level of the ground was ascertained to be 10 feet below the lowest ebb of a spring tide at the present time, confirming the opinion that a general depression of the east coast had taken place.

The first operation in the construction of the works was to form a culvert, 5 feet in diameter, round the head of the dock area, to receive and carry off the upland waters. Dams were then formed of the materials from the excavations, consisting partly of clay and partly of slake, and after their completion the water was run off by sluices. Shortly after the first course of masonry of the foundations was laid for the north or 60-feet lock, the floor was observed to rise very regularly, about 3 inches

Digitized by Google

in the centre. A bore hole was then put down, when a strong feeder of water came away. The hole was therefore kept open during the progress of the works, and similar holes were made in other places. The flooring of the lock went back partially after the hole had been opened several days; and it was brought nearly to its original level by being weighted with stone.

In building a quay wall opposite the Jarrow Chemical Works, it was found that the slake would not bear the weight of the bank behind it, unless at a slope of 1 to 5. As so flat a slope was inadmissible, the plan adopted for overcoming the difficulty was by weighting the top with gravel, by which the toe of the slope was forced out. It was not until 150,000 tons of gravel had been deposited that the whole came to a state of rest. The slope was at present 1¼ to 1. It was pitched with stone, and rested at the bottom on a strong row of piles.

With a view of testing practically the sustaining power of the mud or slake, a bed of concrete 10 feet square was gradually loaded with iron, to the extent of 7 cwt. per superficial foot, without any settlement taking place; but as soon as that weight was exceeded the whole began to sink. The foundations of the timber jetties for the shipment of coals were therefore laid on a wide-spread base of concrete, with timber cill-pieces; care being taken not to exceed a weight of 5 cwt. per superficial foot. It was satisfactory to be able to state that there had not been the slightest appearance of settlement.

Immediately below the entrance to the tidal basin there was a canch of hard clay running out into the river. This had been entirely removed by dredging, and the flood and ebb tide now took their course as nearly as possible over the same channel, guided by the concave river wall. The latter was entirely constructed of creosoted timber, by means of one of Nasmyth's steam pile engines. A description was then given of this machine, which was so arranged that it formed its own roadway throughout; and it was remarked, that where there was a large amount of straightforward piling, or in cases of difficult driving, this machine was without an equal.

The dock gates were generally on the same plan as those of the Victoria (London) Docks. The only difference was that the Tyne Dock gates were curved both on plan and in section, the pivot of the heel-post being raised 3 ft. 6 in. above the level of the cill. There was thus less danger of anything lodging behind the heel-post, and the invert of the lock was carried right through from the end of the pointing cill. It involved however some large and rather intricate masonry, and necessitated great accuracy in fitting the doubly-curved wood cills to the doubly-curved masonry; but this had been successfully accomplished, and the cills were perfectly tight. One of the advantages in the use of wrought-iron for dock gates was that from their flotation the weight on the rollers might be adjusted at pleasure. The sluices were all made to work with brass against brass. The dock gates and sluices were arranged to be worked either by hand or by hydraulic power, the machinery for the purpose having been furnished by Sir W. G. Armstrong and Co.

The primary object of the construction of the Tyne Docks was to provide accommodation for the shipment of the large quantity of coals brought to South Shields, from the coal-fields of Durham and Northumberland, by the extensive system of railways belonging to the North Eastern Railway Company. The coal trade of the northern coal-fields had been gradually increasing for many years past; and in 1858 the quantity shipped at South Shields amounted to 1,203,524 tons, although the facilities were so limited that it was necessary to work night and day throughout the whole year. This was now wholly shipped at the Tyne Docks, and the work was generally done in fifteen hours.

A brief account was then given of the different methods of shipping coals used at the northern coal ports during the last forty-seven years. The system of "keels" was first described; and it was stated that it still existed to a limited extent both on the river Wear and on the river Tyne, in the case of those collieries not having direct railway communication to a place of shipment. Where the vessels could reach the shipping places, as at the Wall's End Colliery, the mode of shipment was by spouts, in general principle the same as those adopted at the Tyne Docks; but without for a long time any arrangement for allowing for the difference in the level of the tide and in the size of the vessel. The first innovation on the "spout" system took place in 1812, when a coal-drop was erected at Pelaw Main Spout, on the river Tyne, by Mr. B. Thompson, further improved by him in 1813, and since generally followed, with various modifications. The principle of all these drops was, that the loaded waggon in its descent raised a counterbalance weight; and when the coals were let out of the waggon, the counterbalance weight brought the waggon back to its previous position. The system of tubs fitted into "keels" in order to avoid the breakage of the coal was then alluded to, and the machinery by which they were transferred to the vessel was briefly described.

It was stated that after mature deliberation and careful examination of all the different plans, it was decided to adopt in the Tyne docks the system of shipping by spouts. The angle of inclination of the spouts was 50°, that having been found by experiment to be the angle at which coals would slide on smooth iron plates without rolling. In order to allow for the varying level of the ship's deck, which it was shown might amount under certain circumstances to 20 feet, arrangements were made to deliver the coals at four different levels. The coals were directed into any one of four divisions by the opening or shutting of trap doors, turning on hinges, and well balanced, so as to be easily moved. The spout was also raised or lowered in guides, and was operated by winches, the men standing on the level at which they worked when shipping coals. Traps were also provided for regulating the descent of the coals into the ship. In some cases the spouts were made to slide in a frame turning on a pivot, the object being to give a greater range into the ship's hold, particularly with screw colliers, and thus avoid the necessity of moving the ship. In practice the plan was to keep the spout nearly full, merely letting the coals slide sufficiently down to allow of the next waggon being teamed; so that although in the first filling of the spout, or on altering the level of the spout, the coal had a few feet to fall, yet this only applied to a small quantity of coal. Afterwards the whole mass slowly descended, and no further breakage took place.

Two jetties, on which there were twenty shipping places, were already at work. The shipping places were 100 feet apart from centre to centre, and were so arranged that the vessels overlapped each other. Arrangements were made so that the number of shipping places could be increased to fifty, as the trade required. In laying out the ground the saving of manual labour had been a primary consideration, and gravity had been called into operation to the utmost possible extent. The sidings into which the locomotive engines brought the waggons were on an inclination of 1 in 132. From these sidings the waggons were sorted by gravity into one or other of fourteen additional sidings, also on an inclination of 1 in 132, but at the curves and switches of 1 in 66. This sorting was effected by one man and one boy (who attended to the switches) for each jetty. When the waggons were wanted for shipment, they were brought out of the sidings, and descended by gravity, converging to one point, where there was a weighing machine; when passing over this machine at a rate not exceeding two miles an hour, the weights were easily taken. The lines then branched out again to the different spouts, the waggons being directed into their proper roads by switches, the working of which was attended to by one boy. There was a considerable amount of standage provided for each spout, and the length of single line of rails for each jetty was six miles. The standage was on inclinations varying from 1 in 32 to 1 in 100. Where the waggons descended from this standage to the spouts, the inclination varied from 1 in 20 to 1 in 87. The empty waggons were returned along two lines, one on each side of the jetty, having an inclination of 1 in 100. The impetus of the loaded waggons in descending carried them up this gradient, to or beyond the places where they were to be emptied, and when emptied gravity took them away. Experience had shown that twelve chaldron waggons, or six 8-ton waggons, might be taken down at a time. They were all run past the hopper, then dropped back by gravity, and were emptied three or two at a time, as they passed over the spout, without being uncoupled. Great expedition resulted from this arrangement; and on the day of the opening a screw steamer entered the docks, received on board 420 tons of coal in fifty-five minutes, and immediately went to sea.

In order to ship the quantity of coals now transferred to and being shipped in the Tyne Docks, there were employed last year at South Shields thirty-four horses and four pilot engines, and the work was carried on throughout the whole twenty-four hours. Under the present arrangement not a single horse was employed, and only two pilot engines, and the work was done generally in fifteen hours. At present there was rather a deficiency of standage for light waggons, but this was in course of remedy, and when completed no engine would be necessary. The cost of labour for carrying the coal along the jetty, a distance of 1050 yards, for the shipment, and for returning the empty waggons to the point where the engine took them up, was about seven-sixteenths of a penny per ton.

SUBMARINE TELEGRAPHS.

The great cost of gutta-percha—about 2*s.* 6*d.* per lb.—coupled with its now well-known deficiencies as an insulator, has roused the chemical world into efforts to discover some substitute which, while possessing all non-electrical and mechanical essentials, will at the same time relieve telegraph companies from the immense outlay now required for coating their wires with gutta-percha. Several experiments have been made with this object. Messrs. Silver and Co. have been foremost among the experimentalists, but instead of devising a new substance, resolved to trust the well-known properties of india-rubber, and with this view have coated several miles of wire with a double layer of that material laid on in spiral folds or bands, with their edges closely joined so as to be perfectly impervious to water at any pressure. Even at the present high price of india-rubber, wires can be thus coated at very little more than half the price charged for gutta-percha. The cost, however, is one of the least advantages of the material. India-rubber is almost as incompressible as water, and compared with gutta-percha requires a very high degree of heat to melt it, boiling water having no effect upon it whatever. Some lengths of the wire thus coated at Messrs. Silver's works have been

Digitized by Google

subjected in a hydraulic machine, for a considerable time, to a pressure of 7½ tons on the circular inch, and when tested, while still exposed to this pressure, the most sensitive of Mr. Henley's galvanometers showed the insulation perfect. An attempt to apply a higher rate of pressure than this terminated in the bursting of the hydraulic cylinder. When it is recollected that 5 tons pressure to the square inch crushes granite, it will be seen that a more complete test of the value of india-rubber as an insulator to resist pressure could hardly have been devised. The importance of its possessing this quality is far greater than would at first sight be supposed. A pressure of 7½ tons to the inch is equal to the pressure caused by the weight of water at a depth of eight miles. The greatest depth at which the Atlantic cable was submerged was three miles, and the weight of this mass of water upon the rope at the bottom of the sea was about 2½ tons. Gutta-percha at such a pressure is reduced to less than half its bulk. To this apparently insignificant fact it is possibly owing that the cable is now useless, for it follows, that when the core of the rope shrank to half its original diameter the outside wires stretched in proportion, while the gutta-percha could not but tear under the strain, and leave the conductor exposed in many places. The advantage, therefore, of india-rubber over gutta-percha in this respect is apparent, since it exactly reverses the unfavourable conditions of the latter, being incompressible and highly elastic. During the course of the experiments a considerable length of wire insulated with two coats of india-rubber was immersed in a large boiler of boiling water. Though the external part of the covering was boiled almost white, the insulation remained perfect. A similar length of wire coated with gutta-percha of the same thickness as the india-rubber was, of course, destroyed as a non-conductor immediately on its immersion, as gutta-percha melts easily at 100 degrees. It is true that submarine cables when laid are not required to encounter a heat of 212 degrees, but it is well known that while in process of manufacture, and especially when packed in ships' holds for the purpose of being submerged, they are often exposed to an amount of heat to which gutta-percha yields. This melting at a low temperature, together with the wire being badly centred at the Gutta Percha Company's Works, was a source of incessant anxiety to those on board the Agamemnon and Niagara during the expedition of last summer. The deck coils, from being exposed to the sun, were more liable than others to this danger, and some portions of them had to be cut out in consequence of the copper wire having pushed through the soft gutta-percha. On both these important points, therefore, the introduction of india-rubber would be of immense benefit, and it is believed that if it were clearly shown that the supply of material might be depended on, and the rate at which the wires could be covered would be equal to the demand, it would soon entirely supersede gutta-percha as a means of insulation. Experiments are also being carried out by another firm for the purpose of devising an insulator from a combination of india-rubber and shellac. These tests, however, are not sufficiently advanced to be made public, though the results up to the present give promise of success. When such efforts are making on all sides, it seems improbable that the use of a faulty and expensive insulator like gutta-percha will be much longer continued.—*Times.*

NEW CHURCH OF ALL SAINTS, MARGARET STREET.

THIS magnificent structure, the completion of which was, for want of funds, delayed for several years, has at last been finished, and was consecrated and opened on Saturday the 28th inst.

The site is a square of about 110 feet, occupied by the church and two houses; the church and houses surround on three sides a court yard which is open on the fourth side to the street. The two blocks of houses are connected by a low brick and stone screen with an effective archway in centre. The wall is surmounted by an arcade of open ironwork. The houses and screen form the entire elevation to the line of street. The church, situated at the back of these houses, occupies the whole length and remaining width of the ground behind them, from east to west, and parallel with the street. The church consists of nave and chancel, with aisles (north and south) to both nave and chancel, and of tower and vestry. The tower is at the west end of the south aisle and is embedded in its lower stage between the western house and the south aisle. The lower story serves as the baptistery. The whole of the church is carried on vaults of massive brickwork, upon the arches of which the concrete floor of the church is laid. There are no windows in the north wall of the church nor east end of chancel; owing to the confined nature of the site they could not be obtained, which has called forth peculiar treatment of the wall spaces. The architect has admirably turned the opportunity to account, and produced an effect most pleasing and novel.

The materials of the walls of the buildings generally are of red and black bricks and stone; internally, red and black bricks of a superior kind (made by Minton, of Stoke, Staffordshire) are freely used; Caen stone, marbles, and alabaster, in bands and mosaic, granite and other select stones, are used constructionally. The stonework internally is to a great extent decorated with inlaid patterns in dark cements. The marbles are chiefly of English production; the alabaster is from Derbyshire. The nave arches are of Caen stone, boldly moulded, supported by polished Peterhead granite clustered columns standing on black marble plinths. The capitals are of alabaster, carved in a masterly style, and of excellent design. A fine well moulded equilateral arch of alabaster, springing from a detached marble column on each side, divides the nave and chancel. The chancel is in its length divided into two bays, and is vaulted with chalk and alabaster; its western bays are each occupied by a traceried arch, opening into the chancel aisles. The heads of the arches contain tracery supported by circular columns of Cornish Serpentine with carved caps of statuary marble. The lower portion of the opening is filled up with an elegant brass and iron screen and gates. The eastern bays together with the east wall are arcaded in three heights; the whole arcading and wall space, sculptured cornices, and ribs of vaulting being entirely of alabaster, interspersed with Caen stone inlaid. The upper portion of north and south walls is occupied by tracery windows, filling up the triangular space formed by vaulting. The vaulting is enriched with inlays, gilding, and characteristic devices in colour. The arcade of east wall contains frescoes, by Dyce, representing in its two middle compartments, the Virgin and Infant Saviour, and the Crucifixion; six niches on each side contain the Apostles; surmounting them, and occupying the triangular upper space of wall, is a representation of Our Lord enthroned, surrounded by saints and emblamatic figures. All the figures are well designed and beautifully painted. The arcading of side walls is filled in with diapering in gold and colour. The nave and aisle roofs are of timber framing, with coloured enrichment. The rafters are all exposed, and ceiled between. The principals, purlins, and wall plates of nave roof are double, and are connected by rows of quatrefoils. The nave has a well proportioned arcaded clerestory, every fourth space being a blank to be filled with frescoes. Each of the other divisions of the arcade contains a two-light tracery window, from which the light for the interior is principally derived. The north wall of aisle is formed into panels by bands of incised stone, and will eventually be enriched with frescoes. The floor of the nave and aisles is laid with Minton's plain red and black tiles arranged in patterns, and divided longitudinally and diagonally by narrow stone bands; encaustic tiles are introduced at the junctions of the tile bands. The floor of chancel and beneath the tower is laid with various marbles intermixed with encaustic tiles.

A low screen separates the chancel from nave: the body of it is of alabaster, arcaded, panelled, and richly carved; the base, coping, and shafts are of various marbles. Brass gates of good design occupy the centre of the screen. The pulpit and font are of sculptured marbles of various tints. The metal-work in the church consists of brass gates in the chancel screen, and the side screens and gates dividing the chancel from its aisles. These screens are surmounted by rows of gas burners. The oak pyramidal cover of the font is also largely decorated with metal-work, and a brass lectern stands in the middle of the chancel. In the nave brass gas brackets of simple design are attached to the aisle-side of the columns. The metal-work was executed by Potter, from designs by the architect. The church is heated by hot water. The organ (constructed by Hill) is divided into two parts, and stands in the two chancel aisles; the two parts being connected by trackers beneath in the vaults.

The clerestory windows of nave and chancel are fitted with elegant bright-toned stained glass, designed by the architect. The west and south windows contain most unsuitable stained glass by Mr. Gerente, who, we believe, was commissioned by Mr. Hope. The chancel stalls are of oak and walnut, elaborately carved. The altar is of moulded and carved wood, and is surmounted by an alabaster super-altar, enriched with quatrefoils. An elegant metal cross is fixed immediately above it on the east wall.

Digitized by Google

The floor-space of the church is perfectly clear; chairs only will be used by the congregation. The mouldings and proportions of the work generally are bold and large, so as to give to the building an appearance of size which its actual dimensions would fail to impart.

The site was purchased by Mr. Beresford Hope, M.P. Mr. Henry Tritton, of Portland-place, we understand, provided the largest proportion of the building funds. Other subscriptions to it, we believe, have been comparatively small.

This building must not be compared with some of similar character which of late years have been erected by architects who have followed in the path struck out by Mr. Butterfield; for when this building was founded it stood alone as an example of revived principles of Gothic art adapted to modern requirements. It was intended to be truly a town church, built of materials of every-day use, produced in our own locality and country, and exhibiting the advantage of the truthful system of constructive decoration. The style of architecture adopted by Mr. Butterfield is the Early Decorated, in detail partaking of that exhibited by the ancient examples of France and Italy, but treated with considerable freedom and originality. It is but just that the author of this building should be placed in his true position as the pioneer and founder of the new school of Gothic art. Through the unfortunate stoppage of the works for a long period, other structures founded on the same principles were erected in the meantime, but from the similarity of treatment and peculiarities of detail which they possess, we must say that the authors are greatly indebted to the architect of All Saints' Church for their first principles.

ASSOCIATIONS FOR THE PROMOTION OF ART.

By G. F. Mulvaney, R.H.A.*

The author, after stating that he did not intend discussing any of the various phases or principles of art, but rather to draw attention to the condition of art in Ireland,—how it may be promoted, and the latent genius of the country be developed, said—

"It must be admitted that the state of art in Ireland is far from creditable to the country. It cannot be asserted that this is attributable to any deficiency of natural genius, or to any want of industry and zeal on the part of artists themselves. It results mainly, if not solely, from the want of public encouragement,—of that demand which has in all ages and in all countries led to the fullest development of human ingenuity and skill. The most frequent argument raised in defence of such a state of art-abeyance is, that we have not wealth enough for its adequate encouragement. The argument is unfortunately not without weight as regards individual patronage; but given its fullest weight, it is an argument *à fortiori* in favour of the associative principle which does so much for art in more wealthy communities. Perhaps it would be more candid to admit that taste, as a diffused social element—rather than wealth—is wanting. To generate and cultivate this public taste must be the first aim of all who desire to promote art in Ireland, and it is the chief aim of all art associations. Education of artists and of the public by schools and exhibitions are the functions of some; while others seek by the purchase and dissemination of the works of living artists to reward merit and stimulate taste by facilitating the possession of good works of art.

I propose to draw your attention principally to these latter institutions, but I cannot in the interest of the associative principle, especially within these walls, omit to pay my tribute of grateful admiration to the parent association for the promotion of the fine and useful arts in these countries. The Royal Dublin Society, established for the advancement of husbandry and the useful arts, promptly recognised the value of the fine arts in connection with industry. The principle so asserted by the establishment of its schools more than a century past, is now the recognised principle of government schools of design. The Society's schools rapidly acquired an importance not perhaps at first designed. Under the auspices of this Society, those wonderful achievements of ancient art—those marvellous embodiments of perfect form in almost breathing marble, the sculptured gods of classic Greece—became known in this remote island, awoke the artist's spirit to a new sense of beauty, and led rapidly to a new development of power.

Artists as they multiplied naturally sought strength in association; but beyond their influence in education and their efforts to maintain public exhibitions, I do not regard societies of artists as, strictly speaking, associations for the encouragement of art. They are producers, not patrons: they seek to cultivate art,—they are valuable rallying centres of professional union and distinction. It is their duty and their aim to raise the standard of public taste; but they are themselves dependent for existence and success upon an appreciative public. When incorporated by charter or royal sanction on the continent they are subsidised by the state. In these countries they are mainly dependent on the revenue from annual exhibitions: when these are prosperous, as in London and Edinburgh, the royal academies prosper, and acquire influence and power of effecting public good. The Royal Academy of London is perhaps the wealthiest association of artists in the world. It enjoys a revenue of £6000 or £7000 per annum from its exhibitions: and after maintaining its schools and establishment, and devoting much of its funds to charitable support of distressed artists and their families, it has amassed a large fund. The Scottish Academy has from similar sources of success derived a large income, and has made a noble use of it, by accumulating a fund for charitable relief, and the acquisition of a valuable collection of pictures at a cost of upwards of £15,000, which is now deposited in the National Gallery of Scotland. The Royal Hibernian Academy is unhappily, as regards worldly prosperity, but too true a reflex of the want of encouragement of art in the country.

Other associations may be referred to, such as the British and the Royal Irish Institutions, designed to afford objects of study to the young artist, and to cultivate public taste by the exhibition from year to year of works by the ancient masters, the property of private individuals. The latter named institution had but a brief existence, but it has found after the lapse of years a successor in the Irish Institution, established in 1853, with the ultimate aim of the formation of a National Gallery. The building now in course of erection in Leinster Lawn, to which the Dargan Testimonial fund has been devoted, combined with parliamentary grants, is the best evidence of the work done by the Institution, and assures to Ireland its long-desired National Gallery.

From the period however when the Dublin Society established its schools—when Barry and Barrett first won distinction, and carried off their fifty-pound prizes—to the present, the history of art in Ireland, with some fluctuations, has been the same: upspringing genius—well-directed philanthropic efforts to facilitate education—honour and reward to the student—struggles, difficulties, and non-appreciation for the artist. Hence it arose that so many distinguished Irish artists have followed Barry and Barrett to swell the fame of the British school, while many whose natural gifts and educated powers were at least equal to those of the emigrants, have remained at home—forced too often to devote talents calculated for higher development, to the mere drudgery of art.

I am far from undervaluing what has been done for the promotion of art in Ireland by the education of artists, or the cultivation of public taste; on the contrary, I honour those who have persevered through all difficulties in the good cause, and I rejoice that we may regard our educational facilities as being nearly placed on an efficient basis. But what I wish particularly to enforce is, that in point of national economy all those energies are without their proper return, if we do not find means to secure prosperity to the artist as well as education to the student. The developed intellect, skill, and productive power of a country are, even in an economic point of view, amongst its acknowledged elements of wealth. I need not, therefore, dwell on the importance of developing a national school of art—of keeping our gifted men at home, instead of forcing them to bring their talents and wealth-producing powers elsewhere. It will be better to show how this public good can be achieved. Example is better than precept or argument, and fortunately an example is found in the progress of art in Scotland.

Twenty-five years ago, the state of art in Scotland was not dissimilar to its present state in Ireland. There was perhaps more private patronage of art, but the public interest in its progress or demand for its productions was small indeed. The Royal Association for the promotion of Fine Arts in Scotland was established, I believe, in 1834. It was the first effort to introduce into these countries the German system of *kunst-vereine*, or art-unions. It has been signally successful in its operations. In its first year the funds subscribed did not exceed £700 or £800; its

* Paper read before the Royal Dublin Society.

Digitized by Google

average income now is about £5000 per annum. Not only has this association evoked a Scottish school of art, to do which was its first aim by the purchase of resident Scottish artists' works, but it has expanded its operations to the purchase of works of art without reference to the country of their production.

Strong objections were raised to the system of art-unions at the period of their introduction. It was said that they were calculated to interfere with private purchase of works of art, which, as the result of discriminating taste, and the legitimate expression of demand, was morally and economically the true encouragement to art. This objection was strongly urged by artists themselves; but experience has shown that it was not valid, and art-unions so far from diminishing, have considerably stimulated and increased both private and state patronage. I cannot better illustrate the force of these early objections and the power of successful experience in dispelling illusions, than by a short quotation from a speech made by Mr. Harvey, a distinguished member of the Royal Scottish Academy, at a dinner given by the committee and members of the Edinburgh Association in 1846. Mr. Harvey said:—'When the Royal Association for the promotion of art in Scotland was formed, rather more than twenty years ago, I at that time felt it my duty to be one of its resolute opposers, thinking it likely that the purposes of art would be better served by such works as might be produced being purchased by private parties in the usual way, rather than by funds acquired by public subscription, and the subsequent disposal of the paintings by lot. My friend, Mr. Glassford Bell, who was the great promoter of the scheme at the time, kindly said he would meet my opposition by the purchase of my paintings, should I produce anything which the association might consider worthy of buying; and accordingly I had an offer made to me in the ordinary way for one of my works shortly after. This offer, to be consistent, I declined, and I have the painting in my possession still. Since that time, however, I have seen fit to alter my opinion on this subject. In fact, when I call to mind that in, I think, either the second or third year of the Academy's existence, the entire sum received for works of art sold during the period of the annual exhibition was, if my recollection serves me rightly, only thirty-five guineas—one painting having been bought by the present Lord Justice Clerk, then Dean of Faculty, for thirty guineas, and one by some person else for five—it was evident that in this state of things something required to be done one way or another.'

This candid admission on the part of Mr. Harvey speaks volumes for the cause of such associations as we are now considering. In fact, such was the success of the Edinburgh Association, and so much was the demand and love for art increased in Scotland, that in 1842 the Glasgow Art Union was established. The success of this latter institution, at least as to amount of funds, is unparalleled in the brief history of art-unions. Of course the annual amount varies; but in 1856 it exceeded £20,000; and in the last report of the council of the Scottish Academy it is stated —such was the competition between art-union committees and private purchasers—that, on the opening day of the exhibition of 1858, nearly £5000 were expended in purchases in the gallery. A happy contrast, certainly, to the season referred to by Mr. Harvey, when the total amount of purchases was 35 guineas.

When the Art Union of London was established in 1837, there was no lack of purchasers, as the numerous and prosperous art exhibitions of that metropolis testified. However, beyond the enjoyment which those exhibitions afforded, the luxury, the home enjoyment of art was confined to the wealthier classes. So little were the purposes of art-unions understood, or so coldly was their interference with private purchasers regarded, that in the first year of the London Art Union, the subscriptions only amounted to £489 6*s*. The great middle classes, however, soon recognised the importance of the institution, and the total subscription for 22 years amounted to £238,932. The beneficial results of so large an expenditure, in addition to the undiminished amount of private purchase, must be obvious to every one. Some object to it as an artificial stimulus calculated to produce a superabundant mediocrity. I cannot regard it in any such light; for mediocrity in art will only be tolerated by mediocre taste, and the constant diffusion of good works of art through means of art-unions—the increased stimulus to good local exhibitions throughout the country—the very excitement about art so caused, must lead to improved taste. The works of the first-rate artists are never in the market for art-union purchase; not because those societies do not occasionally give high prices, but because those artists are pre-engaged often for years by private individuals. Through all these means a public opinion has been created, recognising the social value of art, and the importance of its highest development, which has stimulated the state—ever slow to move until it feels the pressure from without—to expenditure in the patronage of the higher branches of painting and sculpture, as well as to a gradually expanding system of education in art by schools and public galleries. Nor must we overlook another important fact in connection with such associations: it is not the wealth of particular localities that is represented in the large annual incomes of the London, the Edinburgh, or Glasgow associations. They draw their resources from all countries, and especially from our vast and increasing colonies, while it must be observed that the benefits of the expenditure is mainly confined to England and Scotland. From Ireland alone these three art-unions in 1858 drew upwards of 1150 guineas. The committee of the Glasgow Art Union remark in their last report, as a reason for not being more exclusively purchasers of Scottish artists' works, 'that a comparatively small amount of their subscriptions are obtained in Scotland.' Surely for us these are suggestive facts.

I have drawn your attention in the first instance to these institutions in Scotland, on account of the priority of their establishment, and because there exists a greater analogy between the circumstances of this country and that, than between those of Ireland and England. I would also say that the analogy was illustrated forcibly by the brief experience we had in Ireland of a prosperous art union. A gleam of promise—our national sunburst—shed its influence on art and art institutions. The exhibitions of the Royal Hibernian Academy expanded in size, interest and merit, and a consequent rapid improvement took place in the exhibition receipts. The energies of resident artists were awakened, and their ambition aroused. It was, unfortunately, a brief success, but it was enough to convince any thinking man, that in the associative system of encouragement lay the best hope of developing the latent talent of this country. I think too much stress is laid upon the failure of our first Art Union. It would be far better to regard the very large amount of success it achieved, as showing what can be done by well-directed energy. There may have been errors in the system, or improvidence in the management, which left the institution unprepared for the fearful ordeal through which this country had suddenly to pass; but, taught by experience, a system more calculated for permanence can be devised, and there is nothing in the present position of Ireland or its prospects to forbid the hope of resuscitating art, and establishing a school worthy of the country and 'racy of the soil.'"

THE OPERA FLORAL ARCADE, COVENT GARDEN.

When completed this building will be among the handsomest markets of its kind in the world, and an important addition to the ornamental edifices in London. The Arcade is now in rapid course of construction in the form of a lofty glass and iron edifice of striking and elegant proportions.

The ground plan and shape of the building may be best described as resembling the letter L; the handsomest and principal entrance being by the side of the Italian Opera, at the end of the longer arm of the letter, while the other opens upon Covent-garden Market, by the side of the piazza, at the end of the shorter arm. Over the space formed by the junction of the two arcades, at right angles, will be a lofty dome,—the first time that ever anything of the kind has been attempted in glass and iron only. The extreme length of the Arcade, from the Bow-street entrance to the west wall, will be 228 feet; and the short arm, from Covent-garden to the theatre wall, 100 feet. The width of both parts of the building meeting at the dome is 75 feet, of which the lofty semicircular arched nave occupies 50 feet, with two side aisles between the main columns and the walls, each nearly 13 feet wide. The springing of the arches for the roof is 29 feet from the ground, and as to the top of the arch is 57 feet, the roof is almost a perfect semicircle. The dome, when completed, will likewise be almost a hemisphere, 50 feet in diameter and about 25 feet high, making the total height to the ornamental lantern which will surmount it a little over 90 feet.

The great fault of all our glass and iron structures has been their deficiency in anything like ornamental details. Artists appear to have had nothing to do with them. From this great fault the Floral Arcade has been redeemed by Mr. E. Barry, the architect.

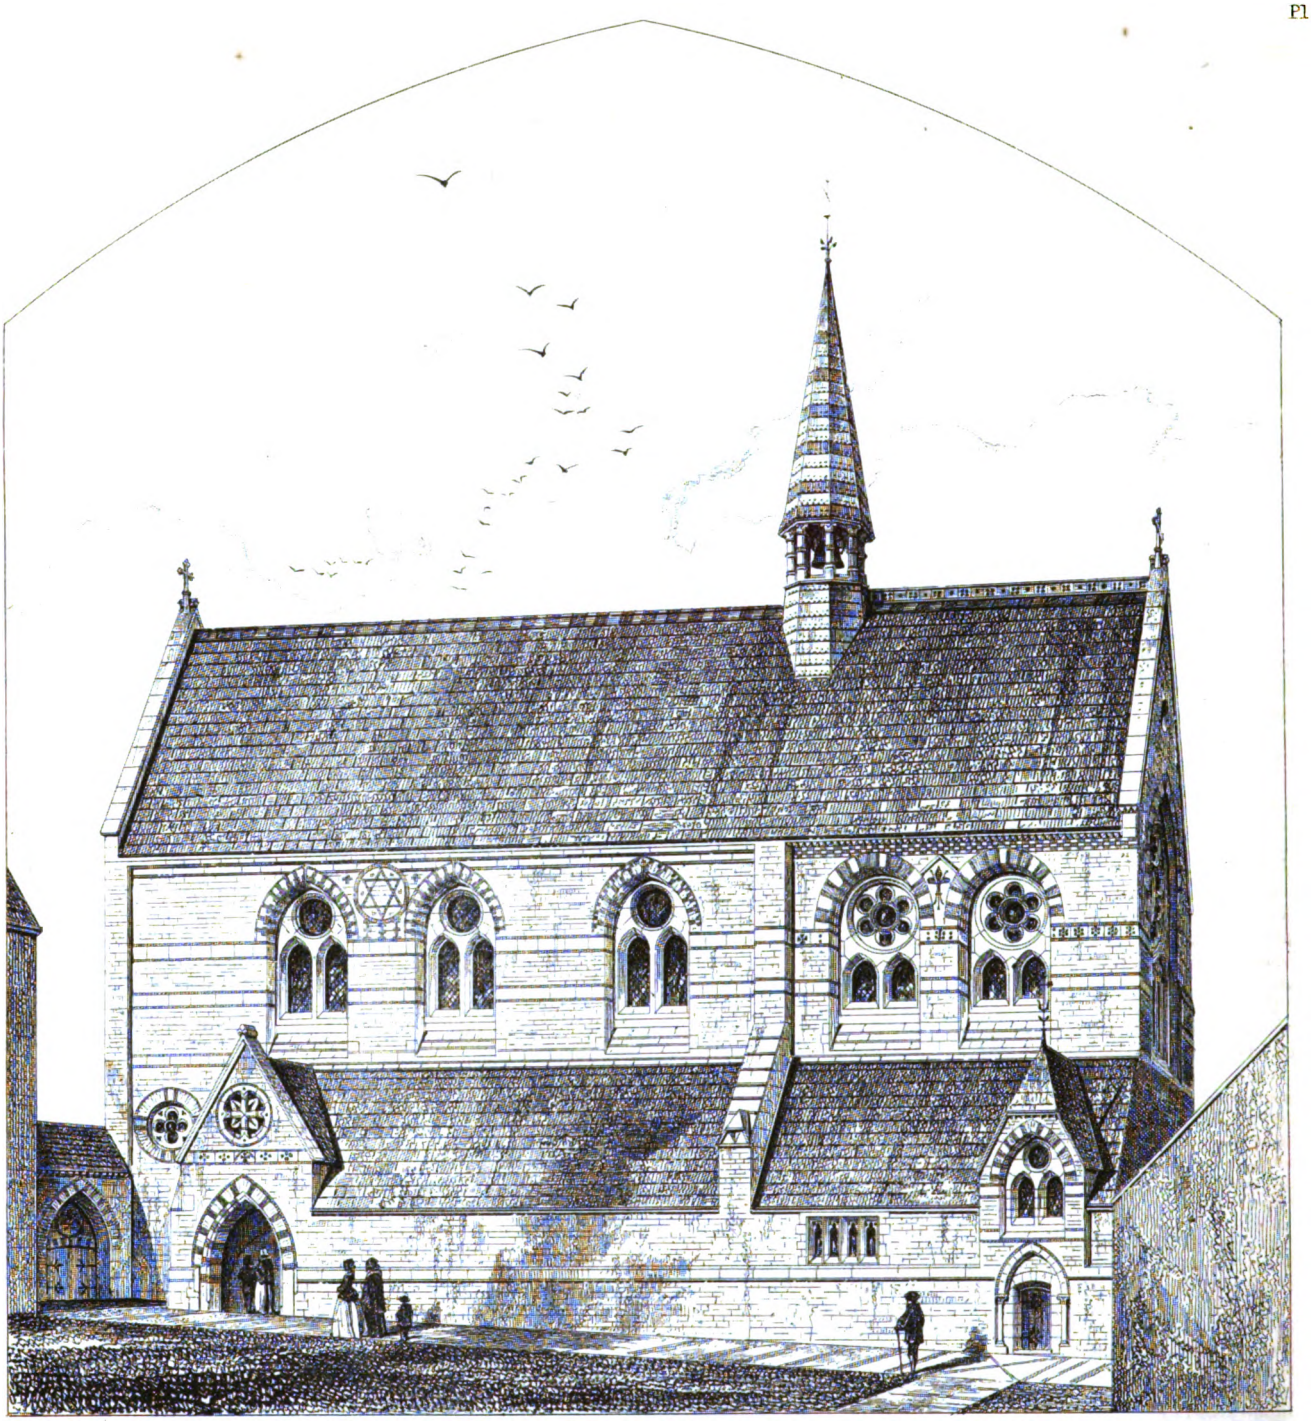
Digitized by Google

The Bow-street entrance is handsome and simple. The doorways are deeply recessed, so as entirely to do away with the flat, boxy, hard appearance which the entrances to such buildings have hitherto possessed. The raised iron arches which give admission to the interior also aid this effect considerably.

The radii of the arched roof seen on the outside are ornamented, and seem to spread out like an elaborate fan; and the curve of the roof over the entrance is surmounted with a kind of corona of elaborate cast-iron work. Glass and iron buildings are of course light in their construction, and this peculiarity, with the ornamental features mentioned, is particularly noticeable in the Floral Arcade. The iron columns supporting the nave roof are graceful looking, and instead of being, as is usually the case, mere iron cylinders, rough and unadorned as lamp-posts, they are all cast of an exceedingly handsome pattern, with rich capitals, which are perforated in order to ventilate the basement story beneath the market, with which the columns communicate. All round the interior at the springing of the arches is an elaborate cast-iron moulding of bold and rich design, which is hereafter to be gilt, when its effect will be exceedingly beautiful. The aisles are nearly 13 feet wide and about 30 high, the theatre wall forming the side of the north aisle, and the wall of the Arcade that of the south. As the theatre wall is pierced with recessed windows, the corresponding wall on the south side will be of the same kind. The arches which carry the roof of the nave are trellised, and apparently of the very lightest possible construction. Yet, light as they are in appearance, they are immensely strong in fact, and have all been tested with a strain far above anything that can ever come upon them, as they have nothing but themselves to support. Between the arched ribs transverse bars of "deck" iron, T-shaped, at intervals of about 6 feet apart, stretch along the whole length of each arcade, and are riveted to the arched principals in such a manner as to give to the whole roof the rigidity of one piece. The dome will be composed of twenty-two ribs, braced round with wrought-iron supports. The ribs form a quarter of a circle, all resting upon an iron collar in the centre, which will carry the lantern. The Covent-garden entrance continues the public way of the Piazza through its front by a roofed glass and iron gallery 50 feet long by 25 broad. The basement under the floor of the Arcade forms one of the most extensive cellars excavated anywhere out of the docks. It has the same immense area as the building above it, and is no less than 16 feet high; 10-inch cast-iron columns, forty-eight in number, carry the floor of the Arcade upon powerful wrought-iron girders equal to fifty times the weight that can ever come upon them. The floor of the Arcade is fireproof, formed of tiled arches between the girders, and over these an ordinary planking floor is laid for warmth and convenience. When the Arcade is complete it will be decorated in white and gold, a style which will admirably suit its light and elegant details. Through all parts of the structure pass hot-water pipes for keeping up the temperature during the winter, and gas is also laid on, so that the interior can be lighted up for night fêtes in an instant. This arcade is intended simply as a flower-market, to bring together in one building especially adapted for the purpose the immense trade which is now scattered all over the suburbs of London, in the hothouses and grounds of the great florists and nurserymen.

PRINCESS'S THEATRE.

THE splendid series of Shakespearean "revivals" which have been in course of production at this theatre for several years, and which have constituted so marked an epoch in theatrical art, is now about to be terminated, owing to the retirement of the manager from the scene of his arduous exertions. As a closing reproduction, well fitted to display the peculiar talents of Mr. C. Kean, and the resources of his establishment, the play of *Henry V.* has been judiciously selected. The interest chiefly centres in the monarch himself, into whose mouth our great bard has put some of the most stirring speeches he ever penned; the rest of the play is unequal, depending on the various accessories, and the abilities of the different impersonators; nevertheless it has always held a high place as a composition, and been a favourite with most of our good actors.



It will be unnecessary to observe that in the production of this play Mr. Kean in no way falls short of his previous successes, and far outshines all his predecessors in the *mise en scène*—a department of which he is so thoroughly a master; while Mrs. Kean, by a happy idea, exchanges the traditional figure of Time—under the semblance of an aged man, who had hitherto represented the "Chorus"—for that of Clio, the muse of History. This Chorus, or Clio, at the commencement of each act, in a kind of descriptive poetry, connects and explains the action as it proceeds, but Shakespeare has not in this instance assigned, as in *Pericles* and the *Winter's Tale*, a distinctive individuality to the character. In the "revival" of the latter play we took occasion to remark at some length on its special features; the present occasion does not call for such analytical criticism; Henry V. at the Princess's is rather to be seen than described: it is a splendid pageant, a complete study of costume and decorations, of which the variety and splendour can scarcely be imagined; and there is the more satisfaction in their contemplation since we are assured that they are, as nearly as can be ascertained, in strict conformity with the usages of the period. Bearing in mind this adherence to consistency observable throughout, we can only account for the declamations of the "Chorus" being made from a *classic* peristyle of the Ionic order, because in the present acceptation it is represented by a classic muse.

Some of the scenes are well deserving of notice. One of these shows "The painted chamber at Westminster" (to which frequent reference is made in history as the room in which Henry V. held his councils), and where the frescoes on the walls, and the superb throne powdered with the letter S, form conspicuous objects.—"A scene in Eastcheap" affords an opportunity for some characteristic groupings of picturesque old timber houses. "The council chamber in Southampton Castle," a venerable Norman interior, with rich tapestry round the walls. "The room in the French king's palace," in act ii., though showy, is not architecturally so good, but the landscape scenes of a "View in Picardy," and the "French camp," are triumphs of artistic skill. A great aim at effect has been successfully achieved in the realisation of the conflicting scenes at the seige of Harfleur, where the king's impassioned address tells with wondrous power on his dispirited army. But the *piece de resistance* is the "Historical Episode" introduced between the fourth and fifth act, and which is supposed to exhibit the reception of King Henry, on returning to his capital after the French expedition. It would be impossible to include the manifold incidents of the royal progress in one scene; neither could all the sites on which they actually took place be successively exhibited. The most prominent are, therefore, selected, and thrown into one locality—the approach to Old London-bridge. It will be recollected that, in the revival of Richard II. a similar interpolation was ventured on, and with so much success as to warrant this second attempt. In the last act there is a charming scene—"France in the neighbourhood of Troyes;" also a carefully rendered "Interior of the cathedral" at the same place. The high metal screen and grille work, in particular, are very accurately given.

Burford's Panorama Galleries, Leicester-square.—In China, India, and Switzerland are laid the scenes of the three panoramas now on view at this favourite place of resort. The former is the latest addition, showing "Canton after its bombardment." It has been painted, we understand, from photographs taken by the Royal Engineers; but if the visitor enter with grandiose expectations as to the probable beauty of one of the chief cities of the celestial empire they will assuredly be dispelled. There is positively nothing attractive nor even pleasing in the look of the buildings, nor is the surrounding landscape particularly enchanting. The dwellings are mean in appearance; they are also for the most part small, detached, and of the simplest and most monotonous character, while none of the streets exceed about 16 feet in width,—if we are credibly informed. Lucknow presents a totally different scene. Here the influence of civilisation and luxury are apparent: the buildings are numerous, large, and handsome; the oft-repeated dome, richly gilded, glitters in the sky; the parapet and balustrade are intermingled with Eastern features in a picturesque and fanciful manner. The roofs of the houses are uniformly flat, and are covered with a kind of cement. The church, a would-be Gothic edifice, has low pitched gables, which are thorough shams, the real roof being, like the houses, flat. Two bridges span the river, and the abundantly luxuriant foliage forms a refreshing feature in a landscape which has well been termed "the garden of India." The "Righi Culm" is well known to travellers as one of the special landmarks of Switzerland.

J.R.Jobbins.

NEW CHURCH OF ST. MICHAEL AND ALL ANGELS, BRIGHTON.

(With an Engraving.)

THIS church, of which we give an exterior view from the south-east, is about to be built at Brighton. The material employed will be brick for the walls both internally and externally. The arches, windows, doorways, &c. will be of Caen or Bath stone. The floor will be a paved one throughout. Moveable seats and chairs will be provided in the nave, and stalls fixed in the chancel. The principal dimensions will be—nave 23 ft. 6 in. wide and 66 feet long; aisles 9 feet wide; chancel 23 ft. 6 in. by 31 ft. 6 in. The height to ridge will be about 65 feet. The cost will be about £4000 for the fabric, and some further decorations will be added. The architect is Mr. G. F. Bodley, of Wimpole-street, London.

THE INSTITUTE OF BRITISH ARCHITECTS.

THE report just printed of the proceedings of the Institute during the past session is, on the whole, of a congratulatory character. Allusion is naturally made to their continued occupancy of the rooms in Grosvenor-street instead of having removed to their new premises in Conduit-street; and this is explained by the protracted difficulties which the Architectural Union met with even after the essential preliminaries had been gone through, in appropriating space, and effecting the alterations required by the several Architectural Societies which had to be located under the same roof. The accession of eight Fellows and ten Associates to the previous list of Members is notified,—the Institute now consisting of 154 Fellows, 139 Associates, 13 Honorary Fellows, 17 Honorary Members, 80 Honorary and Corresponding Members, and 13 Contributing Visitors. The losses to the Institute, occasioned by death, are next recorded, amounting in number to six.

To the subject of the Architectural Union Company reference is made at some length in the body of the report, and we transfer the remarks in full.

"The munificent example set by our noble President in presenting twenty shares in the Architectural Union Company to the Institute, has been followed by our respected Fellow, Mr. Tite, M.P., who has given ten shares, and by Mr. St. Aubyn, Fellow, who has just presented five shares, in the same company. Should these donations be increased by other friends and members, the prospect of the Institute becoming, in a great measure, its own landlord would be far from Utopian. To those who may not think fit to present shares, it may perhaps be permitted to suggest the establishment of an auxiliary fund, on the present occasion of removing to new apartments, in order to meet the heavy demands on the stock of the Institute, by which the annual income will be lessened, while an increase will take place in the rent. (Since this Report was read, Mr. T. L. Donaldson, Fellow, has presented the sum of 25*l.* to the 'Removal,' and the like sum to the 'Travelling' Fund.) The rooms in Conduit-street are fully described in last year's Report: but it may be again mentioned, that on four evenings during the session the Institute will have the right of using the whole suite of spacious galleries at the back of the main building for conversazioni and similar purposes. The council believe that by judicious arrangements, and the zealous co-operation of the body at large, the institution of these conversazioni may be made an important and not unprofitable feature in the sessional proceedings. The organisation of the arrangements, in which they trust they may be aided by an efficient committee, selected mainly from amongst the younger members of the Institute, will doubtless form one of the most interesting duties of the council during the ensuing session.

"The Architectural Exhibition and the Architectural Association have already taken possession of the galleries; and respectively inaugurated the event by very successful opening meetings.

"To the Architectural Exhibition Committee, its zealous Secretaries, and Treasurer, too much praise cannot be given for the spirited manner in which, in face of no ordinary difficulties, they originated the Architectural Union Company, which has carried to a most satisfactory conclusion the intention of providing in spacious, well lighted and well arranged galleries that amount of accommodation for the architectural world in London, which the Royal Academy denied within its walls; and afforded moreover constant means for the display of objects of utility as well as of artistic merit connected with building operations, never attempted before the establishment of the Architectural Exhibition.

"The council feel that they are expressing the feelings of the Institute, when they record their best wishes for the permanent success of the Architectural Union Company, which has united under one roof 'The Architectural Societies of London.'"

In addition to the subjects for papers and discussions brought before the ordinary general meetings, three of great interest have engaged the attention of meetings specially called to consider them. These are as follows, and it will be at once seen that their due investigation is of weighty importance as regards the prospective condition of the profession at large.

"The extension of the elective franchise as well to members of this Institute as to the members of other professions hitherto specially designated 'learned' (as proposed by Her Majesty's government), was considered an act of simple justice, which found expression in a petition agreed to unanimously at one of the meetings; which, having been duly authenticated by the corporate seal, was presented to the House of Commons by our Fellow, Mr. Tite, M.P. for Bath.

"The same unanimity prevailed respecting the necessity for supporting the prayer of a petition on the subject of artistic copyright, before a committee of the House of Lords about to consider the subject; and a committee of the Institute, consisting of Messrs. Donaldson, Godwin, Hayward, Kerr, Norton, and Papworth, has been named by the council (which had been duly empowered by the meeting), to press the purport of that petition before the Lords. Mr. Cockerell, Fellow, R.A., the council regret, is prevented by ill health from affording his valuable assistance as a member of the committee.

"A discussion in the House of Lords respecting the removal of the Royal Academy from Trafalgar-square, in order to devote the entire present building to the national collection, having called attention to the probable readjustment, if not of the constitution, at least of the working system, of the Royal Academy, a memorial to embody the views of the Institute on the subject was submitted to a special general meeting; and further considered at a second. At a third meeting a modified memorial to the council of the Royal Academy was agreed to in the following terms:—

"'The Institute of British Architects conceive it to be their duty at the present juncture, to offer their congratulations to the Royal Academy of Arts upon the probability of its speedily obtaining a site eligible for the erection of buildings more suitable for the requirements of the annual exhibition, library, art collections, schools, lectures, &c., than the premises it has hitherto occupied. By its steady maintenance of these and other educational institutions, it is undeniable that the Royal Academy has conferred inestimable benefits upon the fine arts of this country, and none can be more ready to subscribe to this fact than the Institute of British Architects. So highly indeed do they esteem the advantages which have been hitherto derived by the profession which they, to a certain extent, represent, that they cannot refrain from urging upon the Royal Academy in any re-adjustment of its present arrangements, the expediency, and indeed duty, of yet further extending and developing those advantages.

"'The Royal Institute of British Architects conceive it both more respectful to the Royal Academy, and less likely to prove prejudicial to its interests, to at once state openly their impression of the mode in which this can best be carried out, than it would be to remain silent, and yet not altogether satisfied with the prospect of the bare maintenance for the future of that which may have been sufficient in the past.

"'The following are the general arrangements which, if it were possible, the Royal Institute of British Architects would desire to see carried into effect by the Royal Academy:—

"'1st. A larger proportion of Architectural Royal Academicians and Associates to be appointed.

"'2nd. Powers of independent action to be given to the Architectural Members, upon matters connected with Architecture.

"'3rd. The provision of means of instruction in their art to be provided for Architectural Students, equivalent to those afforded by the Royal Academy to Students in any other branch of the Fine Arts.

"'4th. A more systematic scheme of general instruction in all branches of the Fine Arts to be brought into operation, and more efficient tests by examination, or otherwise, of knowledge and proficiency in practice.

"'The first point (the increase of architectural academicians and associates) the Royal Institute of British Architects conceive essentially due to the great extension which has of late years taken place in the study and practice of architecture, and its subservient arts of design in this country.

"'The second, independent action, is indispensable to prevent the architectural element being rendered powerless through its remaining on all occasions a small minority.

"'The third, architectural education, it is conceived, it would be incompatible with the comprehensive objects for which the Royal Academy was originally instituted, to refuse. And the fourth, a general elevation of academic art-teaching, is unquestionably demanded by the public for students in architecture, if not in all the other departments of the fine arts.

"'As considerable excitement is felt throughout the profession upon the subject of the present communication, it is proposed to give publicity both to it, and to whatever reply the Royal Academy may make to it.'

"The Institute must now await the result of this appeal to the good sense of the Royal Academy. The council must however express the sincere hope, that whatever course may be finally adopted by that body, it may be such as to confer material benefit on each and all of the equally important subdivisions of the fine arts.

"The council, in common it is believed with all well-wishers to the maintenance in an honourable position of the architectural profession, have felt and continue to feel profound anxiety with respect to the establishment of a more systematic course of education for the student in architecture than has hitherto prevailed. Looking naturally to the Royal Academy as the legitimate source of initiation, the council will seriously discuss and endeavour to originate some movement in this matter, in the event of the Royal Academy failing to provide a more active curriculum than it has hithertofore considered necessary. The subject is, however, obviously one of such extent and gravity, that any useful action can be only set on foot by the very hearty concurrence, not of the council or of the Institute alone, but of the whole body of architects practising in the United Kingdom."

Referring to the subject of architectural competitions, it is mentioned that the attention of the Council has been recently invited by Mr. Edward Barry to another phase which the matter is now occasionally assuming, viz., the practice of requiring competitors to undertake the task of deciding upon the designs submitted. The remarks of Mr. Barry were deemed by the council so pertinent, that they have felt that they could not do better than record them, as embodying a reasonable and logical statement of the case; being impressed with the necessity which exists that competitions (if competitions cannot be avoided) should be conducted in the best possible manner.
